

Azure Functions documentation

Azure Functions is a cloud service available on-demand that provides all the continually updated infrastructure and resources needed to run your applications. You focus on the code that matters most to you, in the most productive language for you, and Functions handles the rest. Functions provides serverless compute for Azure. You can use Functions to build web APIs, respond to database changes, process IoT streams, manage message queues, and more.

Azure Functions overview

Article • 05/24/2023

Azure Functions is a serverless solution that allows you to write less code, maintain less infrastructure, and save on costs. Instead of worrying about deploying and maintaining servers, the cloud infrastructure provides all the up-to-date resources needed to keep your applications running.

You focus on the code that matters most to you, in the most productive language for you, and Azure Functions handles the rest.

For the best experience with the Functions documentation, choose your preferred development language from the list of native Functions languages at the top of the article.

Scenarios

Functions provides a comprehensive set of event-driven [triggers and bindings](#) that connect your functions to other services without having to write extra code.

The following are a common, *but by no means exhaustive*, set of integrated scenarios that feature Functions.

If you want to...	then...
Process file uploads	Run code when a file is uploaded or changed in blob storage.
Process data in real time	Capture and transform data from event and IoT source streams on the way to storage.
Infer on data models	Pull text from a queue and present it to various AI services for analysis and classification.
Run scheduled task	Execute data clean-up code on pre-defined timed intervals.
Build a scalable web API	Implement a set of REST endpoints for your web applications using HTTP triggers.
Build a serverless workflow	Create an event-driven workflow from a series of functions using Durable Functions.
Respond to database changes	Run custom logic when a document is created or updated in Azure Cosmos DB.

If you want to...	then...
Create reliable message systems	Process message queues using Queue Storage, Service Bus, or Event Hubs.

These scenarios allow you to build event-driven systems using modern architectural patterns. For more information, see [Azure Functions Scenarios](#).

Development lifecycle

With Functions, you write your function code in your preferred language using your favorite development tools and then deploy your code to the Azure cloud. Functions provides native support for developing in [C#, Java, JavaScript, PowerShell, Python](#), plus the ability to use [more languages](#), such as Rust and Go.

Functions integrates directly with Visual Studio, Visual Studio Code, Maven, and other popular development tools to enable seamless debugging and [deployments](#).

Functions also integrates with Azure Monitor and Azure Application Insights to provide comprehensive runtime telemetry and analysis of your [functions in the cloud](#).

Hosting options

Functions provides a variety [hosting options](#) for your business needs and application workload. [Event-driven scaling hosting options](#) range from fully serverless, where you only pay for execution time (Consumption plan), to always warm instances kept ready for fastest response times (Premium plan).

When you have excess App Service hosting resources, you can host your functions in an existing App Service plan. This kind of Dedicated hosting plan is also a good choice when you need predictable scaling behaviors and costs from your functions.

If you want complete control over your functions runtime environment and dependencies, you can even deploy your functions in containers that you can fully customize. Your custom containers can be hosted by Functions, deployed as part of a microservices architecture in Azure Container Apps, or even self-hosted in Kubernetes.

Azure Functions scenarios

Article • 09/26/2024

We often build systems to react to a series of critical events. Whether you're building a web API, responding to database changes, processing event streams or messages, Azure Functions can be used to implement them.

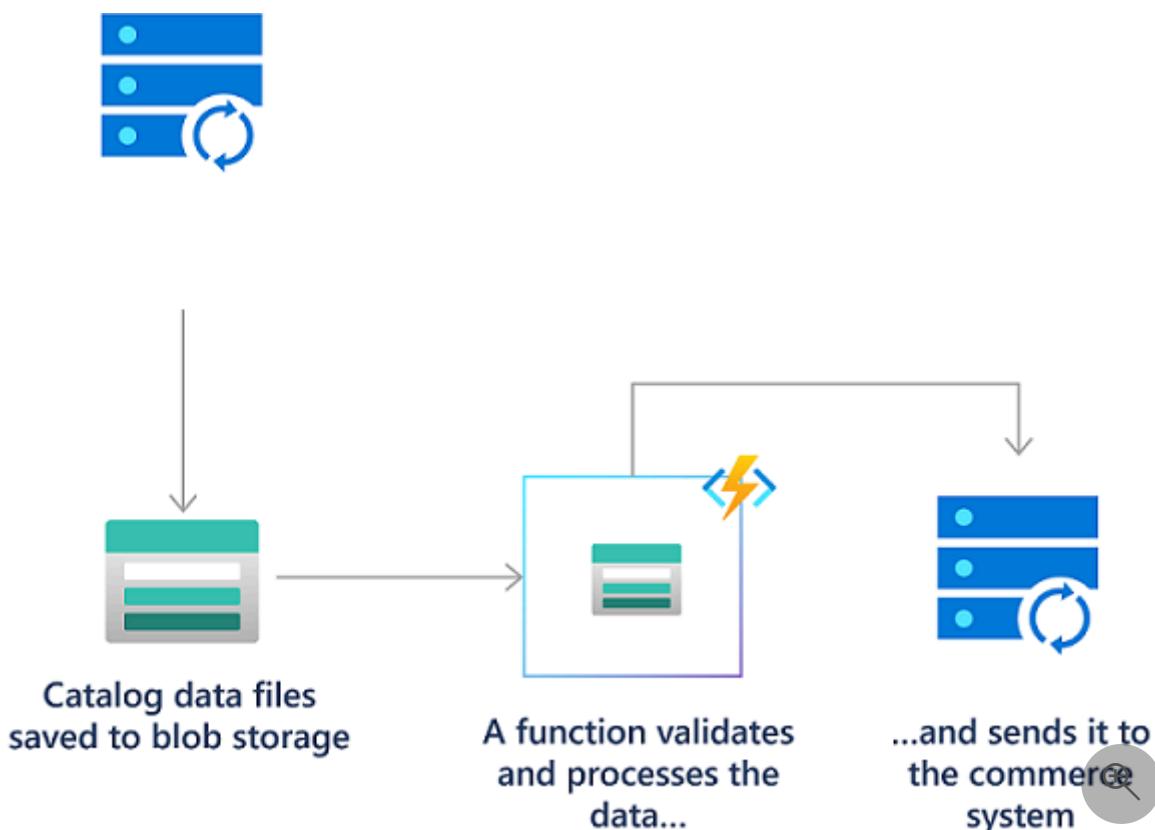

In many cases, a function [integrates with an array of cloud services](#) to provide feature-rich implementations. The following are a common (but by no means exhaustive) set of scenarios for Azure Functions.

Select your development language at the top of the article.

Process file uploads

There are several ways to use functions to process files into or out of a blob storage container. To learn more about options for triggering on a blob container, see [Working with blobs](#) in the best practices documentation.

For example, in a retail solution, a partner system can submit product catalog information as files into blob storage. You can use a blob triggered function to validate, transform, and process the files into the main system as they're uploaded.

The following tutorials use a Blob trigger (Event Grid based) to process files in a blob container:

For example, using the blob trigger with an event subscription on blob containers:

C#

```
[FunctionName("ProcessCatalogData")]
public static async Task Run([BlobTrigger("catalog-uploads/{name}", Source =
BlobTriggerSource.EventGrid, Connection = "
<NAMED_STORAGE_CONNECTION>")]Stream myCatalogData, string name, ILogger log)
{
    log.LogInformation($"C# Blob trigger function Processed blob\n Name:
{name} \n Size: {myCatalogData.Length} Bytes");

    using (var reader = new StreamReader(myCatalogData))
    {
        var catalogEntry = await reader.ReadLineAsync();
        while(catalogEntry !=null)
        {
            // Process the catalog entry
            // ...

            catalogEntry = await reader.ReadLineAsync();
        }
    }
}
```

- Event-based Blob storage triggered function that converts PDF documents to text at scale ↗
- Upload and analyze a file with Azure Functions and Blob Storage
- Automate resizing uploaded images using Event Grid
- Trigger Azure Functions on blob containers using an event subscription

Real-time stream and event processing

So much telemetry is generated and collected from cloud applications, IoT devices, and networking devices. Azure Functions can process that data in near real-time as the hot path, then store it in [Azure Cosmos DB](#) for use in an analytics dashboard.

Your functions can also use low-latency event triggers, like Event Grid, and real-time outputs like SignalR to process data in near-real-time.

For example, using the event hubs trigger to read from an event hub and the output binding to write to an event hub after debatching and transforming the events:

C#

```
[FunctionName("ProcessorFunction")]
public static async Task Run(
    [EventHubTrigger(
        "%Input_EH_Name%",
        Connection = "InputEventHubConnectionString",
        ConsumerGroup = "%Input_EH_ConsumerGroup%")] EventData[]
    inputMessages,
    [EventHub(
        "%Output_EH_Name%",
        Connection = "OutputEventHubConnectionString")]
    IAsyncCollector<SensorDataRecord> outputMessages,
    PartitionContext partitionContext,
    ILogger log)
{
    var debatcher = new Debatcher(log);
    var debatchedMessages = await debatcher.Debatch(inputMessages,
partitionContext.PartitionId);

    var xformer = new Transformer(log);
    await xformer.Transform(debatchedMessages, partitionContext.PartitionId,
outputMessages);
}
```

Machine learning and AI

Besides data processing, Azure Functions can be used to infer on models. The [Azure OpenAI binding extension](#) lets easily integrate features and behaviors of the [Azure OpenAI service](#) into your function code executions.

Functions can connect to an OpenAI resources to enable text and chat completions, use assistants, and leverage embeddings and semantic search.

A function might also call a TensorFlow model or Azure AI services to process and classify a stream of images.

- Sample: [Text completion using Azure OpenAI ↗](#)
- Sample: [Provide assistant skills to your model ↗](#)
- Sample: [Generate embeddings ↗](#)
- Sample: [Leverage semantic search ↗](#)

Run scheduled tasks

Functions enables you to run your code based on a [cron schedule](#) that you define.

Check out how to [Create a function in the Azure portal that runs on a schedule](#).

A financial services customer database, for example, might be analyzed for duplicate entries every 15 minutes to avoid multiple communications going out to the same customer.

C#

```
[FunctionName("TimerTriggerCSharp")]
public static void Run([TimerTrigger("0 */15 * * *")]TimerInfo myTimer,
ILogger log)
{
    if (myTimer.IsPastDue)
    {
        log.LogInformation("Timer is running late!");
    }
    log.LogInformation($"C# Timer trigger function executed at:
{DateTime.Now}");

    // Perform the database deduplication
}
```

- Timer trigger for Azure Functions

Build a scalable web API

An HTTP triggered function defines an HTTP endpoint. These endpoints run function code that can connect to other services directly or by using binding extensions. You can compose the endpoints into a web-based API.

You can also use an HTTP triggered function endpoint as a webhook integration, such as GitHub webhooks. In this way, you can create functions that process data from GitHub events. To learn more, see [Monitor GitHub events by using a webhook with Azure Functions](#).

For examples, see the following:

C#

```
[FunctionName("InsertName")]
public static async Task<IActionResult> Run(
    [HttpTrigger(AuthorizationLevel.Function, "post")] HttpRequest req,
    [CosmosDB(
        databaseName: "my-database",
        collectionName: "my-container",
        ConnectionStringSetting =
    "CosmosDbConnectionString")]IAsyncCollector<dynamic> documentsOut,
    ILogger log)
{
    string requestBody = await new StreamReader(req.Body).ReadToEndAsync();
    dynamic data = JsonConvert.DeserializeObject(requestBody);
    string name = data?.name;

    if (name == null)
    {
        return new BadRequestObjectResult("Please pass a name in the request
body json");
    }

    // Add a JSON document to the output container.
    await documentsOut.AddAsync(new
    {
        // create a random ID
        id = System.Guid.NewGuid().ToString(),
        name = name
    });
}

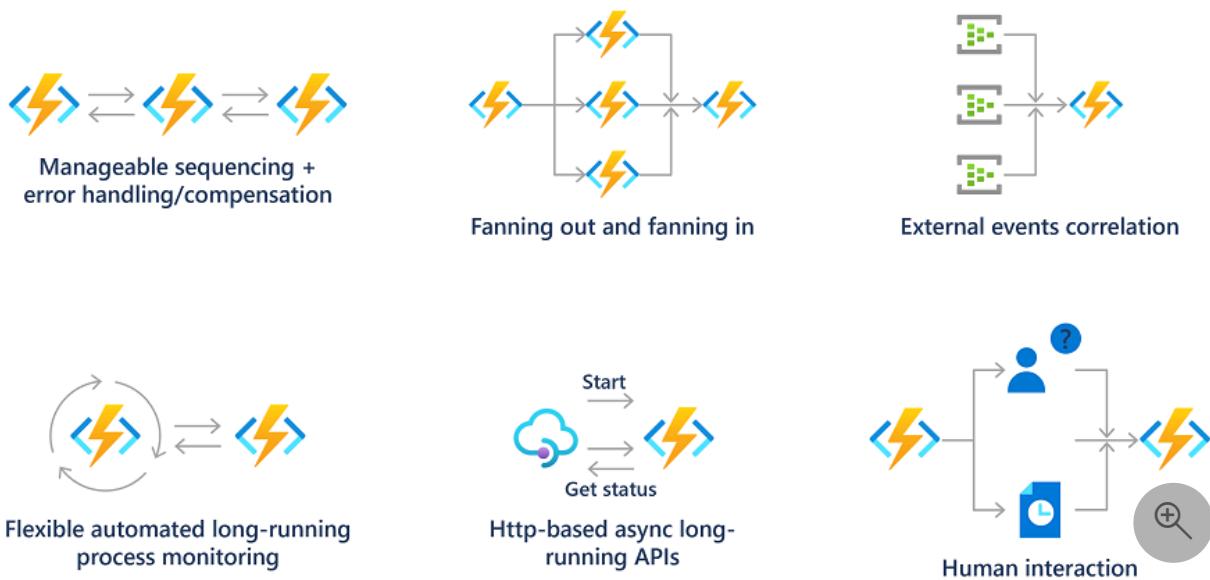

return new OkResult();
}
```

Build a serverless workflow

Functions is often the compute component in a serverless workflow topology, such as a Logic Apps workflow. You can also create long-running orchestrations using the Durable Functions extension. For more information, see [Durable Functions overview](#).

- Tutorial: [Create a function to integrate with Azure Logic Apps](#)
- Quickstart: [Create your first durable function in Azure using C#](#)
- Training: [Deploy serverless APIs with Azure Functions, Logic Apps, and Azure SQL Database](#)

Respond to database changes

There are processes where you might need to log, audit, or perform some other operation when stored data changes. Functions triggers provide a good way to get notified of data changes to initial such an operation.

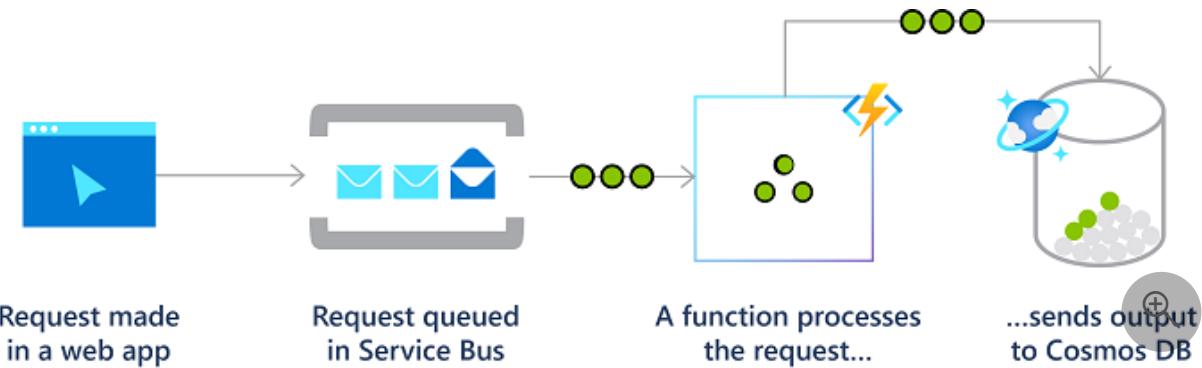

Consider the following examples:

- Article: [Connect Azure Functions to Azure Cosmos DB using Visual Studio Code](#)
- Article: [Connect Azure Functions to Azure SQL Database using Visual Studio Code](#)
- Article: [Use Azure Functions to clean-up an Azure SQL Database](#)

Create reliable message systems

You can use Functions with Azure messaging services to create advanced event-driven messaging solutions.

For example, you can use triggers on Azure Storage queues as a way to chain together a series of function executions. Or use service bus queues and triggers for an online ordering system.

The following article shows how to write output to a storage queue.

- Article: [Connect Azure Functions to Azure Storage using Visual Studio Code](#)
- Article: [Create a function triggered by Azure Queue storage \(Azure portal\)](#)

And these articles show how to trigger from an Azure Service Bus queue or topic.

Getting started with Azure Functions

Article • 09/19/2024

Azure Functions allows you to implement your system's logic as event-driven, readily available blocks of code. These code blocks are called "functions". This article is to help you find your way to the most helpful Azure Functions content as quickly as possible. For more general information about Azure Functions, see the [Introduction to Azure Functions](#).

Make sure to choose your preferred development language at the top of the article.

Create your first function

Complete one of our quickstart articles to create and deploy your first functions in less than five minutes.

You can create C# functions by using one of the following tools:

- [Azure Developer CLI \(azd\)](#)
- [Command line](#)
- [Visual Studio](#)
- [Visual Studio Code](#)

Review end-to-end samples

These sites let you browse existing functions reference projects and samples in your desired language:

What are Durable Functions?

Article • 08/04/2023

Durable Functions is an extension of [Azure Functions](#) that lets you write stateful functions in a serverless compute environment. The extension lets you define stateful workflows by writing *orchestrator functions* and stateful entities by writing *entity functions* using the Azure Functions programming model. Behind the scenes, the extension manages state, checkpoints, and restarts for you, allowing you to focus on your business logic.

Supported languages

Durable Functions is designed to work with all Azure Functions programming languages but may have different minimum requirements for each language. The following table shows the minimum supported app configurations:

Language stack	Azure Functions Runtime versions	Language worker version	Minimum bundles version
.NET / C# / F#	Functions 1.0+	In-process Out-of-process	n/a
JavaScript/TypeScript (V3 prog. model)	Functions 2.0+	Node 8+	2.x bundles
JavaScript/TypeScript (V4 prog. model)	Functions 4.16.5+	Node 18+	3.15+ bundles
Python	Functions 2.0+	Python 3.7+	2.x bundles
Python (V2 prog. model)	Functions 4.0+	Python 3.7+	3.15+ bundles
PowerShell	Functions 3.0+	PowerShell 7+	2.x bundles
Java	Functions 4.0+	Java 8+	4.x bundles

Like Azure Functions, there are templates to help you develop Durable Functions using [Visual Studio](#), [Visual Studio Code](#), and the [Azure portal](#).

Application patterns

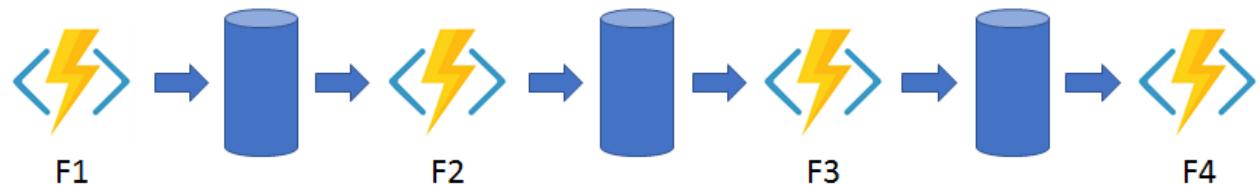

The primary use case for Durable Functions is simplifying complex, stateful coordination requirements in serverless applications. The following sections describe typical

application patterns that can benefit from Durable Functions:

- Function chaining
- Fan-out/fan-in
- Async HTTP APIs
- Monitoring
- Human interaction
- Aggregator (stateful entities)

Pattern #1: Function chaining

In the function chaining pattern, a sequence of functions executes in a specific order. In this pattern, the output of one function is applied to the input of another function. The use of queues between each function ensures that the system stays durable and scalable, even though there is a flow of control from one function to the next.

You can use Durable Functions to implement the function chaining pattern concisely as shown in the following example.

In this example, the values `F1`, `F2`, `F3`, and `F4` are the names of other functions in the same function app. You can implement control flow by using normal imperative coding constructs. Code executes from the top down. The code can involve existing language control flow semantics, like conditionals and loops. You can include error handling logic in `try/catch/finally` blocks.

C# (InProc)

C#

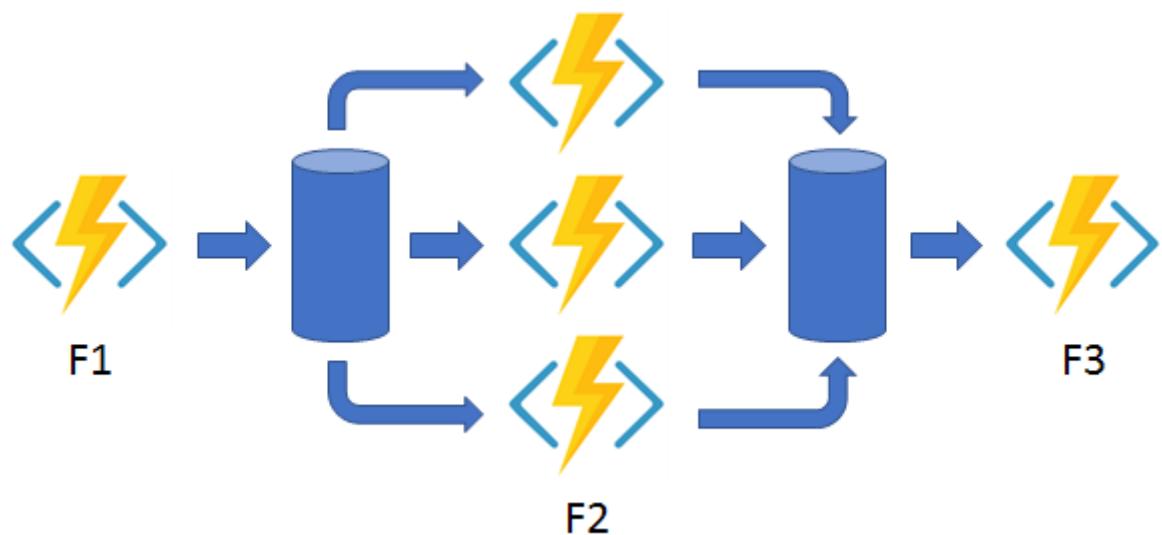

```
[FunctionName("Chaining")]
public static async Task<object> Run(
    [OrchestrationTrigger] IDurableOrchestrationContext context)
{
    try
    {
        var x = await context.CallActivityAsync<object>("F1", null);
        var y = await context.CallActivityAsync<object>("F2", x);
        var z = await context.CallActivityAsync<object>("F3", y);
        return await context.CallActivityAsync<object>("F4", z);
    }
}
```

```
        }
        catch (Exception)
        {
            // Error handling or compensation goes here.
        }
    }
```

You can use the `context` parameter to invoke other functions by name, pass parameters, and return function output. Each time the code calls `await`, the Durable Functions framework checkpoints the progress of the current function instance. If the process or virtual machine recycles midway through the execution, the function instance resumes from the preceding `await` call. For more information, see the next section, Pattern #2: Fan out/fan in.

Pattern #2: Fan out/fan in

In the fan out/fan in pattern, you execute multiple functions in parallel and then wait for all functions to finish. Often, some aggregation work is done on the results that are returned from the functions.

With normal functions, you can fan out by having the function send multiple messages to a queue. Fanning back in is much more challenging. To fan in, in a normal function, you write code to track when the queue-triggered functions end, and then store function outputs.

The Durable Functions extension handles this pattern with relatively simple code:

C# (InProc)

C#

```
[FunctionName("FanOutFanIn")]
public static async Task Run(
    [OrchestrationTrigger] IDurableOrchestrationContext context)
{
    var parallelTasks = new List<Task<int>>();

    // Get a list of N work items to process in parallel.
    object[] workBatch = await context.CallActivityAsync<object[]>("F1",
null);
    for (int i = 0; i < workBatch.Length; i++)
    {
        Task<int> task = context.CallActivityAsync<int>("F2",
workBatch[i]);
        parallelTasks.Add(task);
    }

    await Task.WhenAll(parallelTasks);

    // Aggregate all N outputs and send the result to F3.
    int sum = parallelTasks.Sum(t => t.Result);
    await context.CallActivityAsync("F3", sum);
}
```

The fan-out work is distributed to multiple instances of the `F2` function. The work is tracked by using a dynamic list of tasks. `Task.WhenAll` is called to wait for all the called functions to finish. Then, the `F2` function outputs are aggregated from the dynamic task list and passed to the `F3` function.

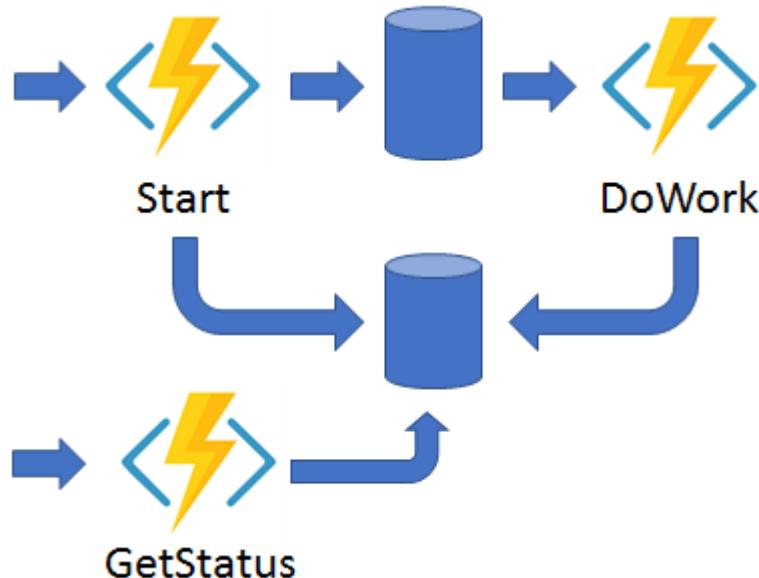

The automatic checkpointing that happens at the `await` call on `Task.WhenAll` ensures that a potential midway crash or reboot doesn't require restarting an already completed task.

ⓘ Note

In rare circumstances, it's possible that a crash could happen in the window after an activity function completes but before its completion is saved into the orchestration history. If this happens, the activity function would re-run from the beginning after the process recovers.

Pattern #3: Async HTTP APIs

The async HTTP API pattern addresses the problem of coordinating the state of long-running operations with external clients. A common way to implement this pattern is by having an HTTP endpoint trigger the long-running action. Then, redirect the client to a status endpoint that the client polls to learn when the operation is finished.

Durable Functions provides **built-in support** for this pattern, simplifying or even removing the code you need to write to interact with long-running function executions. For example, the Durable Functions quickstart samples ([C#](#), [JavaScript](#), [TypeScript](#), [Python](#), [PowerShell](#), and [Java](#)) show a simple REST command that you can use to start new orchestrator function instances. After an instance starts, the extension exposes webhook HTTP APIs that query the orchestrator function status.

The following example shows REST commands that start an orchestrator and query its status. For clarity, some protocol details are omitted from the example.

```
> curl -X POST https://myfunc.azurewebsites.net/api/orchestrators/DoWork -H "Content-Length: 0" -i
HTTP/1.1 202 Accepted
Content-Type: application/json
Location:
https://myfunc.azurewebsites.net/runtime/webhooks/durabletask/instances/b79baf67f717453ca9e86c5da21e03ec

{"id":"b79baf67f717453ca9e86c5da21e03ec", ...}

> curl
https://myfunc.azurewebsites.net/runtime/webhooks/durabletask/instances/b79baf67f717453ca9e86c5da21e03ec -i
HTTP/1.1 202 Accepted
Content-Type: application/json
Location:
```

```
https://myfunc.azurewebsites.net/runtime/webhooks/durabletask/instances/b79b  
af67f717453ca9e86c5da21e03ec
```

```
{"runtimeStatus": "Running", "lastUpdatedTime": "2019-03-16T21:20:47Z", ...}
```

```
> curl
```

```
https://myfunc.azurewebsites.net/runtime/webhooks/durabletask/instances/b79b  
af67f717453ca9e86c5da21e03ec -i
```

```
HTTP/1.1 200 OK
```

```
Content-Length: 175
```

```
Content-Type: application/json
```

```
{"runtimeStatus": "Completed", "lastUpdatedTime": "2019-03-16T21:20:57Z", ...}
```

Because the Durable Functions runtime manages state for you, you don't need to implement your own status-tracking mechanism.

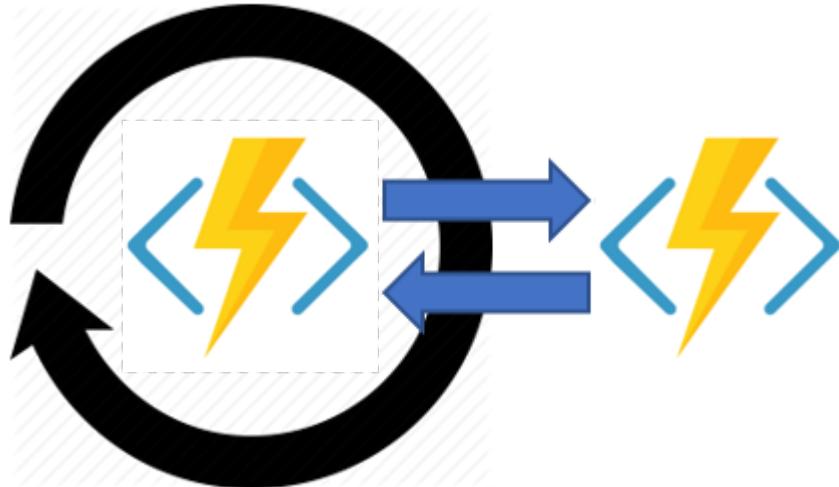

The Durable Functions extension exposes built-in HTTP APIs that manage long-running orchestrations. You can alternatively implement this pattern yourself by using your own function triggers (such as HTTP, a queue, or Azure Event Hubs) and the [durable client binding](#). For example, you might use a queue message to trigger termination. Or, you might use an HTTP trigger that's protected by an Azure Active Directory authentication policy instead of the built-in HTTP APIs that use a generated key for authentication.

For more information, see the [HTTP features](#) article, which explains how you can expose asynchronous, long-running processes over HTTP using the Durable Functions extension.

Pattern #4: Monitor

The monitor pattern refers to a flexible, recurring process in a workflow. An example is polling until specific conditions are met. You can use a regular [timer trigger](#) to address a basic scenario, such as a periodic cleanup job, but its interval is static and managing instance lifetimes becomes complex. You can use Durable Functions to create flexible recurrence intervals, manage task lifetimes, and create multiple monitor processes from a single orchestration.

An example of the monitor pattern is to reverse the earlier async HTTP API scenario. Instead of exposing an endpoint for an external client to monitor a long-running operation, the long-running monitor consumes an external endpoint, and then waits for a state change.

In a few lines of code, you can use Durable Functions to create multiple monitors that observe arbitrary endpoints. The monitors can end execution when a condition is met, or another function can use the durable orchestration client to terminate the monitors. You can change a monitor's `wait` interval based on a specific condition (for example, exponential backoff.)

The following code implements a basic monitor:

C# (InProc)

```
C#  
  
[FunctionName("MonitorJobStatus")]
public static async Task Run(
    [OrchestrationTrigger] IDurableOrchestrationContext context)
{
    int jobId = context.GetInput<int>();
    int pollingInterval = GetPollingInterval();
    DateTime expiryTime = GetExpiryTime();

    while (context.CurrentUtcDateTime < expiryTime)
    {
        var jobStatus = await context.CallActivityAsync<string>
("GetJobStatus", jobId);
        if (jobStatus == "Completed")
        {
            // Perform an action when a condition is met.
            await context.CallActivityAsync("SendAlert", jobId);
            break;
        }

        // Orchestration sleeps until this time.
        var nextCheck =
            context.CurrentUtcDateTime.AddSeconds(pollingInterval);
```

```

        await context.CreateTimer(nextCheck, CancellationToken.None);
    }

    // Perform more work here, or let the orchestration end.
}

```

When a request is received, a new orchestration instance is created for that job ID. The instance polls a status until either a condition is met or until a timeout expires. A durable timer controls the polling interval. Then, more work can be performed, or the orchestration can end.

Pattern #5: Human interaction

Many automated processes involve some kind of human interaction. Involving humans in an automated process is tricky because people aren't as highly available and as responsive as cloud services. An automated process might allow for this interaction by using timeouts and compensation logic.

An approval process is an example of a business process that involves human interaction. Approval from a manager might be required for an expense report that exceeds a certain dollar amount. If the manager doesn't approve the expense report within 72 hours (maybe the manager went on vacation), an escalation process kicks in to get the approval from someone else (perhaps the manager's manager).

You can implement the pattern in this example by using an orchestrator function. The orchestrator uses a [durable timer](#) to request approval. The orchestrator escalates if timeout occurs. The orchestrator waits for an [external event](#), such as a notification that's generated by a human interaction.

These examples create an approval process to demonstrate the human interaction pattern:

```
C#  
  
[FunctionName("ApprovalWorkflow")]
public static async Task Run(
    [OrchestrationTrigger] IDurableOrchestrationContext context)
{
    await context.CallActivityAsync("RequestApproval", null);
    using (var timeoutCts = new CancellationTokenSource())
    {
        DateTime dueTime = context.CurrentUtcDateTime.AddHours(72);
        Task durableTimeout = context.CreateTimer(dueTime,
            timeoutCts.Token);  
  

        Task<bool> approvalEvent = context.WaitForExternalEvent<bool>
            ("ApprovalEvent");
        if (approvalEvent == await Task.WhenAny(approvalEvent,
            durableTimeout))
        {
            timeoutCts.Cancel();
            await context.CallActivityAsync("ProcessApproval",
                approvalEvent.Result);
        }
        else
        {
            await context.CallActivityAsync("Escalate", null);
        }
    }
}
```

To create the durable timer, call `context.CreateTimer`. The notification is received by `context.WaitForExternalEvent`. Then, `Task.WhenAny` is called to decide whether to escalate (timeout happens first) or process the approval (the approval is received before timeout).

ⓘ Note

There is no charge for time spent waiting for external events when running in the Consumption plan.

An external client can deliver the event notification to a waiting orchestrator function by using the [built-in HTTP APIs](#):

```
curl -d "true"  
http://localhost:7071/runtime/webhooks/durabletask/instances/{instanceId}/ra  
iseEvent/ApprovalEvent -H "Content-Type: application/json"
```

An event can also be raised using the durable orchestration client from another function in the same function app:

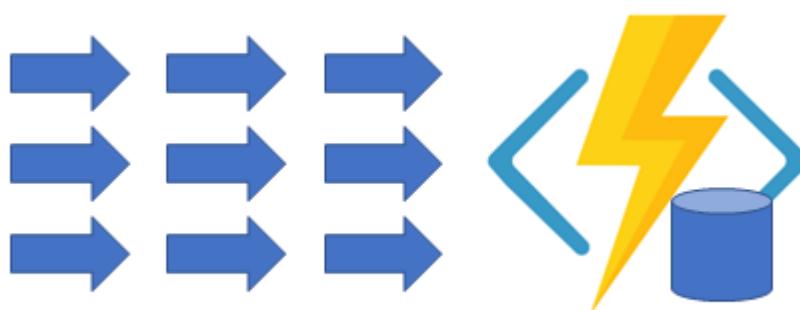

C# (InProc)

C#

```
[FunctionName("RaiseEventToOrchestration")]
public static async Task Run(
    [HttpTrigger] string instanceId,
    [DurableClient] IDurableOrchestrationClient client)
{
    bool isApproved = true;
    await client.RaiseEventAsync(instanceId, "ApprovalEvent",
        isApproved);
}
```

Pattern #6: Aggregator (stateful entities)

The sixth pattern is about aggregating event data over a period of time into a single, addressable *entity*. In this pattern, the data being aggregated may come from multiple sources, may be delivered in batches, or may be scattered over long-periods of time. The aggregator might need to take action on event data as it arrives, and external clients may need to query the aggregated data.

The tricky thing about trying to implement this pattern with normal, stateless functions is that concurrency control becomes a huge challenge. Not only do you need to worry

about multiple threads modifying the same data at the same time, you also need to worry about ensuring that the aggregator only runs on a single VM at a time.

You can use [Durable entities](#) to easily implement this pattern as a single function.

C# (InProc)

```
C#  
  
[FunctionName("Counter")]
public static void Counter([EntityTrigger] IDurableEntityContext ctx)
{
    int currentValue = ctx.GetState<int>();
    switch (ctx.OperationName.ToLowerInvariant())
    {
        case "add":
            int amount = ctx.GetInput<int>();
            ctx.SetState(currentValue + amount);
            break;
        case "reset":
            ctx.SetState(0);
            break;
        case "get":
            ctx.Return(currentValue);
            break;
    }
}
```

Durable entities can also be modeled as classes in .NET. This model can be useful if the list of operations is fixed and becomes large. The following example is an equivalent implementation of the `Counter` entity using .NET classes and methods.

C#

```
public class Counter
{
    [JsonProperty("value")]
    public int CurrentValue { get; set; }

    public void Add(int amount) => this.CurrentValue += amount;

    public void Reset() => this.CurrentValue = 0;

    public int Get() => this.CurrentValue;

    [FunctionName(nameof(Counter))]
    public static Task Run([EntityTrigger] IDurableEntityContext ctx)
```

```
=> ctx.DispatchAsync<Counter>();  
}
```

Clients can enqueue *operations* for (also known as "signaling") an entity function using the [entity client binding](#).

C# (InProc)

C#

```
[FunctionName("EventHubTriggerCSharp")]
public static async Task Run(
    [EventHubTrigger("device-sensor-events")] EventData eventData,
    [DurableClient] IDurableEntityClient entityClient)
{
    var metricType = (string)eventData.Properties["metric"];
    var delta = BitConverter.ToInt32(eventData.Body,
        eventData.Body.Offset);

    // The "Counter/{metricType}" entity is created on-demand.
    var entityId = new EntityId("Counter", metricType);
    await entityClient.SignalEntityAsync(entityId, "add", delta);
}
```

ⓘ Note

Dynamically generated proxies are also available in .NET for signaling entities in a type-safe way. And in addition to signaling, clients can also query for the state of an entity function using **type-safe methods** on the orchestration client binding.

Entity functions are available in [Durable Functions 2.0](#) and above for C#, JavaScript, and Python.

The technology

Behind the scenes, the Durable Functions extension is built on top of the [Durable Task Framework](#), an open-source library on GitHub that's used to build workflows in code. Like Azure Functions is the serverless evolution of Azure WebJobs, Durable Functions is the serverless evolution of the Durable Task Framework. Microsoft and other organizations use the Durable Task Framework extensively to automate mission-critical processes. It's a natural fit for the serverless Azure Functions environment.

Code constraints

In order to provide reliable and long-running execution guarantees, orchestrator functions have a set of coding rules that must be followed. For more information, see the [Orchestrator function code constraints](#) article.

Billing

Durable Functions are billed the same as Azure Functions. For more information, see [Azure Functions pricing](#). When executing orchestrator functions in the Azure Functions [Consumption plan](#), there are some billing behaviors to be aware of. For more information on these behaviors, see the [Durable Functions billing](#) article.

Jump right in

You can get started with Durable Functions in under 10 minutes by completing one of these language-specific quickstart tutorials:

- [C# using Visual Studio 2019](#)
- [JavaScript using Visual Studio Code](#)
- [TypeScript using Visual Studio Code](#)
- [Python using Visual Studio Code](#)
- [PowerShell using Visual Studio Code](#)
- [Java using Maven](#)

In these quickstarts, you locally create and test a "hello world" durable function. You then publish the function code to Azure. The function you create orchestrates and chains together calls to other functions.

Publications

Durable Functions is developed in collaboration with Microsoft Research. As a result, the Durable Functions team actively produces research papers and artifacts; these include:

- [Durable Functions: Semantics for Stateful Serverless](#) (OOPSLA'21)
- [Serverless Workflows with Durable Functions and Netherite](#) (pre-print)

Learn more

The following video highlights the benefits of Durable Functions:

<https://learn.microsoft.com/Shows/Azure-Friday/Durable-Functions-in-Azure-Functions/player>

For a more in-depth discussion of Durable Functions and the underlying technology, see the following video (it's focused on .NET, but the concepts also apply to other supported languages):

<https://learn.microsoft.com/Events/dotnetConf/2018/S204/player>

Because Durable Functions is an advanced extension for [Azure Functions](#), it isn't appropriate for all applications. For a comparison with other Azure orchestration technologies, see [Compare Azure Functions and Azure Logic Apps](#).

Choose the right integration and automation services in Azure

Article • 06/09/2023

This article compares the following Microsoft cloud services:

- [Microsoft Power Automate](#) (was Microsoft Flow)
- [Azure Logic Apps](#)
- [Azure Functions](#)
- [Azure App Service WebJobs](#)

All of these services can solve integration problems and automate business processes. They can all define input, actions, conditions, and output. You can run each of them on a schedule or trigger. Each service has unique advantages, and this article explains the differences.

ⓘ Note

If you're looking for a more general comparison between Azure Functions and other Azure compute options:

- [Criteria for choosing an Azure compute service](#)
- [Choosing an Azure compute option for microservices](#)

For a summary and comparison of automation service options in Azure:

- [Choose the Automation services in Azure](#)

Compare Microsoft Power Automate and Azure Logic Apps

Power Automate and Azure Logic Apps are both *designer-first* integration services that can create workflows. Both services integrate with various SaaS and enterprise applications.

Power Automate is built on the Azure Logic Apps platform. Both provide similar workflow designers and [connectors](#).

Power Automate empowers any office worker to perform simple integrations (for example, an approval process on a SharePoint Document Library) without going through

developers or IT. Logic Apps can also enable advanced integrations (for example, B2B processes) where enterprise-level Azure DevOps and security practices are required. It's typical for a business workflow to grow in complexity over time.

The following table helps you determine whether Power Automate or Logic Apps is best for a particular integration:

	Power Automate	Logic Apps
Users	Office workers, business users, SharePoint administrators	Pro integrators and developers, IT pros
Scenarios	Self-service	Advanced integrations
Design tool	In-browser and mobile app, UI only	In-browser, Visual Studio Code , and Visual Studio with code view available
Application lifecycle management (ALM)	Power Platform provides tools that integrate with DevOps and GitHub Actions to let you build automated pipelines in the ALM cycle.	Azure DevOps: source control, testing, support, automation, and manageability in Azure Resource Manager
Admin experience	Manage Power Automate environments and data loss prevention (DLP) policies, track licensing: Admin center	Manage resource groups, connections, access management, and logging: Azure portal
Security	Microsoft 365 security audit logs, DLP, encryption at rest for sensitive data	Security assurance of Azure: Azure security , Microsoft Defender for Cloud , audit logs

Compare Azure Functions and Azure Logic Apps

Functions and Logic Apps are Azure services that enable serverless workloads. Azure Functions is a serverless compute service, whereas Azure Logic Apps is a serverless workflow integration platform. Both can create complex *orchestrations*. An orchestration is a collection of functions, or *actions* in Azure Logic Apps, that you can run to complete a complex task. For example, to process a batch of orders, you might execute many instances of a function in parallel, wait for all instances to finish, and then execute a function that computes a result on the aggregate.

For Azure Functions, you develop orchestrations by writing code and using the [Durable Functions extension](#). For Azure Logic Apps, you create orchestrations by using a GUI or editing configuration files.

You can mix and match services when you build an orchestration, such as calling functions from logic app workflows and calling logic app workflows from functions. Choose how to build each orchestration based on the services' capabilities or your personal preference. The following table lists some key differences between these services:

	Durable Functions	Azure Logic Apps
Development	Code-first (imperative)	Designer-first (declarative)
Connectivity	About a dozen built-in binding types , write code for custom bindings	Large collection of connectors , Enterprise Integration Pack for B2B scenarios, build custom connectors
Actions	Each activity is an Azure function; write code for activity functions	Large collection of ready-made actions
Monitoring	Azure Application Insights	Azure portal , Azure Monitor Logs , Microsoft Defender for Cloud
Management	REST API , Visual Studio	Azure portal , REST API , PowerShell , Visual Studio
Execution context	Can run locally or in the cloud	Runs in Azure, locally, or on premises. For more information, see What is Azure Logic Apps .

Compare Functions and WebJobs

Like Azure Functions, Azure App Service WebJobs with the WebJobs SDK is a *code-first* integration service that is designed for developers. Both are built on [Azure App Service](#) and support features such as [source control integration](#), [authentication](#), and [monitoring with Application Insights integration](#).

WebJobs and the WebJobs SDK

You can use the *WebJobs* feature of App Service to run a script or code in the context of an App Service web app. The *WebJobs SDK* is a framework designed for WebJobs that simplifies the code you write to respond to events in Azure services. For example, you might respond to the creation of an image blob in Azure Storage by creating a thumbnail image. The WebJobs SDK runs as a .NET console application, which you can deploy to a WebJob.

WebJobs and the WebJobs SDK work best together, but you can use WebJobs without the WebJobs SDK and vice versa. A WebJob can run any program or script that runs in the App Service sandbox. A WebJobs SDK console application can run anywhere console applications run, such as on-premises servers.

Comparison table

Azure Functions is built on the WebJobs SDK, so it shares many of the same event triggers and connections to other Azure services. Here are some factors to consider when you're choosing between Azure Functions and WebJobs with the WebJobs SDK:

	Functions	WebJobs with WebJobs SDK
Serverless app model  with automatic scaling	✓	
Develop and test in browser	✓	
Pay-per-use pricing	✓	
Integration with Logic Apps	✓	
Trigger events	Timer Azure Storage queues and blobs Azure Service Bus queues and topics Azure Cosmos DB Azure Event Hubs HTTP/WebHook (GitHub, Slack) Azure Event Grid	Timer Azure Storage queues and blobs Azure Service Bus queues and topics Azure Cosmos DB Azure Event Hubs File system 
Supported languages	C# F# JavaScript Java Python PowerShell	C# ¹
Package managers	npm and NuGet	NuGet ²

¹ WebJobs (without the WebJobs SDK) supports languages such as C#, Java, JavaScript, Bash, .cmd, .bat, PowerShell, PHP, TypeScript, Python, and more. A WebJob can run any program or script that can run in the App Service sandbox.

² WebJobs (without the WebJobs SDK) supports npm and NuGet.

Summary

Azure Functions offers more developer productivity than Azure App Service WebJobs does. It also offers more options for programming languages, development environments, Azure service integration, and pricing. For most scenarios, it's the best choice.

Here are two scenarios for which WebJobs may be the best choice:

- You need more control over the code that listens for events, the `JobHost` object. Functions offers a limited number of ways to customize `JobHost` behavior in the `host.json` file. Sometimes you need to do things that can't be specified by a string in a JSON file. For example, only the WebJobs SDK lets you configure a custom retry policy for Azure Storage.
- You have an App Service app for which you want to run code snippets, and you want to manage them together in the same Azure DevOps environment.

For other scenarios where you want to run code snippets for integrating Azure or third-party services, choose Azure Functions over WebJobs with the WebJobs SDK.

Power Automate, Logic Apps, Functions, and WebJobs together

You don't have to choose just one of these services. They integrate with each other and with external services.

A Power Automate flow can call an Azure Logic Apps workflow. An Azure Logic Apps workflow can call a function in Azure Functions, and vice versa. For example, see [Create a function that integrates with Azure Logic Apps](#).

Between Power Automate, Logic Apps, and Functions, the integration experience between these services continues to improve over time. You can build a component in one service and use that component in the other services.

You can get more information on integration services by using the following links:

- [Leveraging Azure Functions & Azure App Service for integration scenarios by Christopher Anderson ↗](#)

Azure Functions hosting options

Article • 07/16/2024

When you create a function app in Azure, you must choose a hosting option for your app. Azure provides you with these hosting options for your function code:

[+] Expand table

Hosting option	Service	Availability	Container support
Consumption plan	Azure Functions	Generally available (GA)	None
Flex Consumption plan	Azure Functions	Preview	None
Premium plan	Azure Functions	GA	Linux
Dedicated plan	Azure Functions	GA	Linux
Container Apps	Azure Container Apps	GA	Linux

Azure Functions hosting options are facilitated by Azure App Service infrastructure on both Linux and Windows virtual machines. The hosting option you choose dictates the following behaviors:

- How your function app is scaled.
- The resources available to each function app instance.
- Support for advanced functionality, such as Azure Virtual Network connectivity.
- Support for Linux containers.

The plan you choose also impacts the costs for running your function code. For more information, see [Billing](#).

This article provides a detailed comparison between the various hosting options. To learn more about running and managing your function code in Linux containers, see [Linux container support in Azure Functions](#).

Overview of plans

The following is a summary of the benefits of the various options for Azure Functions hosting:

[+] Expand table

Option	Benefits
Consumption plan	<p>Pay for compute resources only when your functions are running (pay-as-you-go) with automatic scale.</p> <p>On the Consumption plan, instances of the Functions host are dynamically added and removed based on the number of incoming events.</p> <ul style="list-style-type: none"> ✓ Default hosting plan that provides true <i>serverless</i> hosting. ✓ Pay only when your functions are running. ✓ Scales automatically, even during periods of high load.
Flex Consumption plan	<p>Get high scalability with compute choices, virtual networking, and pay-as-you-go billing.</p> <p>On the Flex Consumption plan, instances of the Functions host are dynamically added and removed based on the configured per instance concurrency and the number of incoming events.</p> <ul style="list-style-type: none"> ✓ Reduce cold starts by specifying a number of pre-provisioned (always ready) instances. ✓ Supports virtual networking for added security. ✓ Pay when your functions are running. ✓ Scales automatically, even during periods of high load.
Premium plan	<p>Automatically scales based on demand using prewarmed workers, which run applications with no delay after being idle, runs on more powerful instances, and connects to virtual networks.</p> <p>Consider the Azure Functions Premium plan in the following situations:</p> <ul style="list-style-type: none"> ✓ Your function apps run continuously, or nearly continuously. ✓ You want more control of your instances and want to deploy multiple function apps on the same plan with event-driven scaling. ✓ You have a high number of small executions and a high execution bill, but low GB seconds in the Consumption plan. ✓ You need more CPU or memory options than are provided by consumption plans. ✓ Your code needs to run longer than the maximum execution time allowed on the Consumption plan. ✓ You require virtual network connectivity. ✓ You want to provide a custom Linux image in which to run your functions.
Dedicated plan	<p>Run your functions within an App Service plan at regular App Service plan rates.</p> <p>Best for long-running scenarios where Durable Functions can't be used.</p> <p>Consider an App Service plan in the following situations:</p> <ul style="list-style-type: none"> ✓ You have existing and underutilized virtual machines that are already running

Option	Benefits
	<p>other App Service instances.</p> <ul style="list-style-type: none"> ✓ You must have fully predictable billing, or you need to manually scale instances. ✓ You want to run multiple web apps and function apps on the same plan ✓ You need access to larger compute size choices. ✓ Full compute isolation and secure network access provided by an App Service Environment (ASE). ✓ Very high memory usage and high scale (ASE).
Container Apps	<p>Create and deploy containerized function apps in a fully managed environment hosted by Azure Container Apps.</p> <p>Use the Azure Functions programming model to build event-driven, serverless, cloud native function apps. Run your functions alongside other microservices, APIs, websites, and workflows as container-hosted programs. Consider hosting your functions on Container Apps in the following situations:</p> <ul style="list-style-type: none"> ✓ You want to package custom libraries with your function code to support line-of-business apps. ✓ You need to migrate code execution from on-premises or legacy apps to cloud native microservices running in containers. ✓ When you want to avoid the overhead and complexity of managing Kubernetes clusters and dedicated compute. ✓ Your functions need high-end processing power provided by dedicated GPU compute resources.

The remaining tables in this article compare hosting options based on various features and behaviors.

Operating system support

This table shows operating system support for the hosting options.

[\[\]](#) Expand table

Hosting	Linux ¹ deployment	Windows ² deployment
Consumption plan	<ul style="list-style-type: none"> <input checked="" type="checkbox"/> Code-only <input type="checkbox"/> Container (not supported) 	<ul style="list-style-type: none"> <input checked="" type="checkbox"/> Code-only
Flex Consumption plan	<ul style="list-style-type: none"> <input checked="" type="checkbox"/> Code-only <input type="checkbox"/> Container (not supported) 	<ul style="list-style-type: none"> <input type="checkbox"/> Not supported
Premium plan	<ul style="list-style-type: none"> <input checked="" type="checkbox"/> Code-only <input checked="" type="checkbox"/> Container 	<ul style="list-style-type: none"> <input checked="" type="checkbox"/> Code-only

Hosting	Linux ¹ deployment	Windows ² deployment
Dedicated plan	<input checked="" type="checkbox"/> Code-only <input checked="" type="checkbox"/> Container	<input checked="" type="checkbox"/> Code-only
Container Apps	<input checked="" type="checkbox"/> Container-only	 Not supported

1. Linux is the only supported operating system for the [Python runtime stack](#).
2. Windows deployments are code-only. Functions doesn't currently support Windows containers.

Function app timeout duration

The timeout duration for functions in a function app is defined by the `functionTimeout` property in the [host.json](#) project file. This property applies specifically to function executions. After the trigger starts function execution, the function needs to return/respond within the timeout duration. For more information, see [Improve Azure Functions performance and reliability](#).

The following table shows the default and maximum values (in minutes) for specific plans:

[+] [Expand table](#)

Plan	Default	Maximum ¹
Consumption plan	5	10
Flex Consumption plan	30	Unlimited ³
Premium plan	30 ²	Unlimited ³
Dedicated plan	30 ²	Unlimited ³
Container Apps	30 ⁵	Unlimited ³

1. Regardless of the function app timeout setting, 230 seconds is the maximum amount of time that an HTTP triggered function can take to respond to a request. This is because of the [default idle timeout of Azure Load Balancer](#). For longer processing times, consider using the [Durable Functions async pattern](#) or [defer the actual work and return an immediate response](#).
2. The default timeout for version 1.x of the Functions runtime is *unlimited*.
3. Guaranteed for up to 60 minutes. [OS and runtime patching](#), vulnerability patching, and [scale in behaviors](#) can still cancel function executions so [ensure to write robust](#)

functions.

4. In a Flex Consumption plan, the host doesn't enforce an execution time limit. However, there are currently no guarantees because the platform might need to terminate your instances during scale-in, deployments, or to apply updates.
5. When the [minimum number of replicas](#) is set to zero, the default timeout depends on the specific triggers used in the app.

Language support

For details on current native language stack support in Functions, see [Supported languages in Azure Functions](#).

Scale

The following table compares the scaling behaviors of the various hosting plans. Maximum instances are given on a per-function app (Consumption) or per-plan (Premium/Dedicated) basis, unless otherwise indicated.

[+] [Expand table](#)

Plan	Scale out	Max # instances
Consumption plan	Event driven . Scales out automatically, even during periods of high load. Functions infrastructure scales CPU and memory resources by adding more instances of the Functions host, based on the number of incoming trigger events.	Windows: 200 Linux: 100 ¹
Flex Consumption plan	Per-function scaling . Event-driven scaling decisions are calculated on a per-function basis, which provides a more deterministic way of scaling the functions in your app. With the exception of HTTP, Blob storage (Event Grid), and Durable Functions, all other function trigger types in your app scale on independent instances. All HTTP triggers in your app scale together as a group on the same instances, as do all Blob storage (Event Grid) triggers. All Durable Functions triggers also share instances and scale together.	Limited only by total memory usage of all instances across a given region. For more information, see Instance memory .
Premium plan	Event driven . Scale out automatically, even during periods of high load. Azure Functions infrastructure scales CPU and memory resources by adding more instances of the Functions host, based on the number of events that its functions are triggered on.	Windows: 100 Linux: 20-100 ²

Plan	Scale out	Max # instances
Dedicated plan ³	Manual/autoscale	10-30 100 (ASE)
Container Apps	Event driven. Scale out automatically, even during periods of high load. Azure Functions infrastructure scales CPU and memory resources by adding more instances of the Functions host, based on the number of events that its functions are triggered on.	300-1000 ⁴

1. During scale-out, there's currently a limit of 500 instances per subscription per hour for Linux apps on a Consumption plan.
2. In some regions, Linux apps on a Premium plan can scale to 100 instances. For more information, see the [Premium plan article](#).
3. For specific limits for the various App Service plan options, see the [App Service plan limits](#).
4. On Container Apps, the default is 10 instances, but you can set the [maximum number of replicas](#), which has an overall maximum of 1000. This setting is honored as long as there's enough cores quota available. When you create your function app from the Azure portal you're limited to 300 instances.

Cold start behavior

[+] [Expand table](#)

Plan	Details
Consumption plan	Apps can scale to zero when idle, meaning some requests might have more latency at startup. The consumption plan does have some optimizations to help decrease cold start time, including pulling from prewarmed placeholder functions that already have the host and language processes running.
Flex Consumption plan	Supports always ready instances to reduce the delay when provisioning new instances.
Premium plan	Supports always ready instances to avoid cold starts by letting you maintain one or more <i>perpetually warm</i> instances.
Dedicated plan	When running in a Dedicated plan, the Functions host can run continuously on a prescribed number of instances, which means that cold start isn't really an issue.
Container Apps	Depends on the minimum number of replicas : <ul style="list-style-type: none"> • When set to zero: apps can scale to zero when idle and some requests might

Plan	Details
	<p>have more latency at startup.</p> <ul style="list-style-type: none"> When set to one or more: the host process runs continuously, which means that cold start isn't an issue.

Service limits

[\[\]](#) Expand table

Resource	Consumption plan	Flex Consumption plan ¹³	Premium plan	Dedicated plan/ASE	Container Apps
Default timeout duration (min)	5	30	30	30 ¹	30 ¹⁷
Max timeout duration (min)	10	unbounded ¹⁶	unbounded ⁸	unbounded ²	unbounded ¹⁸

Custom domain SSL support	unbounded SNI SSL connection included	unbounded SNI SSL and 1 IP SSL connections included	unbounded SNI SSL and 1 IP SSL connections included	unbounded SNI SSL and 1 IP SSL connections included	not supported

Notes on service limits:

1. By default, the timeout for the Functions 1.x runtime in an App Service plan is unbounded.
2. Requires the App Service plan be set to [Always On](#). Pay at standard [rates](#).
3. These limits are [set in the host](#).
4. The actual number of function apps that you can host depends on the activity of the apps, the size of the machine instances, and the corresponding resource utilization.
5. The storage limit is the total content size in temporary storage across all apps in the same App Service plan. For Consumption plans on Linux, the storage is currently 1.5 GB.
6. Consumption plan uses an Azure Files share for persisted storage. When you provide your own Azure Files share, the specific share size limits depend on the storage account you set for [WEBSITE_CONTENTAZUREFILECONNECTIONSTRING](#). On Linux, you must [explicitly mount your own Azure Files share](#) for both Flex Consumption and Consumption plans.
7. When your function app is hosted in a [Consumption plan](#), only the CNAME option is supported. For function apps in a [Premium plan](#) or an [App Service plan](#), you can

- map a custom domain using either a CNAME or an A record.
8. Guaranteed for up to 60 minutes.
 9. Workers are roles that host customer apps. Workers are available in three fixed sizes: One vCPU/3.5 GB RAM; Two vCPU/7 GB RAM; Four vCPU/14 GB RAM.
 10. See [App Service limits](#) for details.
 11. Including the production slot.
 12. There's currently a limit of 5000 function apps in a given subscription.
 13. The Flex Consumption plan is currently in preview.
 14. Flex Consumption plan instance sizes are currently defined as either 2,048 MB or 4,096 MB. For more information, see [Instance memory](#).
 15. Flex Consumption plan during preview has a regional subscription quota that limits the total memory usage of all instances across a given region. For more information, see [Instance memory](#).
 16. In a Flex Consumption plan, the host doesn't enforce an execution time limit. However, there are currently no guarantees because the platform might need to terminate your instances during scale-in, deployments, or to apply updates.
 17. When the [minimum number of replicas](#) is set to zero, the default timeout depends on the specific triggers used in the app.
 18. When the [minimum number of replicas](#) is set to one or more.
 19. On Container Apps, you can set the [maximum number of replicas](#), which is honored as long as there's enough cores quota available.

Networking features

[] Expand table

Feature	Consumption plan	Flex Consumption plan	Premium plan	Dedicated plan/ASE	Container Apps*

*For more information, see [Networking in Azure Container Apps environment](#).

Billing

[+] [Expand table](#)

Plan	Details
Consumption plan	Pay only for the time your functions run. Billing is based on number of executions, execution time, and memory used.
Flex Consumption plan	Billing is based on number of executions, the memory of instances when they're actively executing functions, plus the cost of any always ready instances . For more information, see Flex Consumption plan billing .
Premium plan	Premium plan is based on the number of core seconds and memory used across needed and prewarmed instances. At least one instance per plan must always be kept warm. This plan provides the most predictable pricing.
Dedicated plan	You pay the same for function apps in an App Service Plan as you would for other App Service resources, like web apps. For an ASE, there's a flat monthly rate that pays for the infrastructure and doesn't change with the size of the environment. There's also a cost per App Service plan vCPU. All apps hosted in an ASE are in the Isolated pricing SKU. For more information, see the ASE overview article .
Container Apps	Billing in Azure Container Apps is based on your plan type. For more information, see Billing in Azure Container Apps .

For a direct cost comparison between dynamic hosting plans (Consumption, Flex Consumption, and Premium), see the [Azure Functions pricing page](#). For pricing of the various Dedicated plan options, see the [App Service pricing page](#). For pricing Container Apps hosting, see [Azure Container Apps pricing](#).

Limitations for creating new function apps in an existing resource group

In some cases, when trying to create a new hosting plan for your function app in an existing resource group you might receive one of the following errors:

- The pricing tier is not allowed in this resource group
- <SKU_name> workers are not available in resource group
<resource_group_name>

This can happen when the following conditions are met:

- You create a function app in an existing resource group that has ever contained another function app or web app. For example, Linux Consumption apps aren't supported in the same resource group as Linux Dedicated or Linux Premium plans.
- Your new function app is created in the same region as the previous app.
- The previous app is in some way incompatible with your new app. This error can happen between SKUs, operating systems, or due to other platform-level features, such as availability zone support.

The reason this happens is due to how function app and web app plans are mapped to different pools of resources when being created. Different SKUs require a different set of infrastructure capabilities. When you create an app in a resource group, that resource group is mapped and assigned to a specific pool of resources. If you try to create another plan in that resource group and the mapped pool does not have the required resources, this error occurs.

When this error occurs, instead create your function app and hosting plan in a new resource group.

Quickstart: Create your first C# function in Azure using Visual Studio

Article • 07/18/2024

Azure Functions lets you use Visual Studio to create local C# function projects and then easily publish this project to run in a scalable serverless environment in Azure. If you prefer to develop your C# apps locally using Visual Studio Code, you should instead consider the [Visual Studio Code-based version](#) of this article.

By default, this article shows you how to create C# functions that run on .NET 8 in an [isolated worker process](#). Function apps that run in an isolated worker process are supported on all versions of .NET that are supported by Functions. For more information, see [Supported versions](#).

In this article, you learn how to:

- ✓ Use Visual Studio to create a C# class library project.
- ✓ Create a function that responds to HTTP requests.
- ✓ Run your code locally to verify function behavior.
- ✓ Deploy your code project to Azure Functions.

Completing this quickstart incurs a small cost of a few USD cents or less in your Azure account.

This video shows you how to create a C# function in Azure.

<https://learn-video.azurefd.net/vod/player?id=efa236ad-db85-4dfc-9f1e-b353c3b09498&locale=en-us&embedUrl=%2Fazure%2Fazure-functions%2Ffunctions-create-your-first-function-visual-studio>

The steps in the video are also described in the following sections.

Prerequisites

- [Visual Studio 2022](#). Make sure to select the **Azure development** workload during installation.
- [Azure subscription](#). If you don't already have an account, [create a free one](#) before you begin.

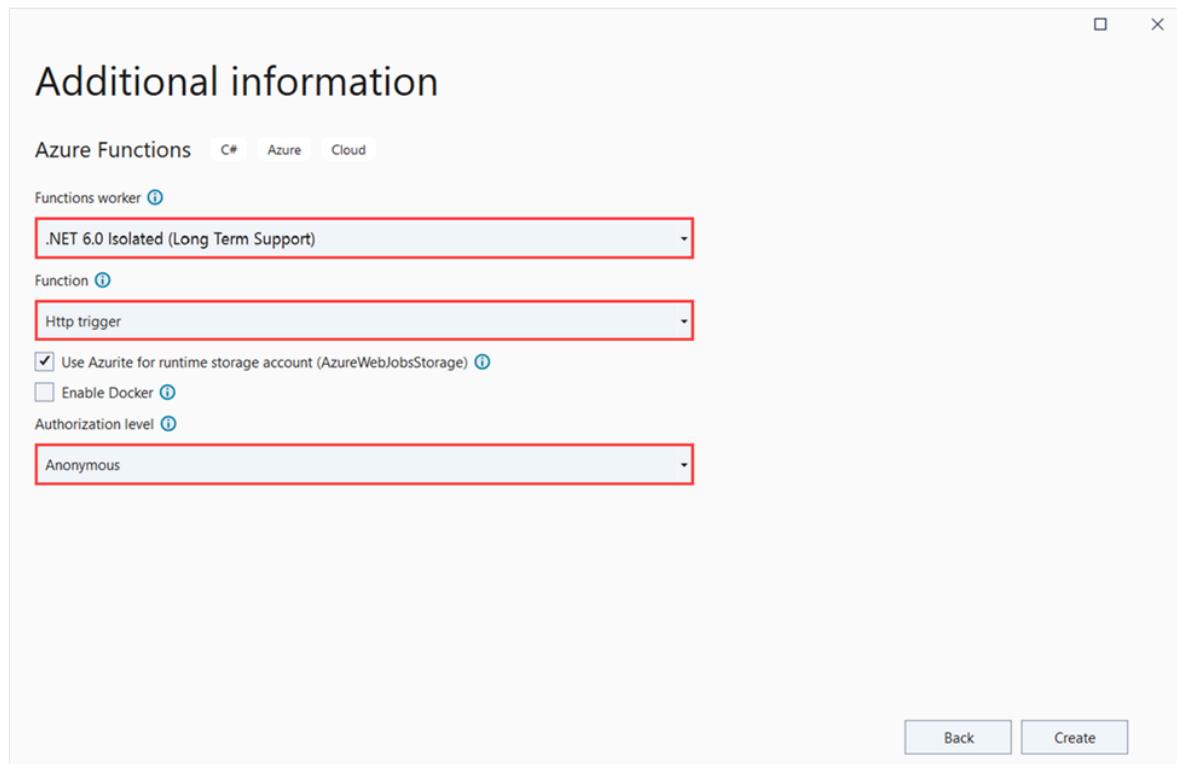

Create a function app project

The Azure Functions project template in Visual Studio creates a C# class library project that you can publish to a function app in Azure. You can use a function app to group functions as a logical unit for easier management, deployment, scaling, and sharing of resources.

1. From the Visual Studio menu, select **File > New > Project**.
2. In **Create a new project**, enter *functions* in the search box, choose the **Azure Functions** template, and then select **Next**.
3. In **Configure your new project**, enter a **Project name** for your project, and then select **Next**. The function app name must be valid as a C# namespace, so don't use underscores, hyphens, or any other nonalphanumeric characters.
4. For the remaining **Additional information** settings,

[+] [Expand table](#)

Setting	Value	Description
Functions worker	.NET 8.0 Isolated (Long Term Support)	Your functions run on .NET 8 in an isolated worker process.
Function	HTTP trigger	This value creates a function triggered by an HTTP request.
Use Azurite for runtime storage account (AzureWebJobsStorage)	Enable	Because a function app in Azure requires a storage account, one is assigned or created when you publish your project to Azure. An HTTP trigger doesn't use an Azure Storage account connection string; all other trigger types require a valid Azure Storage account connection string. When you select this option, the Azurite emulator is used.
Authorization level	Anonymous	The created function can be triggered by any client without providing a key. This authorization setting makes it easy to test your new function. For more information, see Authorization level .

Make sure you set the **Authorization level** to **Anonymous**. If you choose the default level of **Function**, you're required to present the [function key](#) in requests to access your function endpoint in Azure.

5. Select **Create** to create the function project and HTTP trigger function.

Visual Studio creates a project and class that contains boilerplate code for the HTTP trigger function type. The boilerplate code sends an HTTP response that includes a value from the request body or query string. The `HttpTrigger` attribute specifies that the function is triggered by an HTTP request.

Rename the function

The `Function` method attribute sets the name of the function, which by default is generated as `Function1`. Since the tooling doesn't let you override the default function name when you create your project, take a minute to create a better name for the function class, file, and metadata.

1. In **File Explorer**, right-click the `Function1.cs` file and rename it to `HttpExample.cs`.
2. In the code, rename the `Function1` class to `HttpExample`.
3. In the method named `Run`, rename the `Function` method attribute to `HttpExample`.

Your function definition should now look like the following code:

C#

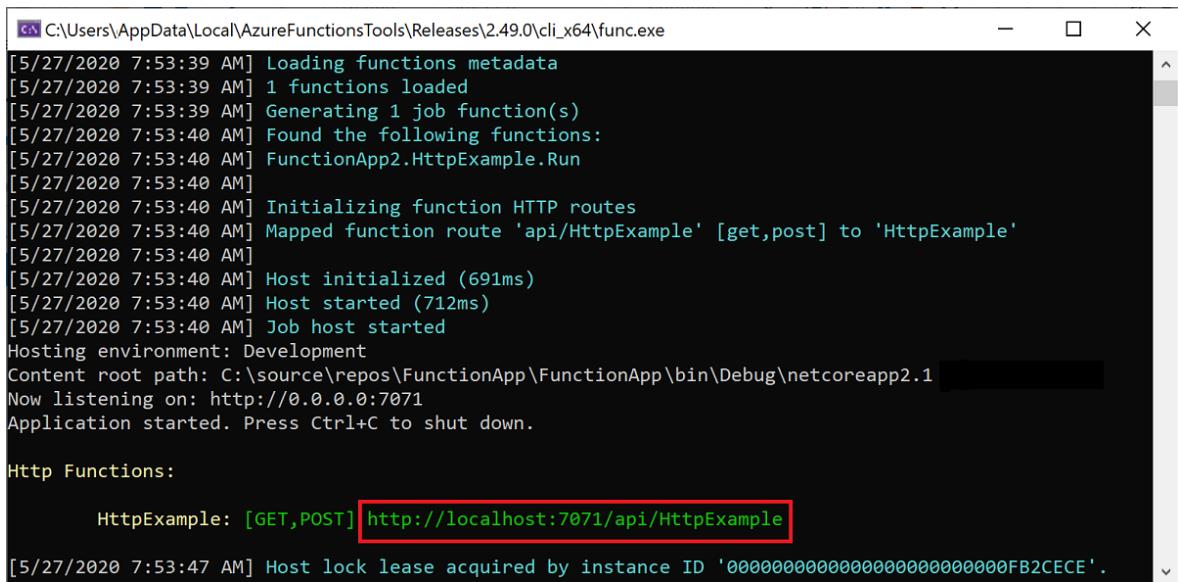

```
[Function("HttpExample")]
public IActionResult Run([HttpTrigger(AuthorizationLevel.AuthLevelValue,
"get", "post")] HttpRequest req)
{
    return new OkObjectResult("Welcome to Azure Functions!");
}
```

Now that you've renamed the function, you can test it on your local computer.

Run the function locally

Visual Studio integrates with Azure Functions Core Tools so that you can test your functions locally using the full Azure Functions runtime.

1. To run your function, press **F5** in Visual Studio. You might need to enable a firewall exception so that the tools can handle HTTP requests. Authorization levels are never enforced when you run a function locally.
2. Copy the URL of your function from the Azure Functions runtime output.

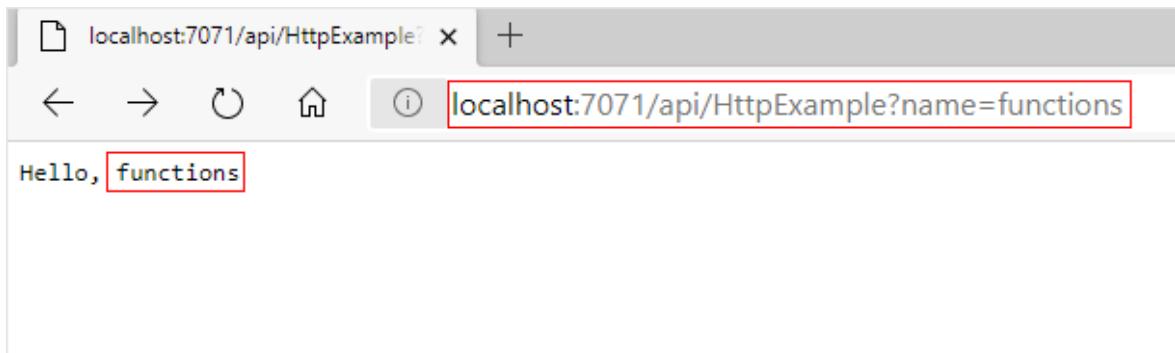

```
C:\Users\AppData\Local\AzureFunctionsTools\Releases\2.49.0\cli_x64\func.exe
[5/27/2020 7:53:39 AM] Loading functions metadata
[5/27/2020 7:53:39 AM] 1 functions loaded
[5/27/2020 7:53:39 AM] Generating 1 job function(s)
[5/27/2020 7:53:40 AM] Found the following functions:
[5/27/2020 7:53:40 AM] FunctionApp2.HttpExample.Run
[5/27/2020 7:53:40 AM]
[5/27/2020 7:53:40 AM] Initializing function HTTP routes
[5/27/2020 7:53:40 AM] Mapped function route 'api/HttpExample' [get,post] to 'HttpExample'
[5/27/2020 7:53:40 AM]
[5/27/2020 7:53:40 AM] Host initialized (691ms)
[5/27/2020 7:53:40 AM] Host started (712ms)
[5/27/2020 7:53:40 AM] Job host started
Hosting environment: Development
Content root path: C:\source\repos\FunctionApp\FunctionApp\bin\Debug\netcoreapp2.1
Now listening on: http://0.0.0.0:7071
Application started. Press Ctrl+C to shut down.

Http Functions:

    HttpExample: [GET,POST] http://localhost:7071/api/HttpExample

[5/27/2020 7:53:47 AM] Host lock lease acquired by instance ID '000000000000000000000000FB2CECE'.
```

3. Paste the URL for the HTTP request into your browser's address bar and run the request. The following image shows the response in the browser to the local GET request returned by the function:

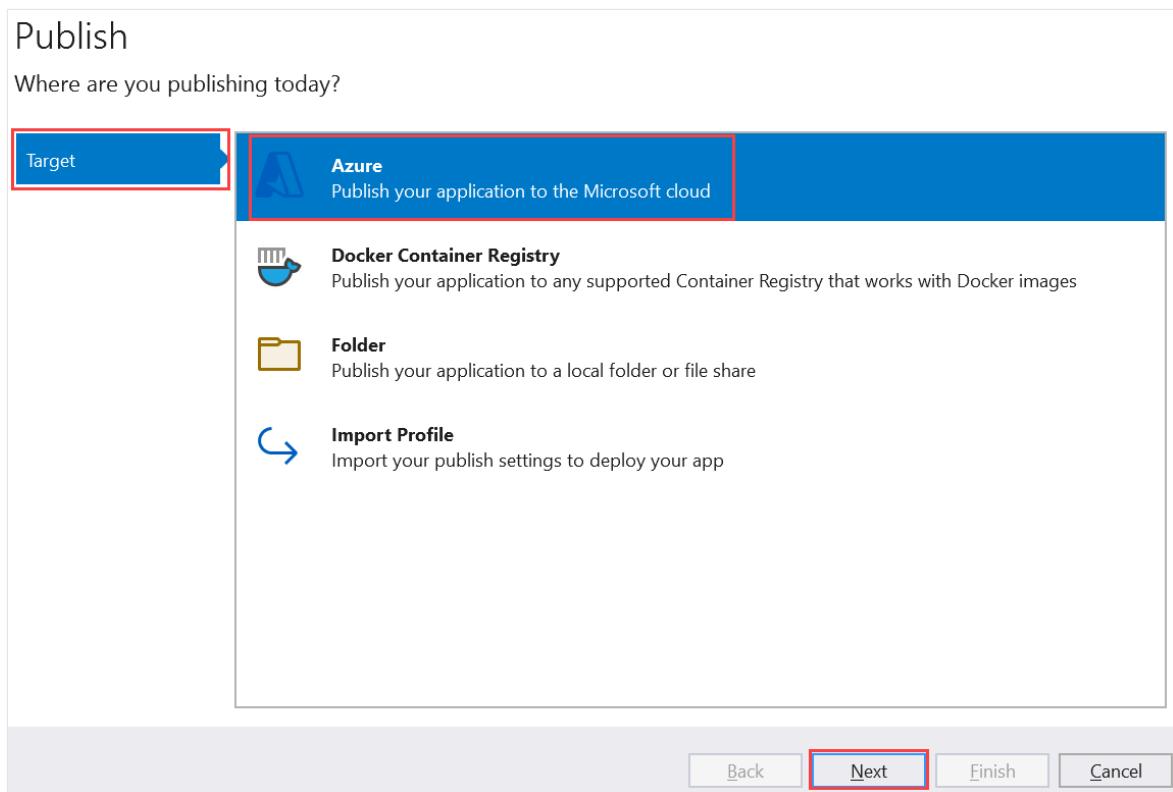

4. To stop debugging, press **Shift** + **F5** in Visual Studio.

After you've verified that the function runs correctly on your local computer, it's time to publish the project to Azure.

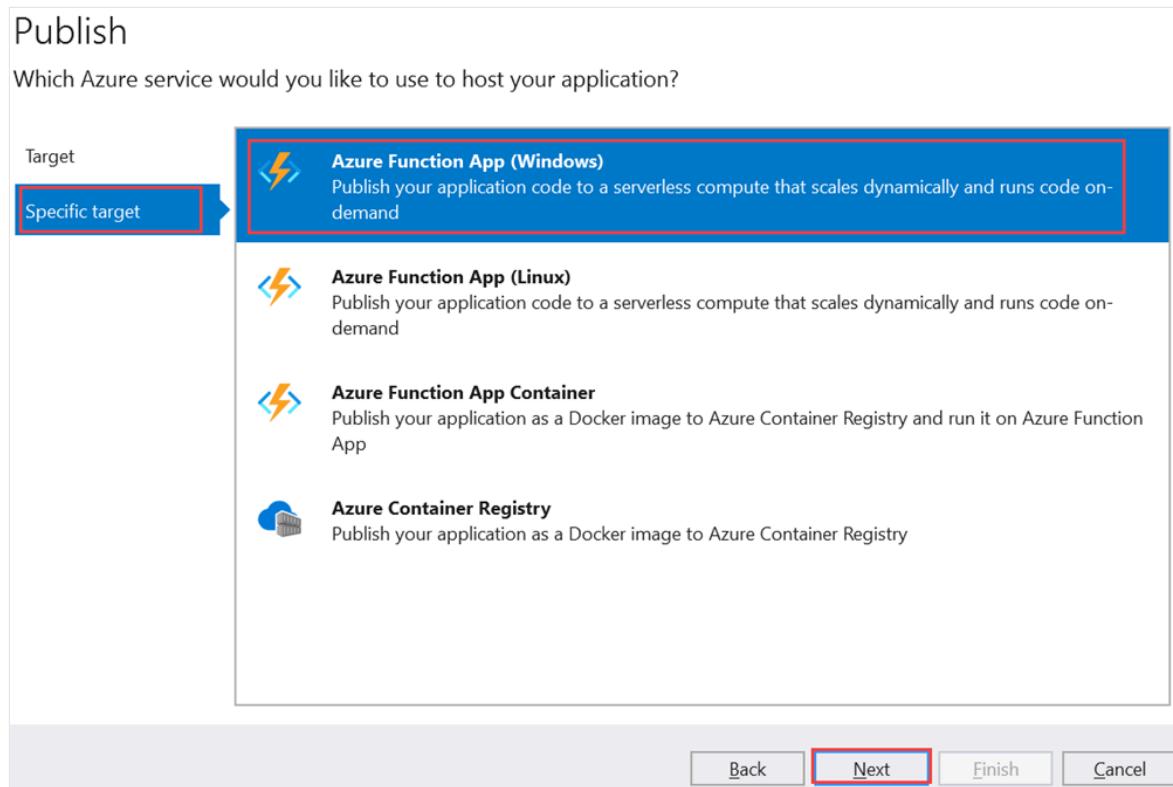

Publish the project to Azure

Visual Studio can publish your local project to Azure. Before you can publish your project, you must have a function app in your Azure subscription. If you don't already have a function app in Azure, Visual Studio publishing creates one for you the first time you publish your project. In this article, you create a function app and related Azure resources.

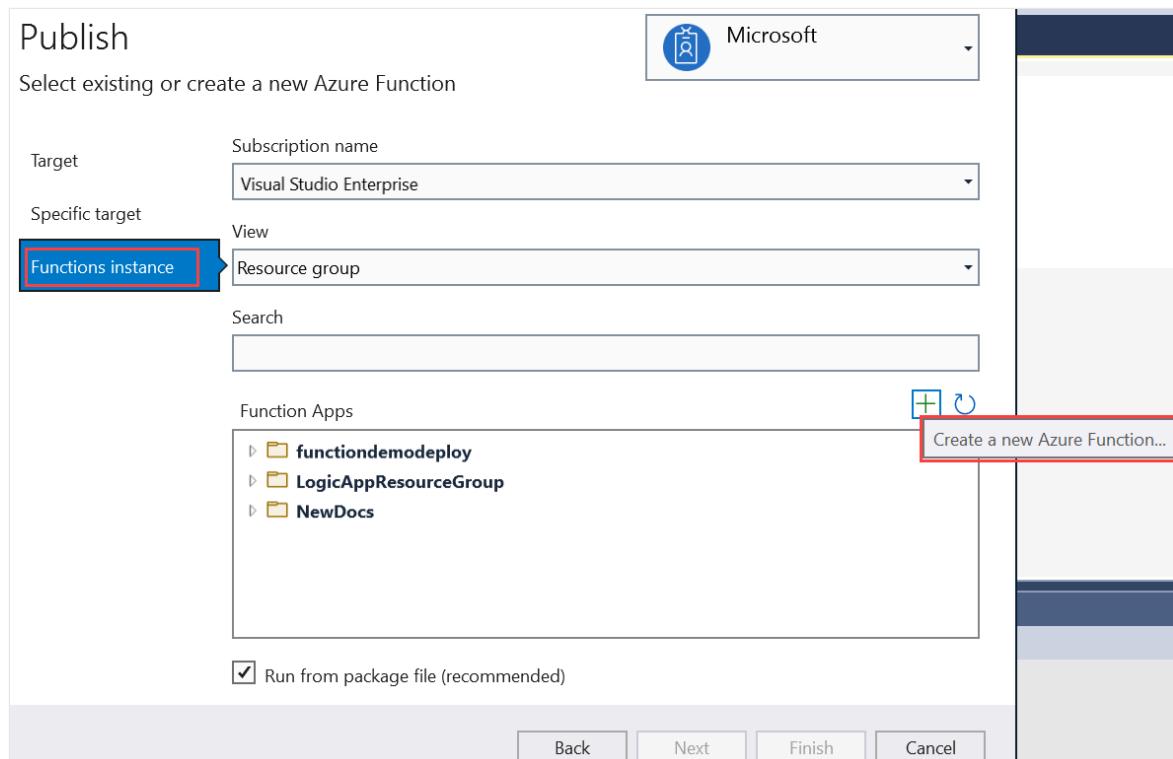

1. In **Solution Explorer**, right-click the project and select **Publish**. In **Target**, select **Azure**, and then select **Next**.

2. On **Specific target**, select **Azure Function App (Windows)**. A function app that runs on Windows is created. Select **Next**.

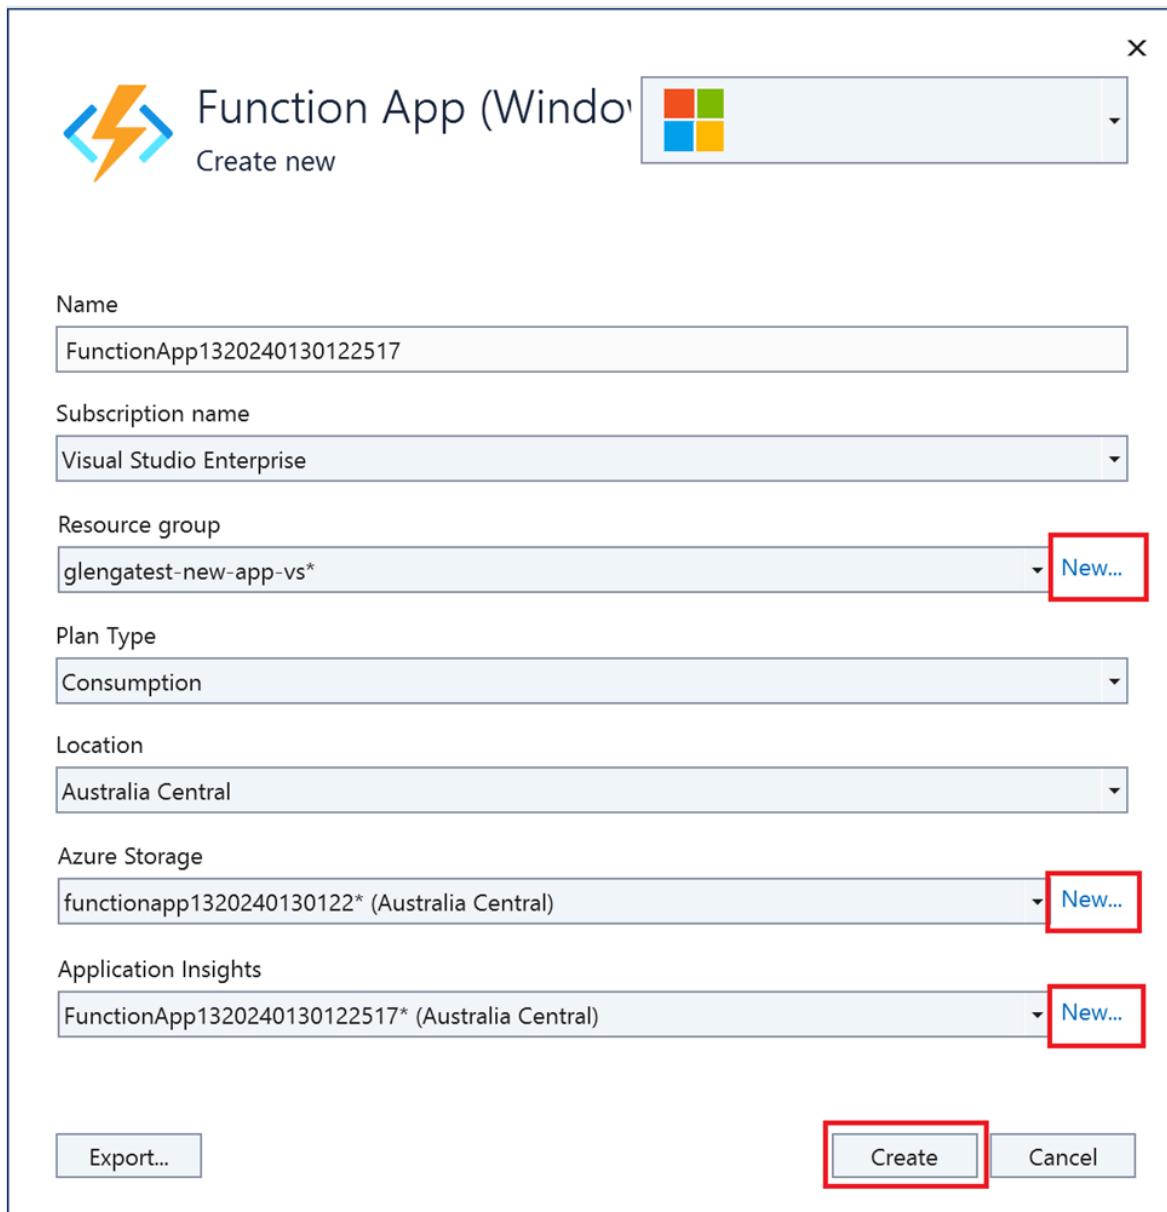

3. On **Functions instance**, select **Create a new Azure Function**.

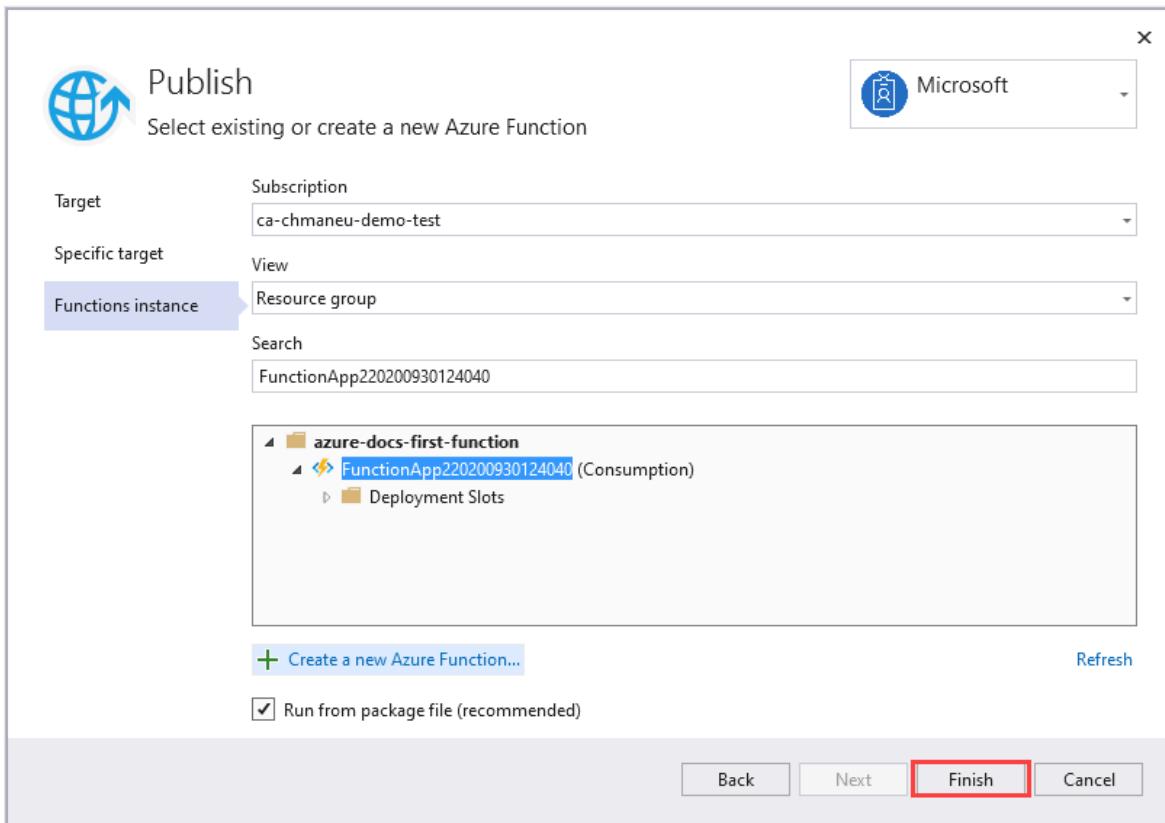

4. Create a new instance by using the values specified in the following table:

[] [Expand table](#)

Setting	Value	Description
Name	Globally unique name	Name that uniquely identifies your new function app. Accept this name or enter a new name. Valid characters are: a-z, 0-9, and -.
Subscription	Your subscription	The Azure subscription to use. Accept this subscription or select a new one from the dropdown list.
Resource group	Name of your resource group	The resource group in which you want to create your function app. Select New to create a new resource group. You can also choose to use an existing resource group from the dropdown list.
Plan Type	Consumption	When you publish your project to a function app that runs in a Consumption plan , you pay only for executions of your functions app. Other hosting plans incur higher costs.
Location	Location of the app service	Select a Location in an Azure region near you or other services your functions access.
Azure Storage	General-purpose storage account	An Azure storage account is required by the Functions runtime. Select New to configure a general-purpose storage account. You can also choose to use an existing account that meets the storage account requirements .
Application Insights	Application Insights instance	You should enable Azure Application Insights integration for your function app. Select New to create a new instance, either in a new or in an existing Log Analytics workspace. You can also choose to use an existing instance.

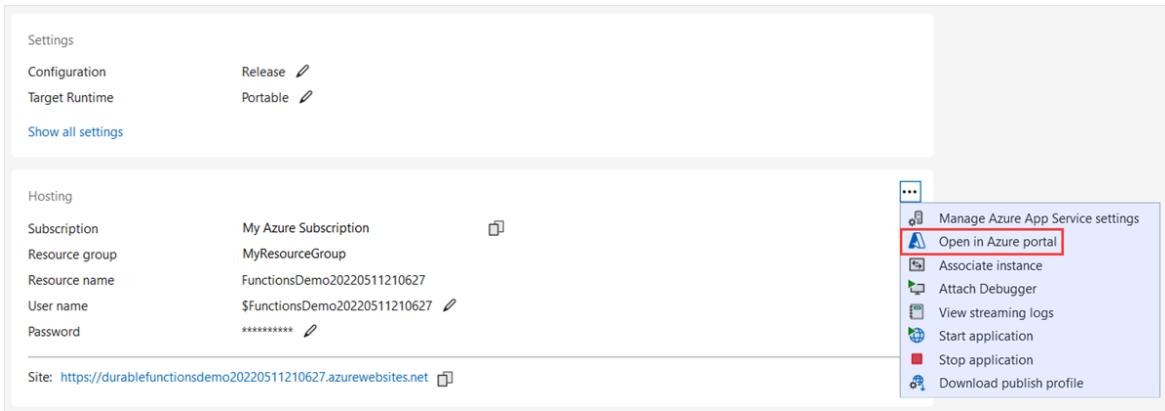

5. Select **Create** to create a function app and its related resources in Azure. The status of resource creation is shown in the lower-left corner of the window.
6. On **Functions instance**, make sure that the **Run from package file** checkbox is selected. Your function app is deployed by using [Zip Deploy](#) with [Run-From-Package](#) mode enabled. Zip Deploy is the recommended deployment method for your functions project for better performance.

7. Select **Finish**, and on the **Publish** pane, select **Publish** to deploy the package that contains your project files to your new function app in Azure.

When deployment is completed, the root URL of the function app in Azure is shown on the **Publish** tab.

8. On the **Publish** tab, in the **Hosting** section, select **Open in Azure portal**. The new function app Azure resource opens in the Azure portal.

Verify your function in Azure

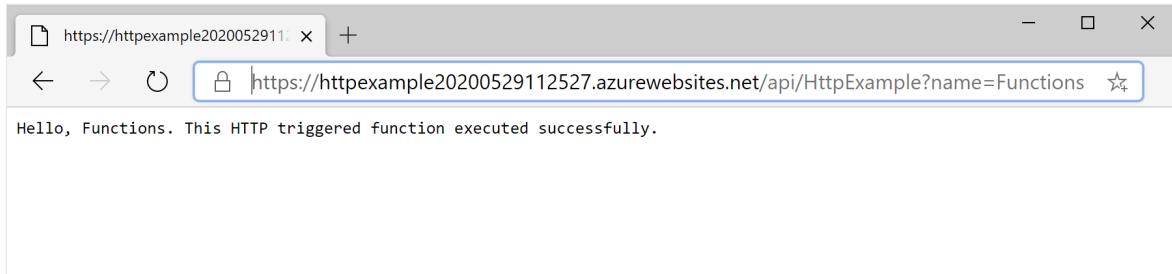

1. In the Azure portal, you should be in the **Overview** page for your new functions app.

2. Under **Functions**, select your new function named **HttpExample**, then in the function page select **Get function URL** and then the **Copy to clipboard** icon.
3. In the address bar in your browser, paste the URL you just copied and run the request.

The URL that calls your HTTP trigger function is in the following format:

```
https://<APP_NAME>.azurewebsites.net/api/HttpExample?name=Functions
```

4. Go to this URL and you see a response in the browser to the remote GET request returned by the function, which looks like the following example:

Clean up resources

Resources in Azure refer to function apps, functions, storage accounts, and so forth. They're grouped into *resource groups*, and you can delete everything in a group by deleting the group.

You created Azure resources to complete this quickstart. You may be billed for these resources, depending on your [account status](#) and [service pricing](#). Other quickstarts in this collection build upon this quickstart. If you plan to work with subsequent quickstarts, tutorials, or with any of the services you've created in this quickstart, don't clean up the resources.

Use the following steps to delete the function app and its related resources to avoid incurring any further costs.

1. In the Visual Studio Publish dialogue, in the Hosting section, select [Open in Azure portal](#).
2. In the function app page, select the **Overview** tab and then select the link under **Resource group**.

The screenshot shows the Azure portal interface for an App Service named 'myfunctionapp'. The left sidebar has a 'Functions' section with options like 'Functions', 'App keys', 'App files', and 'Proxies'. The main content area is titled 'Overview' and shows details for a resource group named 'myResourceGroup'. The details include:

- Status: Running
- Location: Central US
- Subscription: Visual Studio Enterprise
- Subscription ID: 11111111-1111-1111-1111-111111111111
- Tags: Click here to add tags
- URL: https://myfunctionapp.azurewebsites.net
- Operating System: Windows
- App Service Plan: ASP-myResourceGroup-a285 (Y1: 0)
- Properties: See More
- Runtime version: 3.0.13139.0

At the bottom, there are tabs for Metrics, Features (8), Notifications (0), and Quickstart.

3. In the **Resource group** page, review the list of included resources, and verify that they're the ones you want to delete.

4. Select **Delete resource group**, and follow the instructions.

Deletion may take a couple of minutes. When it's done, a notification appears for a few seconds. You can also select the bell icon at the top of the page to view the notification.

Next steps

In this quickstart, you used Visual Studio to create and publish a C# function app in Azure with a simple HTTP trigger function.

To learn more about working with C# functions that run in an isolated worker process, see the [Guide for running C# Azure Functions in an isolated worker process](#). Check out [.NET supported versions](#) to see other versions of supported .NET versions in an isolated worker process.

Advance to the next article to learn how to add an Azure Storage queue binding to your function:

[Add an Azure Storage queue binding to your function](#)

Quickstart: Create a C# function in Azure using Visual Studio Code

Article • 07/18/2024

This article creates an HTTP triggered function that runs on .NET 8 in an isolated worker process. For information about .NET versions supported for C# functions, see [Supported versions](#).

There's also a [CLI-based version](#) of this article.

Completing this quickstart incurs a small cost of a few USD cents or less in your Azure account.

This video shows you how to create a C# function in Azure using VS Code.

[https://learn-video.azurefd.net/vod/player?id=be75e388-1b74-4051-8a62-132b069a3ec9&locale=en-us&embedUrl=%2Fazure%2Fazure-functions%2Fcreate-first-function-vs-code-csharp ↗](https://learn-video.azurefd.net/vod/player?id=be75e388-1b74-4051-8a62-132b069a3ec9&locale=en-us&embedUrl=%2Fazure%2Fazure-functions%2Fcreate-first-function-vs-code-csharp)

The steps in the video are also described in the following sections.

Configure your environment

Before you get started, make sure you have the following requirements in place:

- An Azure account with an active subscription. [Create an account for free ↗](#).
- [.NET 8.0 SDK ↗](#).
- [Visual Studio Code ↗](#) on one of the [supported platforms ↗](#).
- [C# extension ↗](#) for Visual Studio Code.
- [Azure Functions extension ↗](#) for Visual Studio Code.

Install or update Core Tools

The Azure Functions extension for Visual Studio Code integrates with Azure Functions Core Tools so that you can run and debug your functions locally in Visual Studio Code using the Azure Functions runtime. Before getting started, it's a good idea to install Core Tools locally or update an existing installation to use the latest version.

In Visual Studio Code, select F1 to open the command palette, and then search for and run the command **Azure Functions: Install or Update Core Tools**.

This command tries to either start a package-based installation of the latest version of Core Tools or update an existing package-based installation. If you don't have npm or Homebrew installed on your local computer, you must instead [manually install or update Core Tools](#).

Create your local project

In this section, you use Visual Studio Code to create a local Azure Functions project in C#. Later in this article, you'll publish your function code to Azure.

1. In Visual Studio Code, press **F1** to open the command palette and search for and run the command **Azure Functions: Create New Project...**.
2. Select the directory location for your project workspace and choose **Select**. You should either create a new folder or choose an empty folder for the project workspace. Don't choose a project folder that is already part of a workspace.
3. Provide the following information at the prompts:

[+] Expand table

Prompt	Selection
Select a language for your function project	Choose C# .
Select a .NET runtime	Choose .NET 8.0 Isolated (LTS) .
Select a template for your project's first function	Choose HTTP trigger . ¹
Provide a function name	Type HttpExample .
Provide a namespace	Type My.Functions .
Authorization level	Choose Anonymous , which enables anyone to call your function endpoint. For more information, see Authorization level .
Select how you would like to open your project	Select Open in current window .

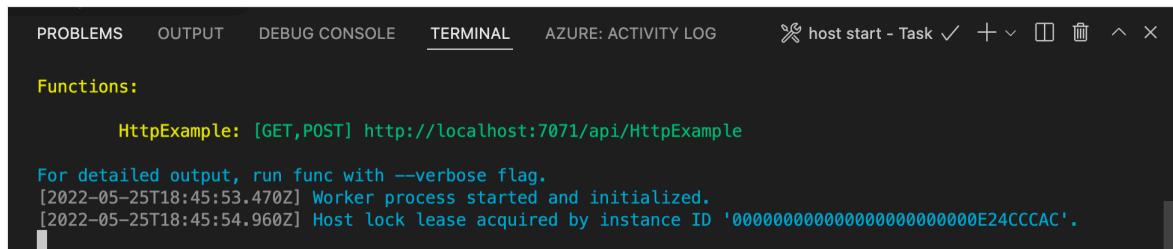

¹ Depending on your VS Code settings, you may need to use the [Change template filter](#) option to see the full list of templates.

4. Visual Studio Code uses the provided information and generates an Azure Functions project with an HTTP trigger. You can view the local project files in the Explorer. For more information about the files that are created, see [Generated project files](#).

Run the function locally

Visual Studio Code integrates with [Azure Functions Core tools](#) to let you run this project on your local development computer before you publish to Azure. If you don't already have Core Tools installed locally, you are prompted to install it the first time you run your project.

1. To call your function, press `F5` to start the function app project. The **Terminal** panel displays the output from Core Tools. Your app starts in the **Terminal** panel. You can see the URL endpoint of your HTTP-triggered function running locally.

The screenshot shows the Visual Studio Code interface with the Terminal tab selected. The terminal window displays the following text:

```
PROBLEMS    OUTPUT    DEBUG CONSOLE    TERMINAL    AZURE: ACTIVITY LOG
✖ host start - Task ✓ + ▾ □ ⌫ ⌄ ×

Functions:

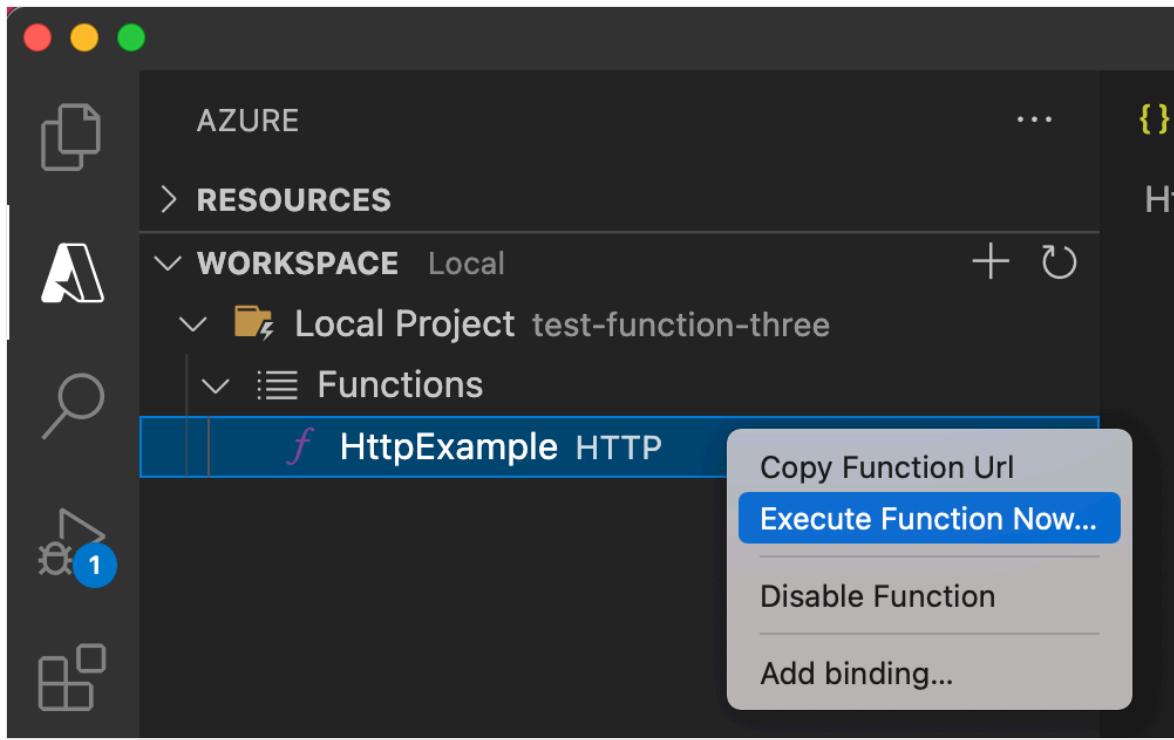

HttpExample: [GET,POST] http://localhost:7071/api/HttpExample

For detailed output, run func with --verbose flag.
[2022-05-25T18:45:53.470Z] Worker process started and initialized.
[2022-05-25T18:45:54.960Z] Host lock lease acquired by instance ID '000000000000000000000000E24CCCAC'.
```

If you don't already have Core Tools installed, select **Install** to install Core Tools when prompted to do so.

If you have trouble running on Windows, make sure that the default terminal for Visual Studio Code isn't set to **WSL Bash**.

2. With the Core Tools running, go to the **Azure: Functions** area. Under **Functions**, expand **Local Project > Functions**. Right-click (Windows) or `ctrl -` click (macOS) the `HttpExample` function and choose **Execute Function Now....**

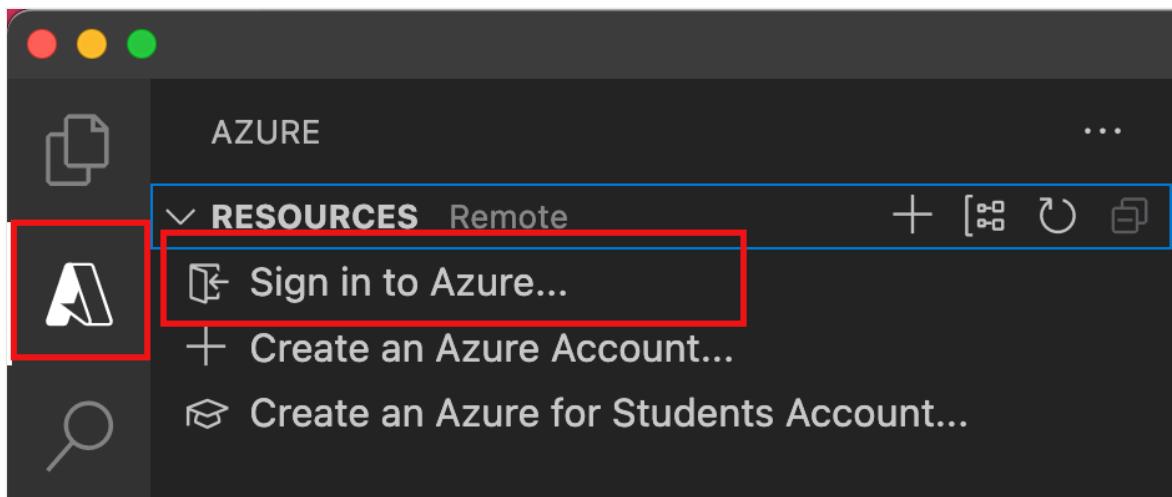

3. In the **Enter request body**, press `Enter` to send a request message to your function.
4. When the function executes locally and returns a response, a notification is raised in Visual Studio Code. Information about the function execution is shown in the **Terminal** panel.
5. Press `ctrl + c` to stop Core Tools and disconnect the debugger.

After checking that the function runs correctly on your local computer, it's time to use Visual Studio Code to publish the project directly to Azure.

Sign in to Azure

Before you can create Azure resources or publish your app, you must sign in to Azure.

1. If you aren't already signed in, in the **Activity bar**, select the Azure icon. Then under **Resources**, select **Sign in to Azure**.

If you're already signed in and can see your existing subscriptions, go to the next section. If you don't yet have an Azure account, select **Create an Azure Account**. Students can select **Create an Azure for Students Account**.

2. When you are prompted in the browser, select your Azure account and sign in by using your Azure account credentials. If you create a new account, you can sign in after your account is created.
3. After you successfully sign in, you can close the new browser window. The subscriptions that belong to your Azure account are displayed in the side bar.

Create the function app in Azure

In this section, you create a function app and related resources in your Azure subscription. Many of the resource creation decisions are made for you based on default behaviors.

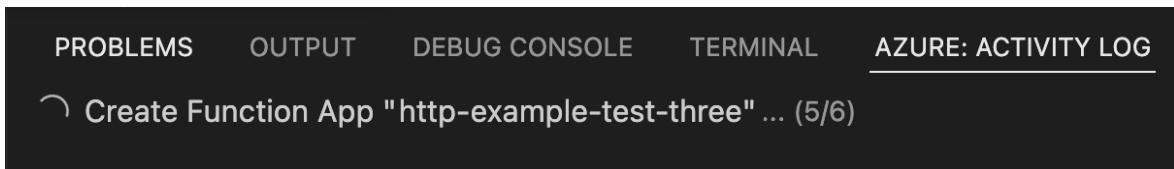

1. In Visual Studio Code, select F1 to open the command palette. At the prompt (>), enter and then select **Azure Functions: Create Function App in Azure**.
2. At the prompts, provide the following information:

[] [Expand table](#)

Prompt	Action
Select subscription	Select the Azure subscription to use. The prompt doesn't appear when you have only one subscription visible under Resources .
Enter a globally unique name for the function app	Enter a name that is valid in a URL path. The name you enter is validated to make sure that it's unique in Azure Functions.

Prompt	Action
Select a runtime stack	Select the language version you currently run locally.
Select a location for new resources	Select an Azure region. For better performance, select a region near you .

In the **Azure: Activity Log** panel, the Azure extension shows the status of individual resources as they're created in Azure.

3. When the function app is created, the following related resources are created in your Azure subscription. The resources are named based on the name you entered for your function app.

- A [resource group](#), which is a logical container for related resources.
- A standard [Azure Storage account](#), which maintains state and other information about your projects.
- A function app, which provides the environment for executing your function code. A function app lets you group functions as a logical unit for easier management, deployment, and sharing of resources within the same hosting plan.
- An Azure App Service plan, which defines the underlying host for your function app.
- An Application Insights instance that's connected to the function app, and which tracks the use of your functions in the app.

A notification is displayed after your function app is created and the deployment package is applied.

💡 Tip

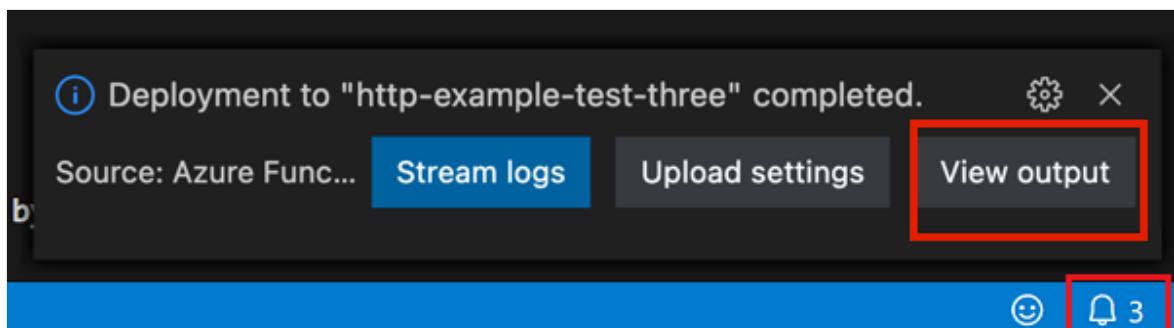

By default, the Azure resources required by your function app are created based on the name you enter for your function app. By default, the resources are created with the function app in the same, new resource group. If you want to customize the names of the associated resources or reuse existing resources, [publish the project with advanced create options](#).

Deploy the project to Azure

ⓘ Important

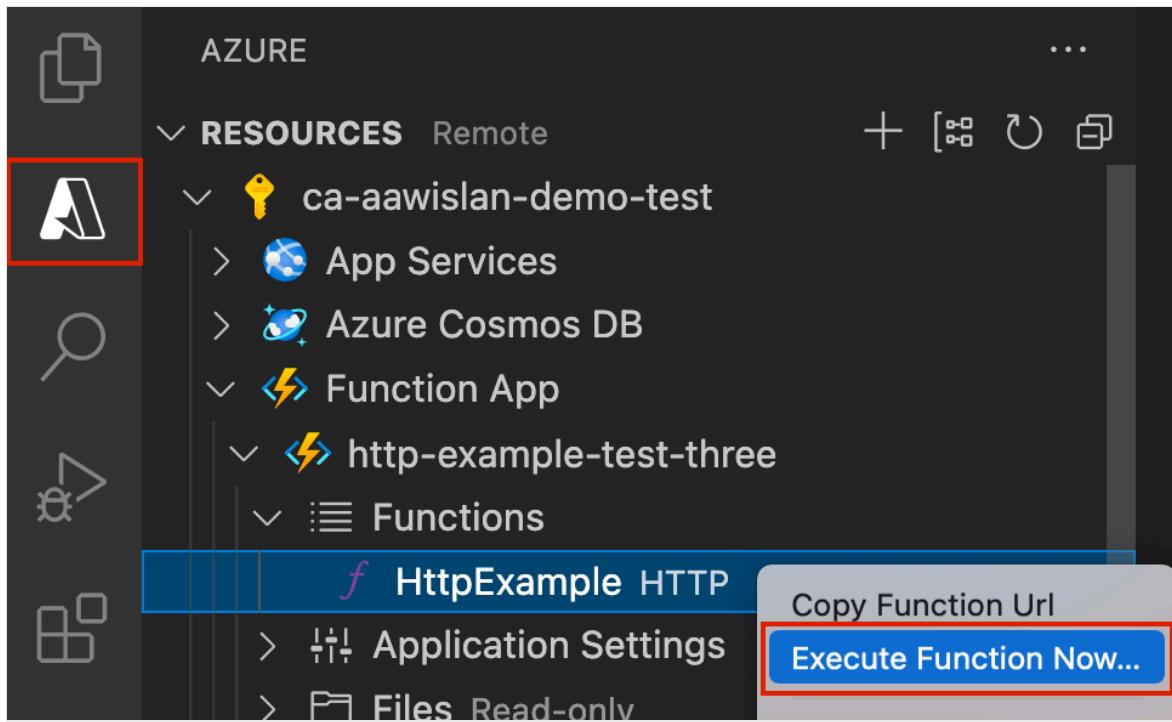

Deploying to an existing function app always overwrites the contents of that app in Azure.

1. In the command palette, enter and then select **Azure Functions: Deploy to Function App**.
2. Select the function app you just created. When prompted about overwriting previous deployments, select **Deploy** to deploy your function code to the new function app resource.
3. When deployment is completed, select **View Output** to view the creation and deployment results, including the Azure resources that you created. If you miss the notification, select the bell icon in the lower-right corner to see it again.

Run the function in Azure

1. Back in the **Resources** area in the side bar, expand your subscription, your new function app, and **Functions**. Right-click (Windows) or **Ctrl + click** (macOS) the `HttpExample` function and choose **Execute Function Now....**

2. In **Enter request body** you see the request message body value of `{ "name": "Azure" }`. Press Enter to send this request message to your function.
3. When the function executes in Azure and returns a response, a notification is raised in Visual Studio Code.

Clean up resources

When you continue to the [next step](#) and add an Azure Storage queue binding to your function, you'll need to keep all your resources in place to build on what you've already done.

Otherwise, you can use the following steps to delete the function app and its related resources to avoid incurring any further costs.

1. In Visual Studio Code, press `F1` to open the command palette. In the command palette, search for and select `Azure: Open in portal`.
2. Choose your function app and press `Enter`. The function app page opens in the Azure portal.
3. In the **Overview** tab, select the named link next to **Resource group**.

The screenshot shows the Azure portal interface for an App Service named 'myfunctionapp'. The left sidebar has a 'Functions' section with options like 'Functions', 'App keys', 'App files', and 'Proxies'. The main content area is titled 'Resource group (change) myResourceGroup' and contains the following information:

Setting	Value
Status	Running
Location	Central US
Subscription	Visual Studio Enterprise
Subscription ID	11111111-1111-1111-1111-111111111111
Tags	Click here to add tags

At the bottom, there are tabs for 'Metrics', 'Features (8)', 'Notifications (0)', and 'Quickstart'. The 'Metrics' tab is currently selected.

4. On the **Resource group** page, review the list of included resources, and verify that they're the ones you want to delete.

5. Select **Delete resource group**, and follow the instructions.

Deletion may take a couple of minutes. When it's done, a notification appears for a few seconds. You can also select the bell icon at the top of the page to view the notification.

For more information about Functions costs, see [Estimating Consumption plan costs](#).

Next steps

You have used [Visual Studio Code](#) to create a function app with a simple HTTP-triggered function. In the next article, you expand that function by connecting to one of the core Azure storage services. To learn more about connecting to other Azure services, see [Add bindings to an existing function in Azure Functions](#).

[Connect to Azure Cosmos DB](#)

Quickstart: Create a C# function in Azure from the command line

Article • 01/25/2024

In this article, you use command-line tools to create a C# function that responds to HTTP requests. After testing the code locally, you deploy it to the serverless environment of Azure Functions.

This article creates an HTTP triggered function that runs on .NET 8 in an isolated worker process. For information about .NET versions supported for C# functions, see [Supported versions](#). There's also a [Visual Studio Code-based version](#) of this article.

Completing this quickstart incurs a small cost of a few USD cents or less in your Azure account.

Configure your local environment

Before you begin, you must have the following:

- [.NET 8.0 SDK](#).
- One of the following tools for creating Azure resources:
 - [Azure CLI version 2.4](#) or later.
 - The Azure [Az PowerShell module](#) version 5.9.0 or later.

You also need an Azure account with an active subscription. [Create an account for free](#).

Install the Azure Functions Core Tools

The recommended way to install Core Tools depends on the operating system of your local development computer.

Windows

The following steps use a Windows installer (MSI) to install Core Tools v4.x. For more information about other package-based installers, see the [Core Tools readme](#).

Download and run the Core Tools installer, based on your version of Windows:

- [v4.x - Windows 64-bit ↗](#) (Recommended. [Visual Studio Code debugging](#) requires 64-bit.)
- [v4.x - Windows 32-bit ↗](#)

If you previously used Windows installer (MSI) to install Core Tools on Windows, you should uninstall the old version from Add Remove Programs before installing the latest version.

Create a local function project

In Azure Functions, a function project is a container for one or more individual functions that each responds to a specific trigger. All functions in a project share the same local and hosting configurations. In this section, you create a function project that contains a single function.

1. Run the `func init` command, as follows, to create a functions project in a folder named *LocalFunctionProj* with the specified runtime:

```
Console  
  
func init LocalFunctionProj --worker-runtime dotnet-isolated --target-framework net8.0
```

2. Navigate into the project folder:

```
Console  
  
cd LocalFunctionProj
```

This folder contains various files for the project, including configurations files named [local.settings.json](#) and [host.json](#). Because *local.settings.json* can contain secrets downloaded from Azure, the file is excluded from source control by default in the *.gitignore* file.

3. Add a function to your project by using the following command, where the `--name` argument is the unique name of your function (HttpExample) and the `--template` argument specifies the function's trigger (HTTP).

```
Console
```

```
func new --name HttpExample --template "HTTP trigger" --authlevel  
"anonymous"
```

`func new` creates an `HttpExample.cs` code file.

(Optional) Examine the file contents

If desired, you can skip to [Run the function locally](#) and examine the file contents later.

HttpExample.cs

`HttpExample.cs` contains a `Run` method that receives request data in the `req` variable as an `HttpRequest` object. That parameter is decorated with the `HttpTriggerAttribute`, to define the trigger behavior.

C#

```
using System.Net;  
using Microsoft.Azure.Functions.Worker;  
using Microsoft.Extensions.Logging;  
using Microsoft.AspNetCore.Http;  
using Microsoft.AspNetCore.Mvc;  
  
namespace Company.Function  
{  
    public class HttpExample  
    {  
        private readonly ILogger<HttpExample> _logger;  
  
        public HttpExample(ILogger<HttpExample> logger)  
        {  
            _logger = logger;  
        }  
  
        [Function("HttpExample")]  
        public IActionResult  
Run([HttpTrigger(AuthorizationLevel.AuthLevelValue, "get", "post")]  
HttpRequest req)  
        {  
            _logger.LogInformation("C# HTTP trigger function processed a  
request.");  
  
            return new OkObjectResult("Welcome to Azure Functions!");  
        }  
    }  
}
```

The return object is an `IActionResult` object that contains the data that's handed back to the HTTP response.

To learn more, see [Azure Functions HTTP triggers and bindings](#).

Run the function locally

1. Run your function by starting the local Azure Functions runtime host from the `LocalFunctionProj` folder:

```
func start
```

Toward the end of the output, the following lines should appear:

```
...
Now listening on: http://0.0.0.0:7071
Application started. Press Ctrl+C to shut down.

Http Functions:

    HttpExample: [GET,POST] http://localhost:7071/api/HttpExample
...
```

ⓘ Note

If `HttpExample` doesn't appear as shown above, you likely started the host from outside the root folder of the project. In that case, use `Ctrl+C` to stop the host, navigate to the project's root folder, and run the previous command again.

2. Copy the URL of your `HttpExample` function from this output to a browser and browse to the function URL and you should receive a *Welcome to Azure Functions* message.
3. When you're done, use `Ctrl+C` and choose `y` to stop the functions host.

Create supporting Azure resources for your function

Before you can deploy your function code to Azure, you need to create three resources:

- A [resource group](#), which is a logical container for related resources.
- A [Storage account](#), which is used to maintain state and other information about your functions.
- A function app, which provides the environment for executing your function code. A function app maps to your local function project and lets you group functions as a logical unit for easier management, deployment, and sharing of resources.

Use the following commands to create these items. Both Azure CLI and PowerShell are supported.

1. If you haven't done so already, sign in to Azure:

```
Azure CLI
az login
```

The `az login` command signs you into your Azure account.

2. Create a resource group named `AzureFunctionsQuickstart-rg` in your chosen region:

```
Azure CLI
az group create --name AzureFunctionsQuickstart-rg --location
<REGION>
```

The `az group create` command creates a resource group. In the above command, replace `<REGION>` with a region near you, using an available region code returned from the [az account list-locations](#) command.

3. Create a general-purpose storage account in your resource group and region:

Azure CLI

Azure CLI

```
az storage account create --name <STORAGE_NAME> --location <REGION>
--resource-group AzureFunctionsQuickstart-rg --sku Standard_LRS --
allow-blob-public-access false
```

The `az storage account create` command creates the storage account.

In the previous example, replace `<STORAGE_NAME>` with a name that is appropriate to you and unique in Azure Storage. Names must contain three to 24 characters numbers and lowercase letters only. `Standard_LRS` specifies a general-purpose account, which is [supported by Functions](#).

 **Important**

The storage account is used to store important app data, sometimes including the application code itself. You should limit access from other apps and users to the storage account.

4. Create the function app in Azure:

Azure CLI

Azure CLI

```
az functionapp create --resource-group AzureFunctionsQuickstart-rg
--consumption-plan-location <REGION> --runtime dotnet-isolated --
functions-version 4 --name <APP_NAME> --storage-account
<STORAGE_NAME>
```

The `az functionapp create` command creates the function app in Azure.

In the previous example, replace `<STORAGE_NAME>` with the name of the account you used in the previous step, and replace `<APP_NAME>` with a globally unique name appropriate to you. The `<APP_NAME>` is also the default DNS domain for the function app.

This command creates a function app running in your specified language runtime under the [Azure Functions Consumption Plan](#), which is free for the amount of

usage you incur here. The command also creates an associated Azure Application Insights instance in the same resource group, with which you can monitor your function app and view logs. For more information, see [Monitor Azure Functions](#). The instance incurs no costs until you activate it.

Deploy the function project to Azure

After you've successfully created your function app in Azure, you're now ready to deploy your local functions project by using the `func azure functionapp publish` command.

In the following example, replace `<APP_NAME>` with the name of your app.

Console

```
func azure functionapp publish <APP_NAME>
```

The publish command shows results similar to the following output (truncated for simplicity):

```
...
Getting site publishing info...
Creating archive for current directory...
Performing remote build for functions project.

...
Deployment successful.
Remote build succeeded!
Syncing triggers...
Functions in msdocs-azurefunctions-qs:
  HttpExample - [httpTrigger]
    Invoke url: https://msdocs-azurefunctions-
qs.azurewebsites.net/api/httpexample
```

Invoke the function on Azure

Because your function uses an HTTP trigger and supports GET requests, you invoke it by making an HTTP request to its URL. It's easiest to do this in a browser.

Copy the complete **Invoke URL** shown in the output of the publish command into a browser address bar. When you navigate to this URL, the browser should display similar output as when you ran the function locally.

Run the following command to view near real-time streaming logs:

Console

```
func azure functionapp logstream <APP_NAME>
```

In a separate terminal window or in the browser, call the remote function again. A verbose log of the function execution in Azure is shown in the terminal.

Clean up resources

If you continue to the [next step](#) and add an Azure Storage queue output binding, keep all your resources in place as you'll build on what you've already done.

Otherwise, use the following command to delete the resource group and all its contained resources to avoid incurring further costs.

Azure CLI

Azure CLI

```
az group delete --name AzureFunctionsQuickstart-rg
```

Next steps

[Connect to Azure Cosmos DB](#)

[Connect to Azure Queue Storage](#)

Quickstart: Create and deploy functions to Azure Functions using the Azure Developer CLI

Article • 09/09/2024

In this Quickstart, you use Azure Developer command-line tools to create functions that respond to HTTP requests. After testing the code locally, you deploy it to a new serverless function app you create running in a Flex Consumption plan in Azure Functions.

The project source uses the Azure Developer CLI (azd) to simplify deploying your code to Azure. This deployment follows current best practices for secure and scalable Azure Functions deployments.

ⓘ Important

The [Flex Consumption plan](#) is currently in preview.

By default, the Flex Consumption plan follows a *pay-for-what-you-use* billing model, which means to complete this quickstart incurs a small cost of a few USD cents or less in your Azure account.

Prerequisites

- An Azure account with an active subscription. [Create an account for free ↗](#).
- [Azure Developer CLI](#).
- [Azure Functions Core Tools](#).
- [.NET 8.0 SDK ↗](#)
- [Azurite storage emulator](#)
- A [secure HTTP test tool](#) for sending requests with JSON payloads to your function endpoints. This article uses `curl`.

Initialize the project

You can use the `azd init` command to create a local Azure Functions code project from a template.

1. In your local terminal or command prompt, run this `azd init` command in an empty folder:

```
Console
```

```
azd init --template functions-quickstart-dotnet-azd -e flexquickstart-dotnet
```

This command pulls the project files from the [template repository](#) and initializes the project in the current folder. The `-e` flag sets a name for the current environment. In `azd`, the environment is used to maintain a unique deployment context for your app, and you can define more than one. It's also used in the name of the resource group you create in Azure.

2. Run this command to navigate to the `http` app folder:

```
Console
```

```
cd http
```

3. Create a file named `local.settings.json` in the `http` folder that contains this JSON data:

```
JSON
```

```
{  
    "IsEncrypted": false,  
    "Values": {  
        "AzureWebJobsStorage": "UseDevelopmentStorage=true",  
        "FUNCTIONS_WORKER_RUNTIME": "dotnet-isolated"  
    }  
}
```

This file is required when running locally.

Run in your local environment

1. Run this command from your app folder in a terminal or command prompt:

```
Console
```

```
func start
```

When the Functions host starts in your local project folder, it writes the URL endpoints of your HTTP triggered functions to the terminal output.

2. In your browser, navigate to the `httpget` endpoint, which should look like this URL:

<http://localhost:7071/api/httpget>

3. From a new terminal or command prompt window, run this `curl` command to send a POST request with a JSON payload to the `httppost` endpoint:

```
Console
```

```
curl -i http://localhost:7071/api/httppost -H "Content-Type: text/json"  
-d @testdata.json
```

This command reads JSON payload data from the `testdata.json` project file. You can find examples of both HTTP requests in the `test.http` project file.

4. When you're done, press **Ctrl+C** in the terminal window to stop the `func.exe` host process.

Review the code (optional)

You can review the code that defines the two HTTP trigger function endpoints:

```
httpget
```

```
C#
```

```
[Function("httpget")]
    public IActionResult
Run([HttpTrigger(AuthorizationLevel.Function, "get")]
    HttpRequest req,
    string name)
{
    var returnValue = string.IsNullOrEmpty(name)
        ? "Hello, World."
        : $"Hello, {name}.";

    _logger.LogInformation($"C# HTTP trigger function processed
a request for {returnValue}.");
}
```

```
        return new OkObjectResult(returnValue);
    }
```

You can review the complete template project [here](#).

After you verify your functions locally, it's time to publish them to Azure.

Deploy to Azure

This project is configured to use the `azd up` command to deploy this project to a new function app in a Flex Consumption plan in Azure.

💡 Tip

This project includes a set of Bicep files that `azd` uses to create a secure deployment to a Flex consumption plan that follows best practices.

1. Run this command to have `azd` create the required Azure resources in Azure and deploy your code project to the new function app:

```
Console
```

```
azd up
```

The root folder contains the `azure.yaml` definition file required by `azd`.

If you aren't already signed-in, you're asked to authenticate with your Azure account.

2. When prompted, provide these required deployment parameters:

[\[+\] Expand table](#)

Parameter	Description
<code>Azure subscription</code>	Subscription in which your resources are created.
<code>Azure location</code>	Azure region in which to create the resource group that contains the new Azure resources. Only regions that currently support the Flex Consumption plan are shown.

The `azd up` command uses your response to these prompts with the Bicep configuration files to complete these deployment tasks:

- Create and configure these required Azure resources (equivalent to `azd provision`):
 - Flex Consumption plan and function app
 - Azure Storage (required) and Application Insights (recommended)
 - Access policies and roles for your account
 - Service-to-service connections using managed identities (instead of stored connection strings)
 - Virtual network to securely run both the function app and the other Azure resources
- Package and deploy your code to the deployment container (equivalent to `azd deploy`). The app is then started and runs in the deployed package.

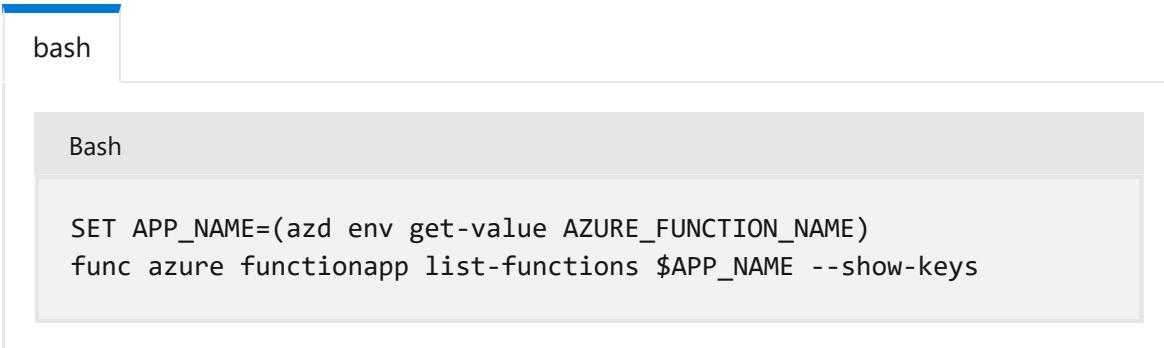

After the command completes successfully, you see links to the resources you created.

Invoke the function on Azure

You can now invoke your function endpoints in Azure by making HTTP requests to their URLs using your HTTP test tool or from the browser (for GET requests). When your functions run in Azure, access key authorization is enforced, and you must provide a function access key with your request.

You can use the Core Tools to obtain the URL endpoints of your functions running in Azure.

1. In your local terminal or command prompt, run these commands to get the URL endpoint values:

```
bash
Bash
SET APP_NAME=(azd env get-value AZURE_FUNCTION_NAME)
func azure functionapp list-functions $APP_NAME --show-keys
```

The `azd env get-value` command gets your function app name from the local environment. Using the `--show-keys` option with `func azure functionapp list-`

`functions` means that the returned **Invoke URL**: value for each endpoint includes a function-level access key.

2. As before, use your HTTP test tool to validate these URLs in your function app running in Azure.

Redeploy your code

You can run the `azd up` command as many times as you need to both provision your Azure resources and deploy code updates to your function app.

Note

Deployed code files are always overwritten by the latest deployment package.

Your initial responses to `azd` prompts and any environment variables generated by `azd` are stored locally in your named environment. Use the `azd env get-values` command to review all of the variables in your environment that were used when creating Azure resources.

Clean up resources

When you're done working with your function app and related resources, you can use this command to delete the function app and its related resources from Azure and avoid incurring any further costs:

Console

```
azd down --no-prompt
```

Note

The `--no-prompt` option instructs `azd` to delete your resource group without a confirmation from you.

This command doesn't affect your local code project.

Create your first function with Java and Eclipse

Article • 03/17/2023

This article shows you how to create a [serverless](#) function project with the Eclipse IDE and Apache Maven, test and debug it, then deploy it to Azure Functions.

If you don't have an [Azure subscription](#), create an [Azure free account](#) before you begin.

Set up your development environment

To develop a functions app with Java and Eclipse, you must have the following installed:

- [Java Developer Kit](#), version 8.
- [Apache Maven](#), version 3.0 or above.
- [Eclipse](#), with Java and Maven support.
- [Azure CLI](#)

Important

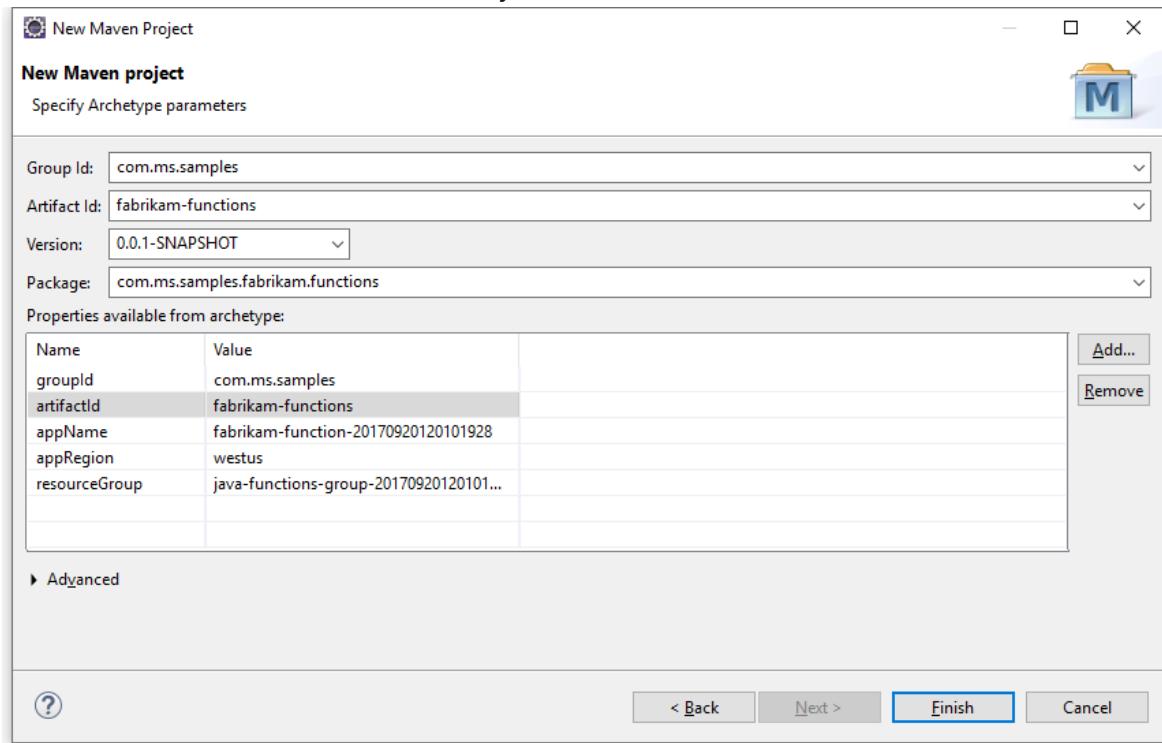

The JAVA_HOME environment variable must be set to the install location of the JDK to complete this quickstart.

It's highly recommended to also install [Azure Functions Core Tools, version 2](#), which provide a local environment for running and debugging Azure Functions.

Create a Functions project

1. In Eclipse, select the **File** menu, then select **New -> Maven Project**.
2. Accept the defaults in the **New Maven Project** dialogue and select **Next**.
3. Find and select the [azure-functions-archetype](#) and click **Next**.
4. Be sure to fill in values for all of the fields including `resourceGroup`, `appName`, and `appRegion` (please use a different `appName` other than `fabrikam-function-`)

20170920120101928), and eventually Finish.

Maven creates the project files in a new folder with a name of *artifactId*. The generated code in the project is a simple [HTTP triggered](#) function that echoes the body of the triggering HTTP request.

Run functions locally in the IDE

ⓘ Note

Azure Functions Core Tools, version 2 must be installed to run and debug functions locally.

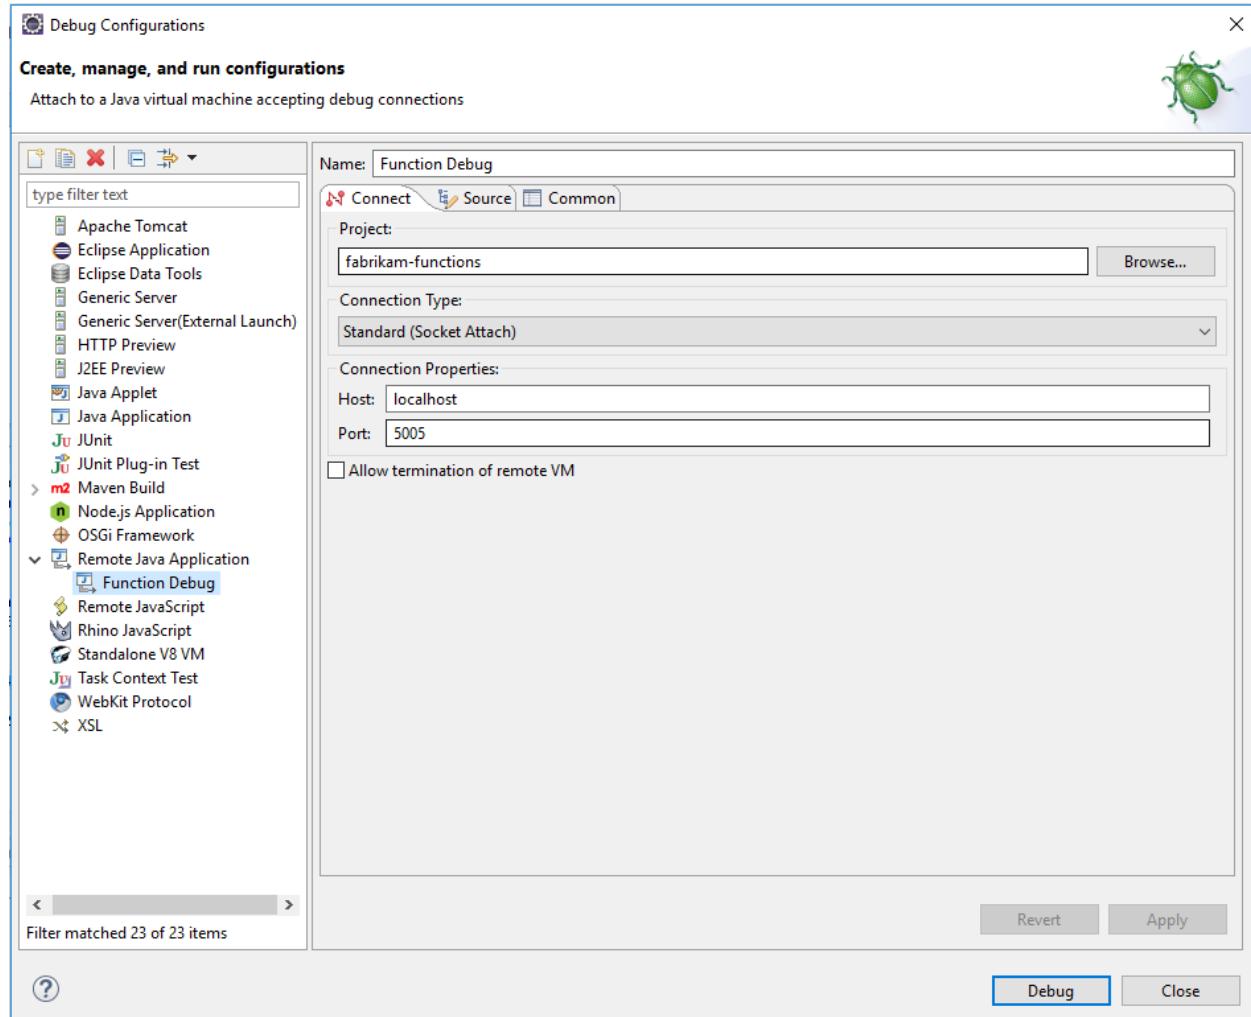

1. Right-click on the generated project, then choose **Run As** and **Maven build**.
2. In the **Edit Configuration** dialog, Enter `package` in the **Goals**, then select **Run**. This will build and package the function code.
3. Once the build is complete, create another Run configuration as above, using `azure-functions:run` as the goal and name. Select **Run** to run the function in the IDE.

Terminate the runtime in the console window when you're done testing your function. Only one function host can be active and running locally at a time.

Debug the function in Eclipse

In your **Run As** configuration set up in the previous step, change `azure-functions:run` to `azure-functions:run -DenableDebug` and run the updated configuration to start the function app in debug mode.

Select the **Run** menu and open **Debug Configurations**. Choose **Remote Java Application** and create a new one. Give your configuration a name and fill in the settings. The port should be consistent with the debug port opened by function host, which by default is `5005`. After setup, click on **Debug** to start debugging.

Set breakpoints and inspect objects in your function using the IDE. When finished, stop the debugger and the running function host. Only one function host can be active and running locally at a time.

Deploy the function to Azure

The deploy process to Azure Functions uses account credentials from the Azure CLI. [Log in with the Azure CLI](#) before continuing using your computer's command prompt.

```
Azure CLI
az login
```

Deploy your code into a new Function app using the `azure-functions:deploy` Maven goal in a new **Run As** configuration.

When the deploy is complete, you see the URL you can use to access your Azure function app:

Output

```
[INFO] Successfully deployed Function App with package.  
[INFO] Deleting deployment package from Azure Storage...  
[INFO] Successfully deleted deployment package fabrikam-function-  
20170920120101928.20170920143621915.zip  
[INFO] Successfully deployed Function App at https://fabrikam-function-  
20170920120101928.azurewebsites.net  
[INFO] -----  
---
```

Next steps

- Review the [Java Functions developer guide](#) for more information on developing Java functions.
- Add additional functions with different triggers to your project using the `azure-functions:add` Maven target.

Use Java and Gradle to create and publish a function to Azure

Article • 07/18/2024

This article shows you how to build and publish a Java function project to Azure Functions with the Gradle command-line tool. When you're done, your function code runs in Azure in a [serverless hosting plan](#) and is triggered by an HTTP request.

ⓘ Note

If Gradle is not your preferred development tool, check out our similar tutorials for Java developers using [Maven](#), [IntelliJ IDEA](#) and [VS Code](#).

Prerequisites

To develop functions using Java, you must have the following installed:

- [Java Developer Kit](#), version 8, 11, 17 or 21. (Java 21 is currently supported in preview on Linux only)
- [Azure CLI](#)
- [Azure Functions Core Tools](#) version 2.6.666 or above
- [Gradle](#), version 6.8 and above

You also need an active Azure subscription. If you don't have an [Azure subscription](#), create an [Azure free account](#) before you begin.

ⓘ Important

The JAVA_HOME environment variable must be set to the install location of the JDK to complete this quickstart.

Prepare a Functions project

Use the following command to clone the sample project:

Bash

```
git clone https://github.com/Azure-Samples/azure-functions-samples-java.git
```

```
cd azure-functions-samples-java/
```

Open `build.gradle` and change the `appName` in the following section to a unique name to avoid domain name conflict when deploying to Azure.

Gradle

```
azurefunctions {  
    resourceGroup = 'java-functions-group'  
    appName = 'azure-functions-sample-demo'  
    pricingTier = 'Consumption'  
    region = 'westus'  
    runtime {  
        os = 'windows'  
    }  
    localDebug = "transport=dt_socket,server=y,suspend=n,address=5005"  
}
```

Open the new `Function.java` file from the `src/main/java` path in a text editor and review the generated code. This code is an [HTTP triggered function](#) that echoes the body of the request.

I ran into an issue

Run the function locally

Run the following command to build then run the function project:

Bash

```
gradle jar --info  
gradle azureFunctionsRun
```

You see output like the following from Azure Functions Core Tools when you run the project locally:

```
...
```

```
Now listening on: http://0.0.0.0:7071  
Application started. Press Ctrl+C to shut down.
```

```
Http Functions:
```

```
HttpExample: [GET,POST] http://localhost:7071/api/HttpExample
```

```
...
```

Trigger the function from the command line using the following cURL command in a new terminal window:

Bash

```
curl -w "\n" http://localhost:7071/api/HttpExample --data AzureFunctions
```

The expected output is the following:

```
Hello, AzureFunctions
```

⚠ Note

If you set authLevel to `FUNCTION` or `ADMIN`, the [access key](#) isn't required when running locally.

Use `Ctrl+C` in the terminal to stop the function code.

I ran into an issue

Deploy the function to Azure

A function app and related resources are created in Azure when you first deploy your function app. Before you can deploy, use the [az login](#) Azure CLI command to sign in to your Azure subscription.

Azure CLI

```
az login
```

💡 Tip

If your account can access multiple subscriptions, use [az account set](#) to set the default subscription for this session.

Use the following command to deploy your project to a new function app.

Bash

```
gradle azureFunctionsDeploy
```

This creates the following resources in Azure, based on the values in the build.gradle file:

- Resource group. Named with the *resourceGroup* you supplied.
- Storage account. Required by Functions. The name is generated randomly based on Storage account name requirements.
- App Service plan. Serverless Consumption plan hosting for your function app in the specified *region*. The name is generated randomly.
- Function app. A function app is the deployment and execution unit for your functions. The name is your *appName*, appended with a randomly generated number.

The deployment also packages the project files and deploys them to the new function app using [zip deployment](#), with run-from-package mode enabled.

The authLevel for HTTP Trigger in sample project is `ANONYMOUS`, which will skip the authentication. However, if you use other authLevel like `FUNCTION` or `ADMIN`, you need to get the function key to call the function endpoint over HTTP. The easiest way to get the function key is from the [Azure portal](#).

[I ran into an issue](#)

Get the HTTP trigger URL

You can get the URL required to trigger your function, with the function key, from the Azure portal.

1. Browse to the [Azure portal](#), sign in, type the *appName* of your function app into **Search** at the top of the page, and press enter.
2. In your function app, select **Functions**, choose your function, then click **Get Function Url** at the top right.

The screenshot shows the Azure Functions portal interface. At the top, there's a search bar with placeholder text 'Search (Ctrl+ /)' and several action buttons: 'Enable', 'Disable', 'Delete', 'Get Function Url' (which is highlighted with a red box), and 'Refresh'. Below this, there's a navigation menu with 'Overview' selected. On the left, there are three tabs: 'Developer', 'Code + Test', and 'Integration'. The main content area displays the following information:

- Function app:** azure-functions-sample-demo
- Status:** Enabled
- Resource group (change):** java-functions-group

3. Choose **default (Function key)** and select **Copy**.

You can now use the copied URL to access your function.

Verify the function in Azure

To verify the function app running on Azure using `cURL`, replace the URL from the sample below with the URL that you copied from the portal.

Console

```
curl -w "\n" http://azure-functions-sample-
demo.azurewebsites.net/api/HttpExample --data AzureFunctions
```

This sends a POST request to the function endpoint with `AzureFunctions` in the body of the request. You see the following response.

Hello, AzureFunctions

I ran into an issue

Next steps

You've created a Java functions project with an HTTP triggered function, run it on your local machine, and deployed it to Azure. Now, extend your function by...

Adding an Azure Storage queue output binding

Create your first Java function in Azure using IntelliJ

Article • 05/29/2024

This article shows you how to use Java and IntelliJ to create an Azure function.

Specifically, this article shows you:

- How to create an HTTP-triggered Java function in an IntelliJ IDEA project.
- Steps for testing and debugging the project in the integrated development environment (IDE) on your own computer.
- Instructions for deploying the function project to Azure Functions.

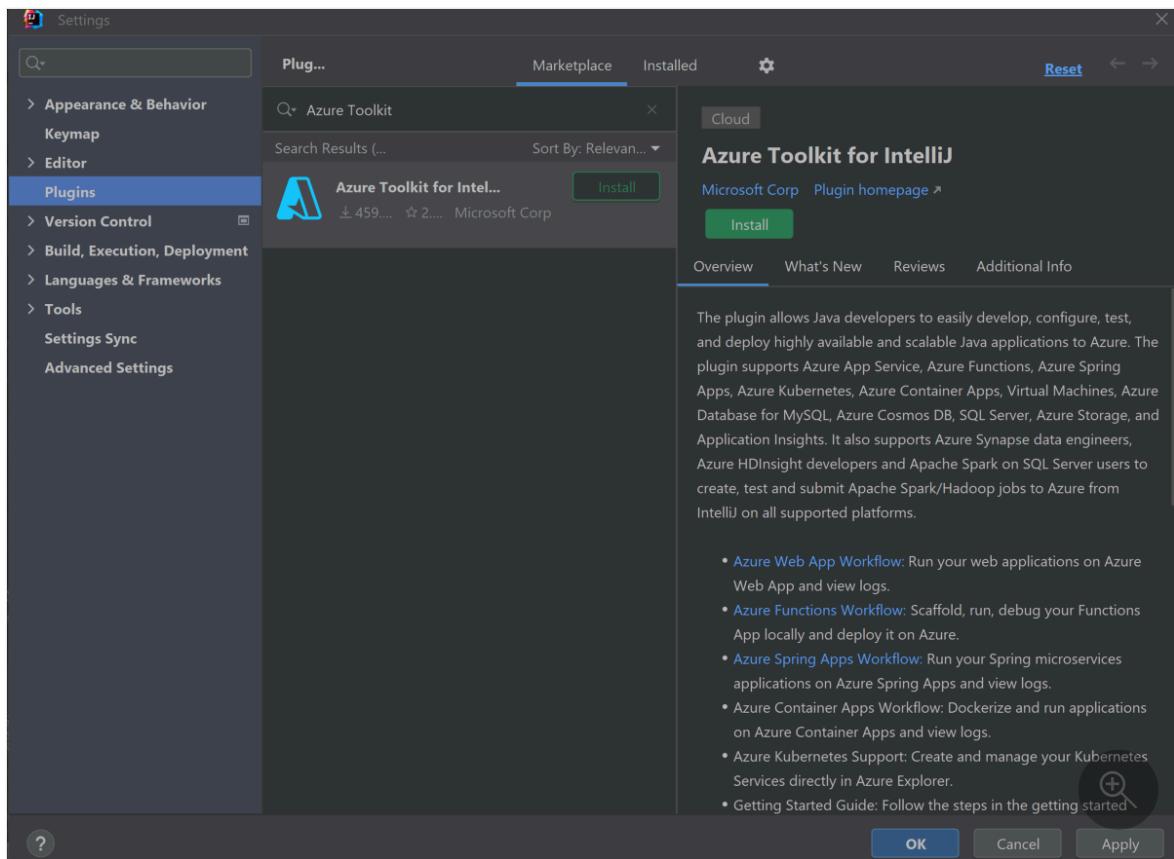

Prerequisites

- An Azure account with an active subscription. [Create an account for free ↗](#).
- An [Azure supported Java Development Kit \(JDK\)](#), version 8, 11, 17 or 21. (Java 21 is currently only supported in preview on Linux only)
- An [IntelliJ IDEA ↗](#) Ultimate Edition or Community Edition installed
- [Maven 3.5.0+ ↗](#)
- Latest [Function Core Tools ↗](#)

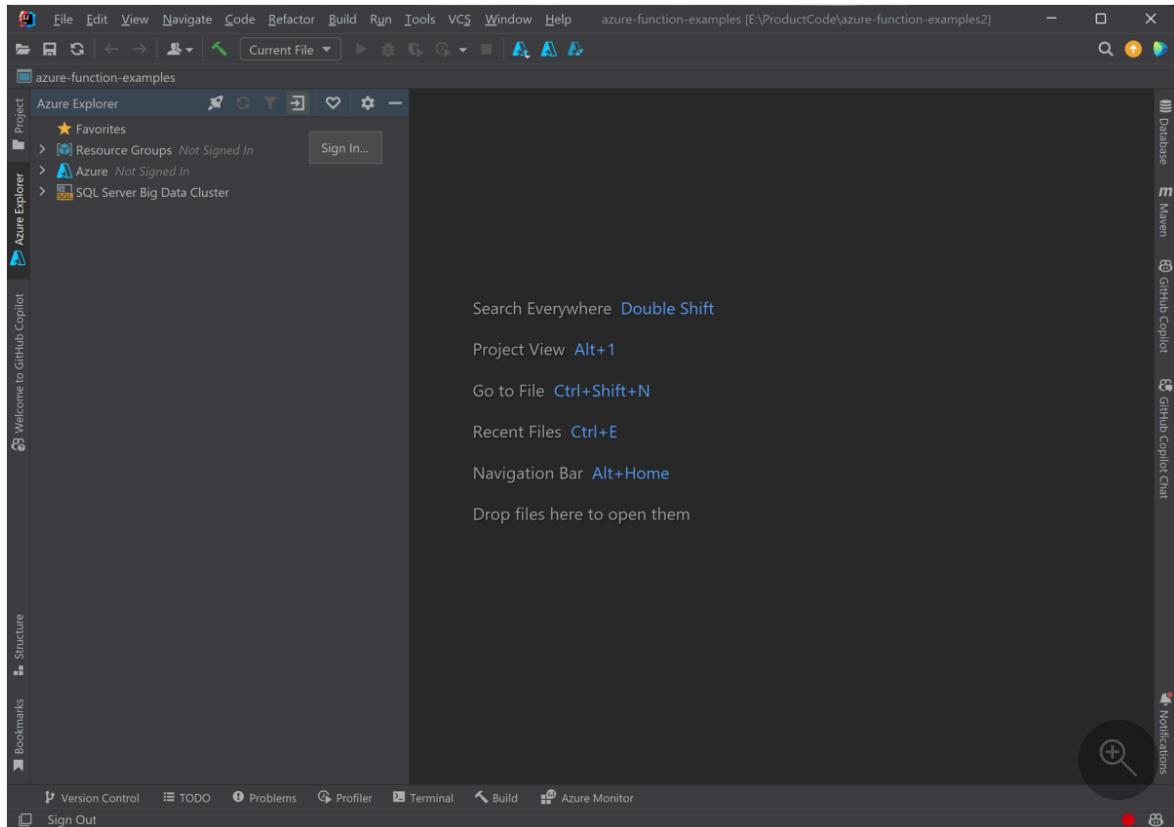

Install plugin and sign in

To install the Azure Toolkit for IntelliJ and then sign in, follow these steps:

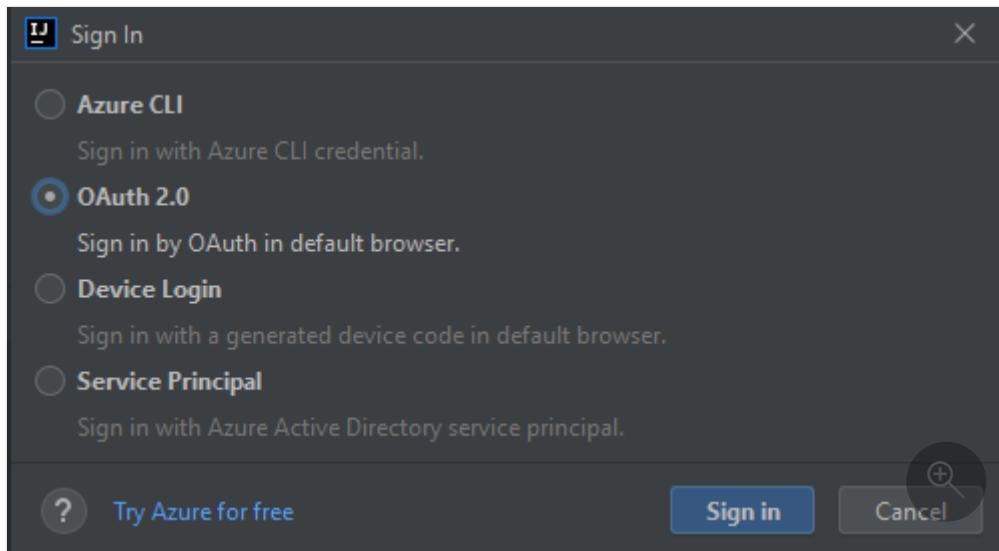

1. In IntelliJ IDEA's **Settings/Preferences** dialog (Ctrl+Alt+S), select **Plugins**. Then, find the **Azure Toolkit for IntelliJ** in the **Marketplace** and select **Install**. After it's installed, select **Restart** to activate the plugin.

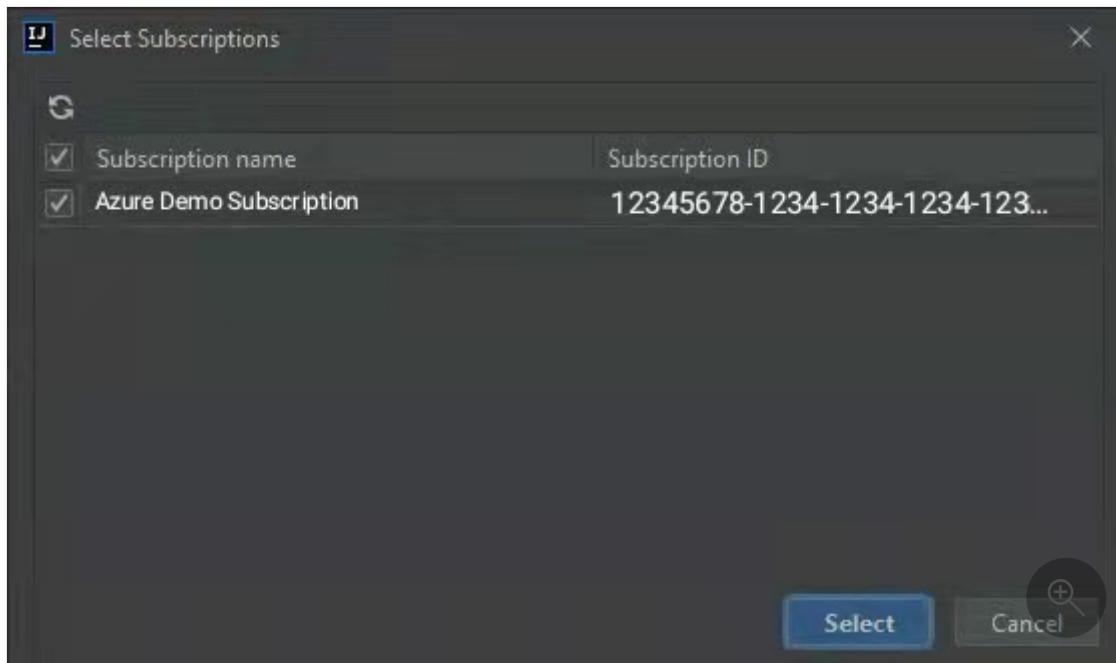

2. To sign in to your Azure account, open the **Azure Explorer** sidebar, and then select the **Azure Sign In** icon in the bar on top (or from the IDEA menu, select **Tools > Azure > Azure Sign in**).

3. In the **Azure Sign In** window, select **OAuth 2.0**, and then select **Sign in**. For other sign-in options, see [Sign-in instructions for the Azure Toolkit for IntelliJ](#).

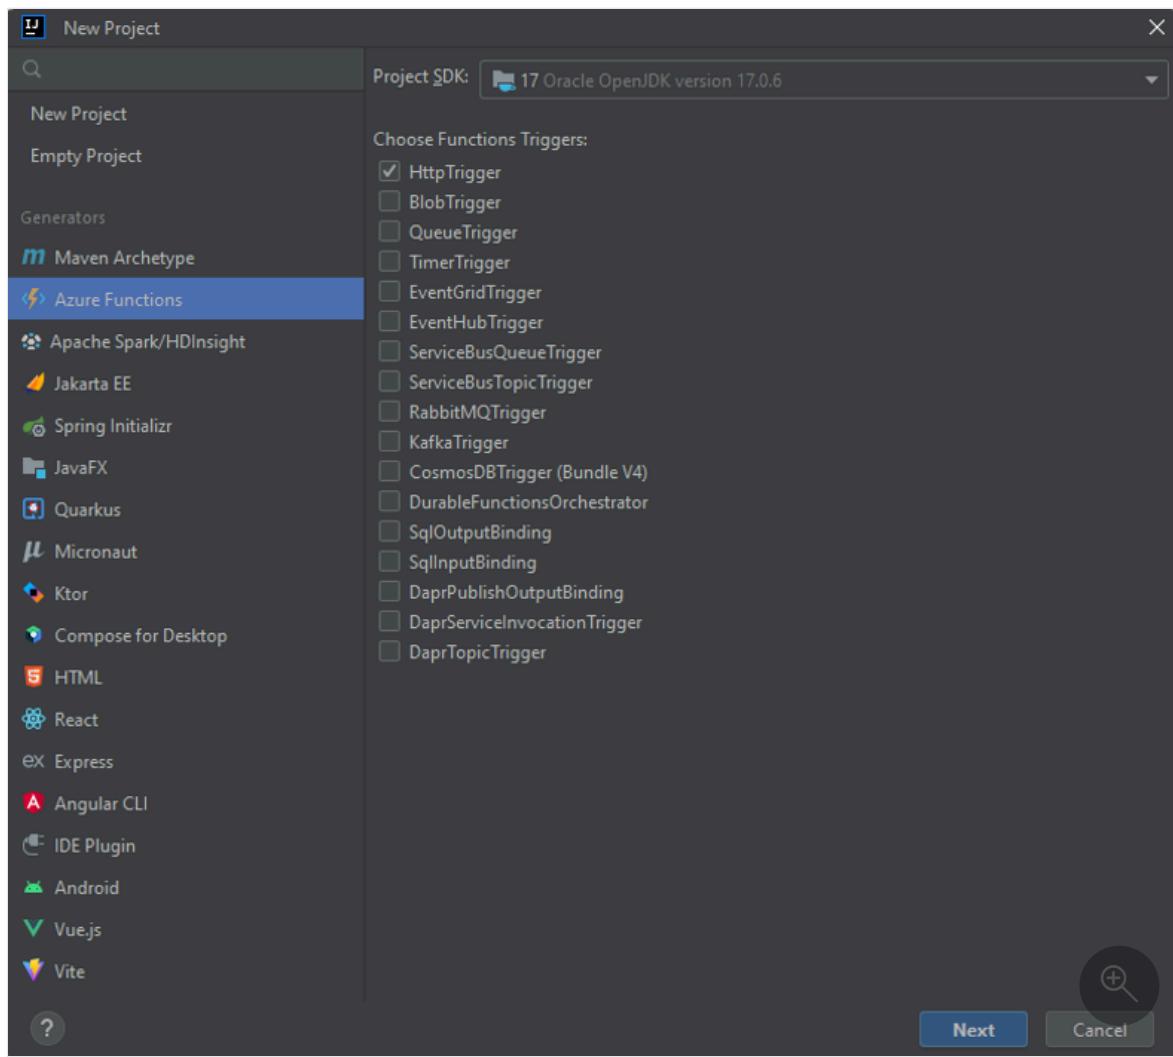

4. In the browser, sign in with your account and then go back to IntelliJ. In the **Select Subscriptions** dialog box, select the subscriptions that you want to use, then select **Select**.

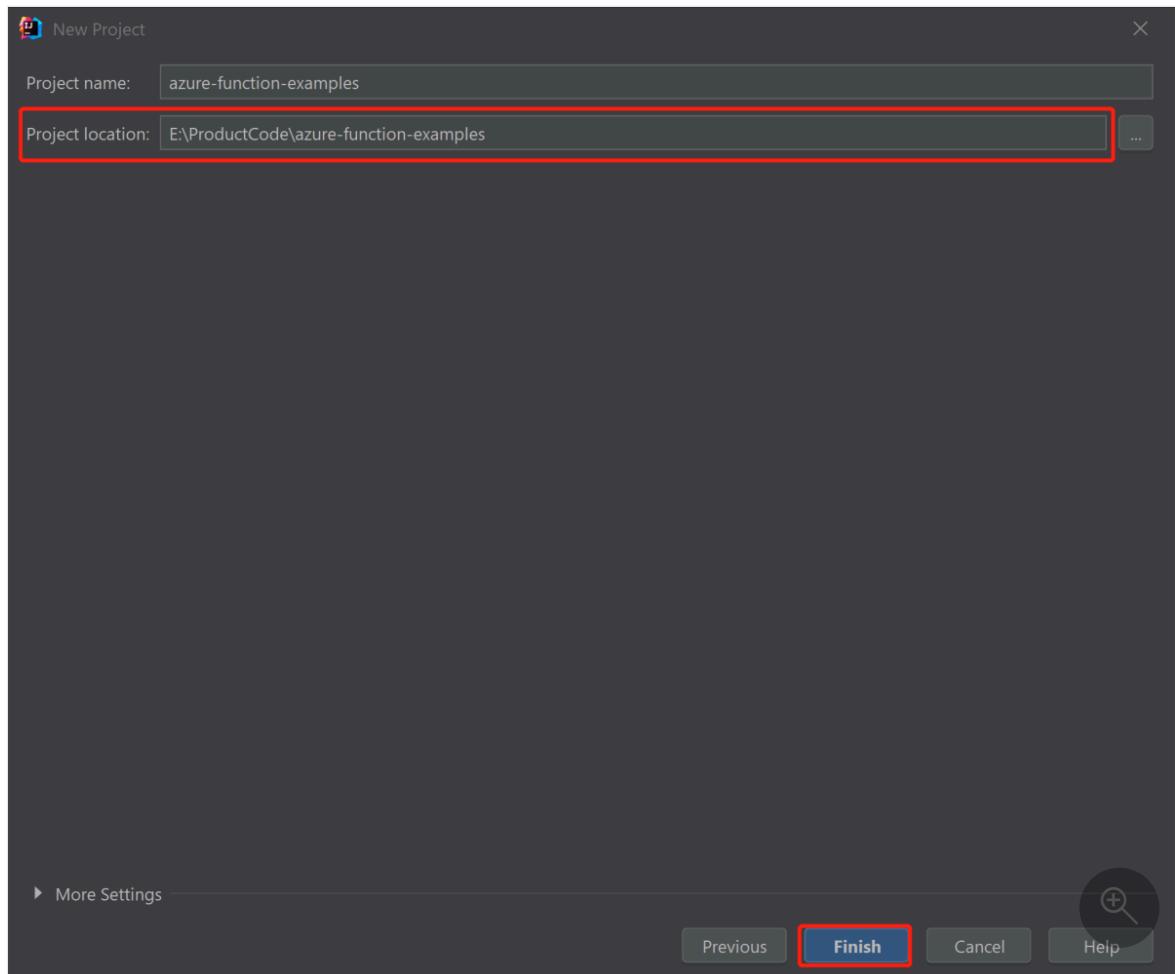

Create your local project

To use Azure Toolkit for IntelliJ to create a local Azure Functions project, follow these steps:

1. Open IntelliJ IDEA's **Welcome** dialog, select **New Project** to open a new project wizard, then select **Azure Functions**.

2. Select **Http Trigger**, then select **Next** and follow the wizard to go through all the configurations in the following pages. Confirm your project location, then select **Finish**. IntelliJ IDEA then opens your new project.

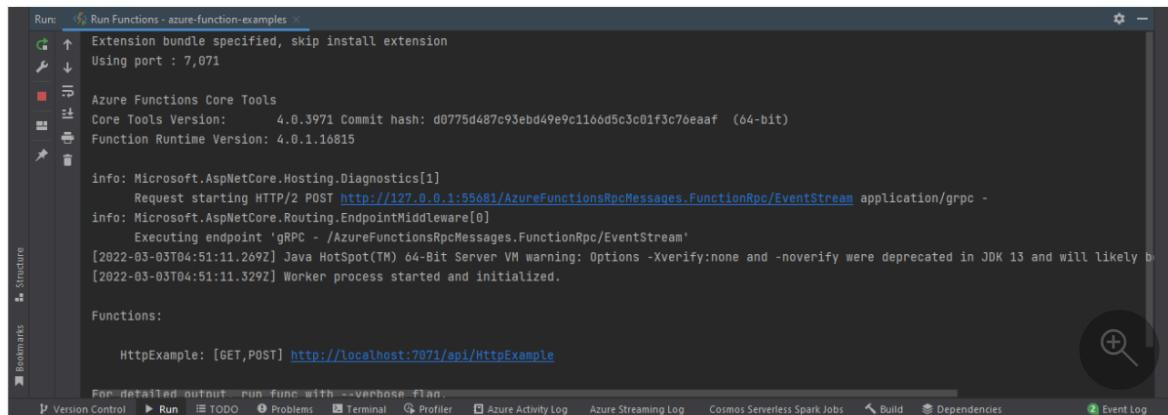

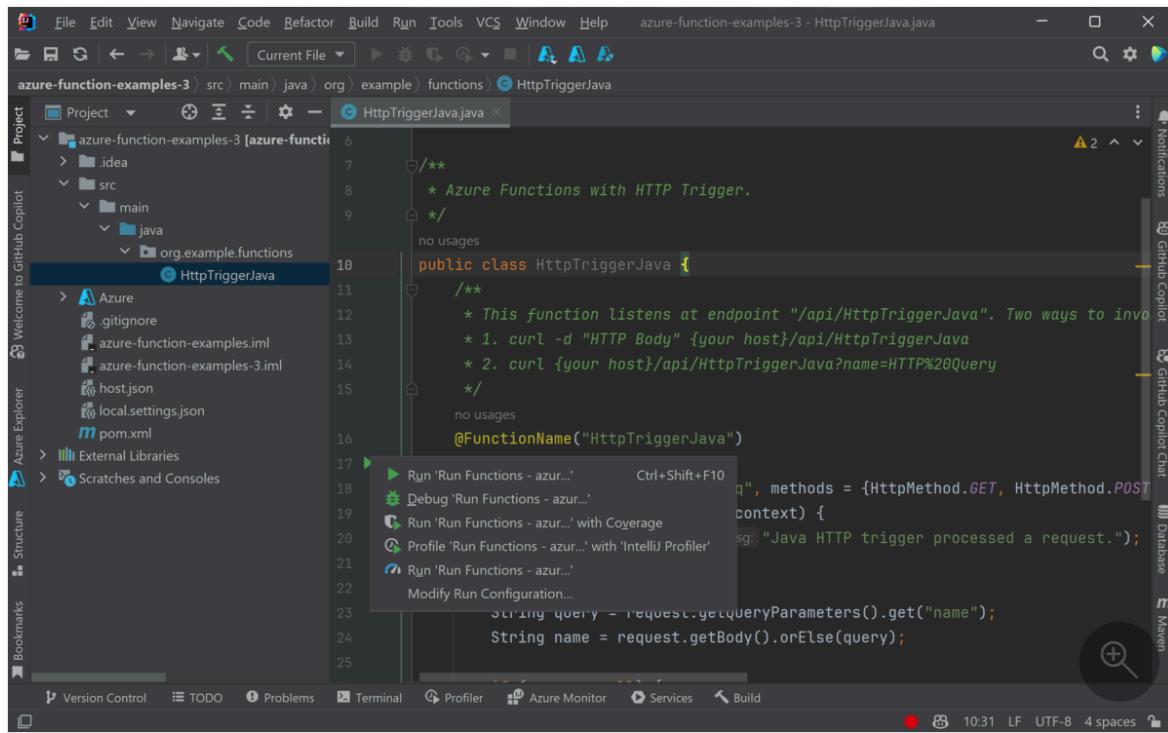

Run the project locally

To run the project locally, follow these steps:

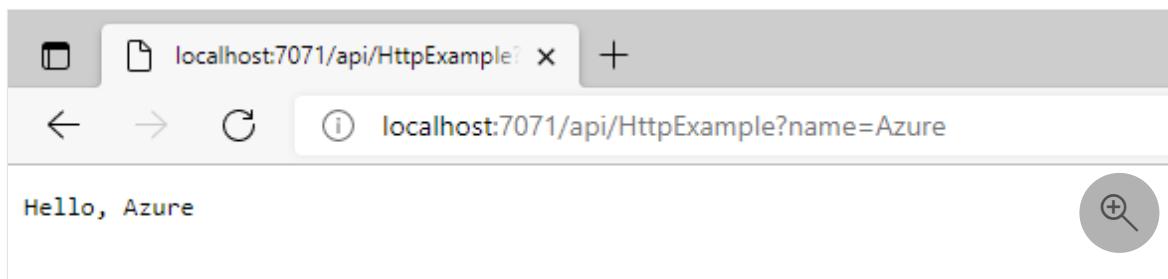

ⓘ Important

You must have the JAVA_HOME environment variable set correctly to the JDK directory that is used during code compiling using Maven. Make sure that the version of the JDK is at least as high as the `Java.version` setting.

1. Navigate to `src/main/java/org/example/functions/HttpTriggerFunction.java` to see the code generated. Beside line 24, you should see a green **Run** button. Select it and then select **Run 'Functions-azur...'**. You should see your function app running locally with a few logs.

2. You can try the function by accessing the displayed endpoint from browser, such as <http://localhost:7071/api/HttpExample?name=Azure>.

3. The log is also displayed in your IDEA. Stop the function app by selecting **Stop**.

```

Run: Run Functions - azure-function-examples
info: Microsoft.AspNetCore.Hosting.Diagnostics[1]
    Request starting HTTP/2 POST http://127.0.0.1:60051/AzureFunctionsRpcMessages.FunctionRpc/EventStream application/grpc -
info: Microsoft.AspNetCore.Routing.EndpointMiddleware[0]
    Executing endpoint 'gRPC - /AzureFunctionsRpcMessages.FunctionRpc/EventStream'
[2022-03-03T04:56:58.644Z] Java HotSpot(TM) 64-Bit Server VM warning: Options -Xverify:none and -noverify were deprecated in JDK 13 and will likely be removed in a future release.
[2022-03-03T04:56:58.742Z] Worker process started and initialized.

Functions:

HttpExample: [GET,POST] http://localhost:7071/api/HttpExample

For detailed output, run func with --verbose flag.
[2022-03-03T04:57:03.684Z] Host lock lease acquired by instance ID '000000000000000000000000003AA62615'.
[2022-03-03T04:57:04.117Z] Executing 'Functions.HttpExample' (Reason='This function was programmatically called via the host APIs.', Id=41fb3f91-c517-4522-8308-a668c5b1c4a3)
[2022-03-03T04:57:04.194Z] Java HTTP trigger processed a request.
[2022-03-03T04:57:04.194Z] Function 'HttpExample' (Id: 41fb3f91-c517-4522-8308-a668c5b1c4a3) invoked by Java Worker
[2022-03-03T04:57:04.280Z] Executed 'Functions.HttpExample' (Succeeded, Id=41fb3f91-c517-4522-8308-a668c5b1c4a3, Duration=179ms)

```

The screenshot shows the Azure Functions Java extension in Visual Studio Code. The 'Run' toolbar button is highlighted with a red box. The terminal window displays logs for a function named 'HttpExample'. The logs show the function being triggered via a Java HTTP request and successfully executed.

Debug the project locally

To debug the project locally, follow these steps:

1. Select the **Debug** button in the toolbar. If you don't see the toolbar, enable it by choosing **View > Appearance > Toolbar**.

The screenshot shows the Azure Functions Java extension in Visual Studio Code. A breakpoint is set on line 20 of the file `HttpTriggerJava.java`. The code defines an HTTP trigger function named `HttpTriggerJava` with a `@FunctionName("HttpTriggerJava")` annotation. The function body includes logic to handle requests and parse query parameters.

```

public class HttpTriggerJava {
    /**
     * This function listens at endpoint "/api/HttpTriggerJava". Two ways to invoke
     * 1. curl -d "HTTP Body" {your host}/api/HttpTriggerJava
     * 2. curl {your host}/api/HttpTriggerJava?name=HTTP%20Query
     */
    @FunctionName("HttpTriggerJava")
    public HttpResponseMessage run(
            @HttpTrigger(name = "req", methods = {HttpMethod.GET, HttpMethod.POST},
            final ExecutionContext context) {
        context.getLogger().info("Java HTTP trigger processed a request.");

        // Parse query parameter
        String query = request.getQueryParameters().get("name");
        String name = request.getBody().orElse(query);

        if (name == null) {
            return request.createResponseBuilder(HttpStatus.BAD_REQUEST).body("Please provide a name query parameter");
        } else {
            return request.createResponseBuilder(HttpStatus.OK).body("Hello " + name);
        }
    }
}

```

2. Select line 20 of the file

`src/main/java/org/example/functions/HttpTriggerFunction.java` to add a breakpoint. Access the endpoint `http://localhost:7071/api/HttpTrigger-Java?name=Azure` again and you should find that the breakpoint is hit. You can then try more debug features like **Step**, **Watch**, and **Evaluation**. Stop the debug session by selecting **Stop**.

```

final ExecutionContext context) { context: ExecutionContext
context.getLogger().info( msg: "Java HTTP trigger processed a request.");
// Parse query parameter
String query = request.getQueryParameters().get("name");
String name = request.getBody().orElse(query);

if (name == null) {
    return request.createResponseBuilder(HttpStatus.BAD_REQUEST).body(
} else {
    return request.createResponseBuilder(HttpStatus.OK).body("Hello, " + name);
}

```

Create the function app in Azure

Use the following steps create a function app and related resources in your Azure subscription:

1. In Azure Explorer in your IDEA, right-click **Function App** and then select **Create**.
2. Select **More Settings** and provide the following information at the prompts:

[Expand table](#)

Prompt	Selection
Subscription	Choose the subscription to use.
Resource Group	Choose the resource group for your function app.
Name	Specify the name for a new function app. Here you can accept the default value.
Platform	Select Windows-Java 17 or another platform as appropriate.
Region	For better performance, choose a region near you.
Hosting Options	Choose the hosting options for your function app.
Plan	Choose the App Service plan pricing tier you want to use, or select + to create a new App Service plan.

ⓘ Important

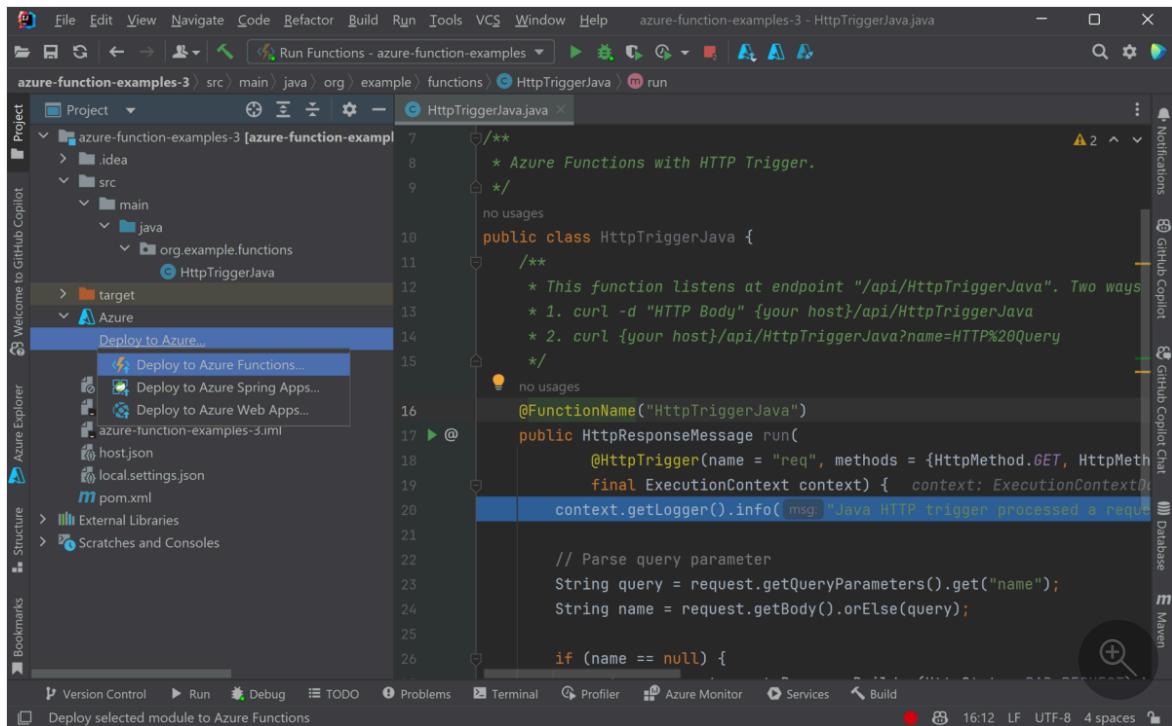

To create your app in the Flex Consumption plan, select **Flex Consumption**.
The [Flex Consumption plan](#) is currently in preview.

3. Select **OK**. A notification is displayed after your function app is created.

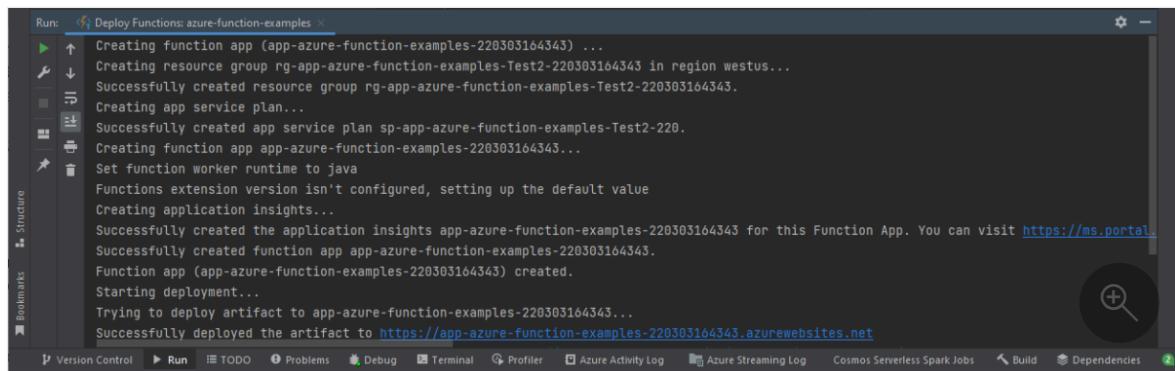

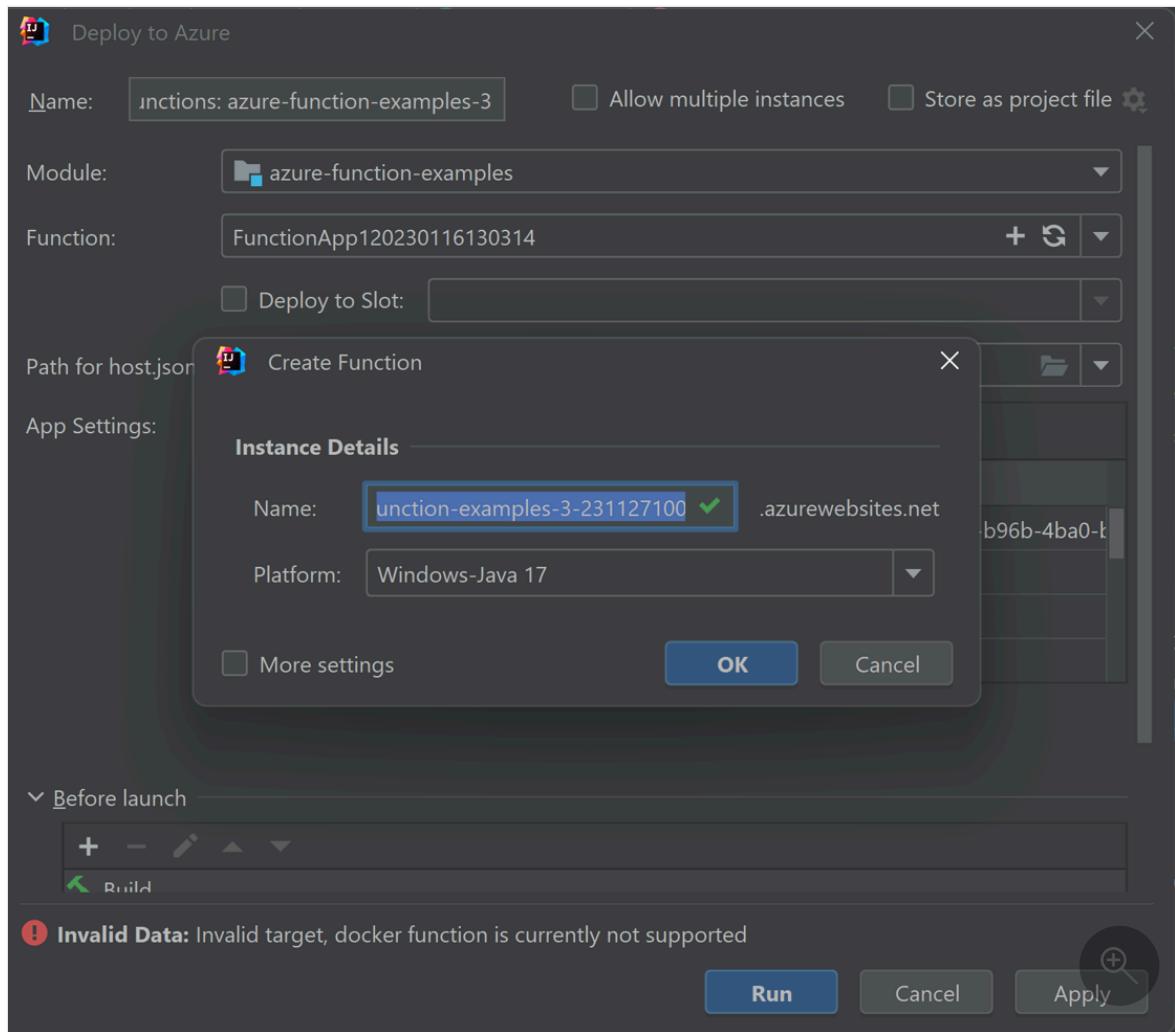

Deploy your project to Azure

To deploy your project to Azure, follow these steps:

1. Select and expand the Azure icon in IntelliJ Project explorer, then select **Deploy to Azure -> Deploy to Azure Functions**.

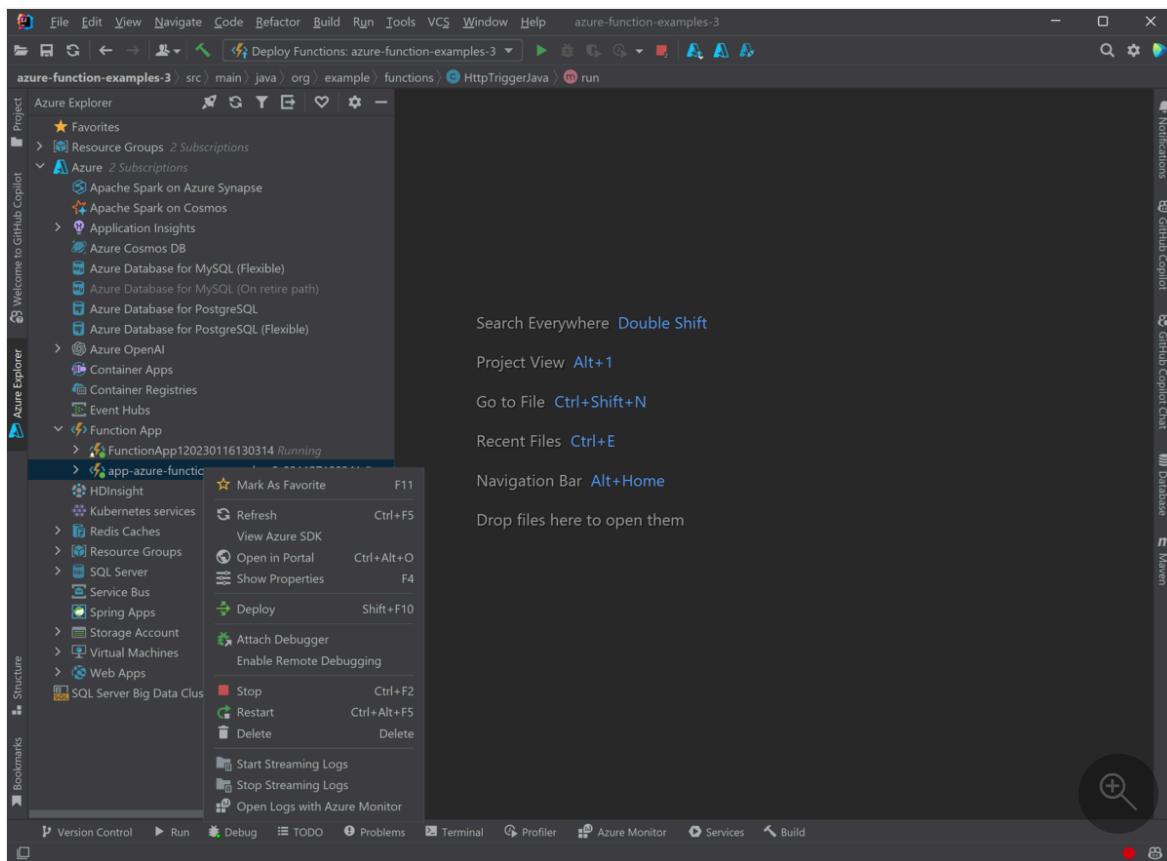

2. You can select the function app from the previous section. To create a new one, select **+** on the **Function** line. Type in the function app name and choose the proper platform. Here, you can accept the default value. Select **OK** and the new function app you created is automatically selected. Select **Run** to deploy your functions.

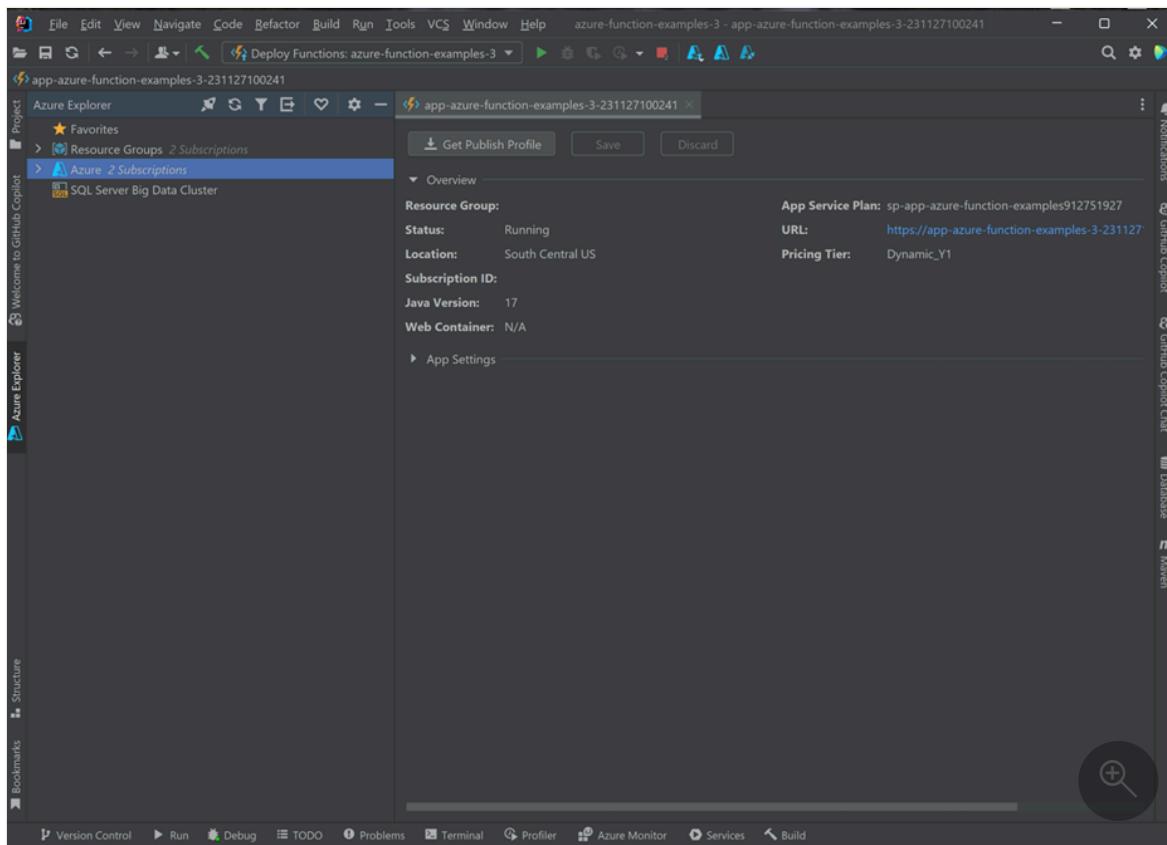

Manage function apps from IDEA

To manage your function apps with **Azure Explorer** in your IDEA, follow these steps:

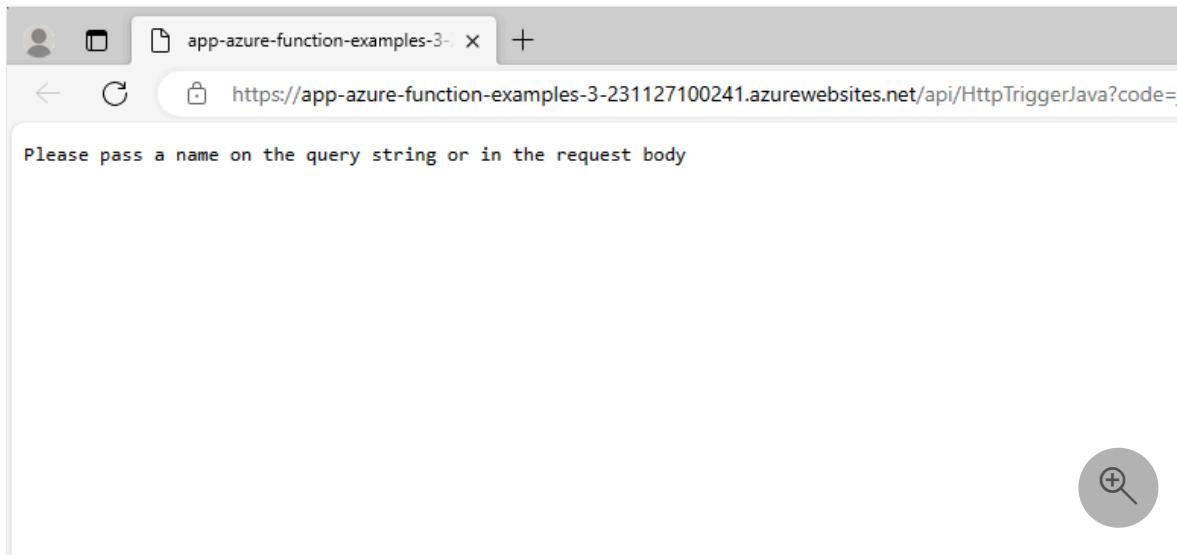

1. Select **Function App** to see all your function apps listed.

2. Select one of your function apps, then right-click and select **Show Properties** to open the detail page.

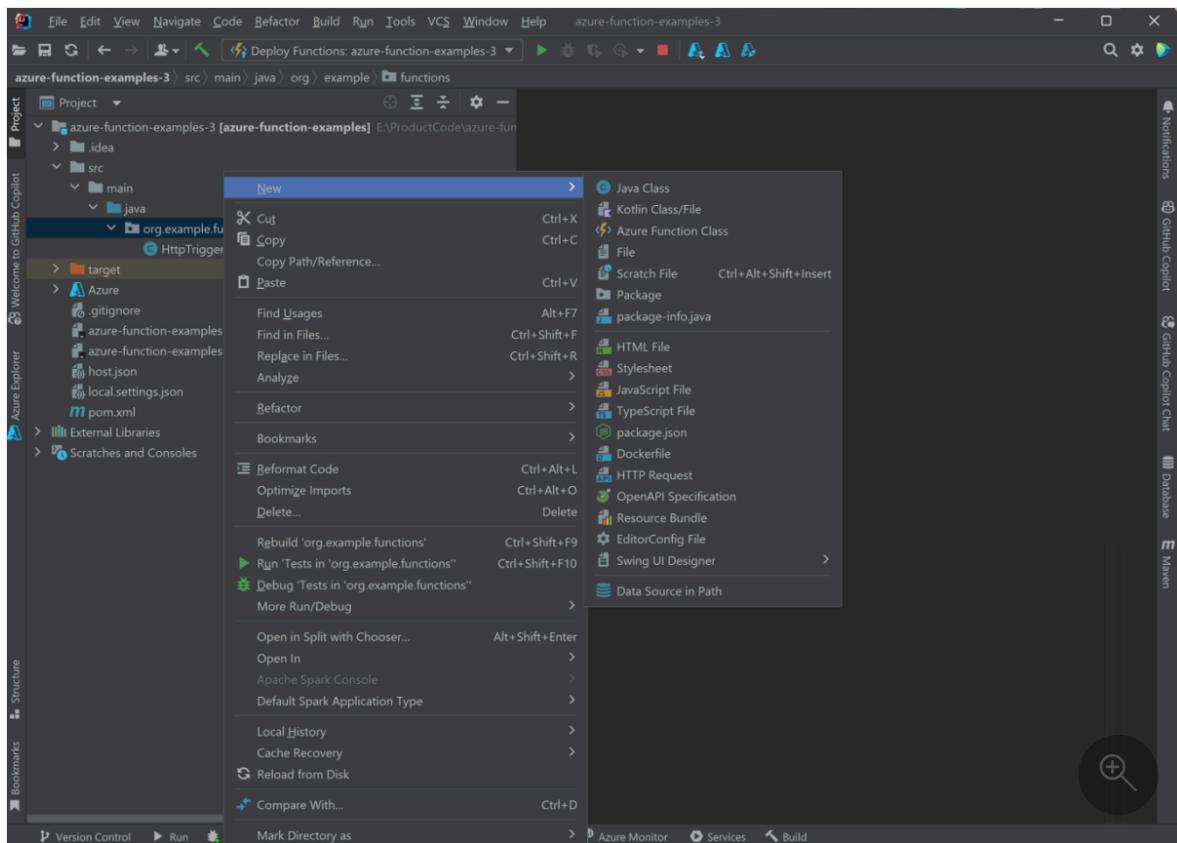

3. Right-click your **HttpTrigger-Java** function app, then select **Trigger Function in Browser**. You should see that the browser is opened with the trigger URL.

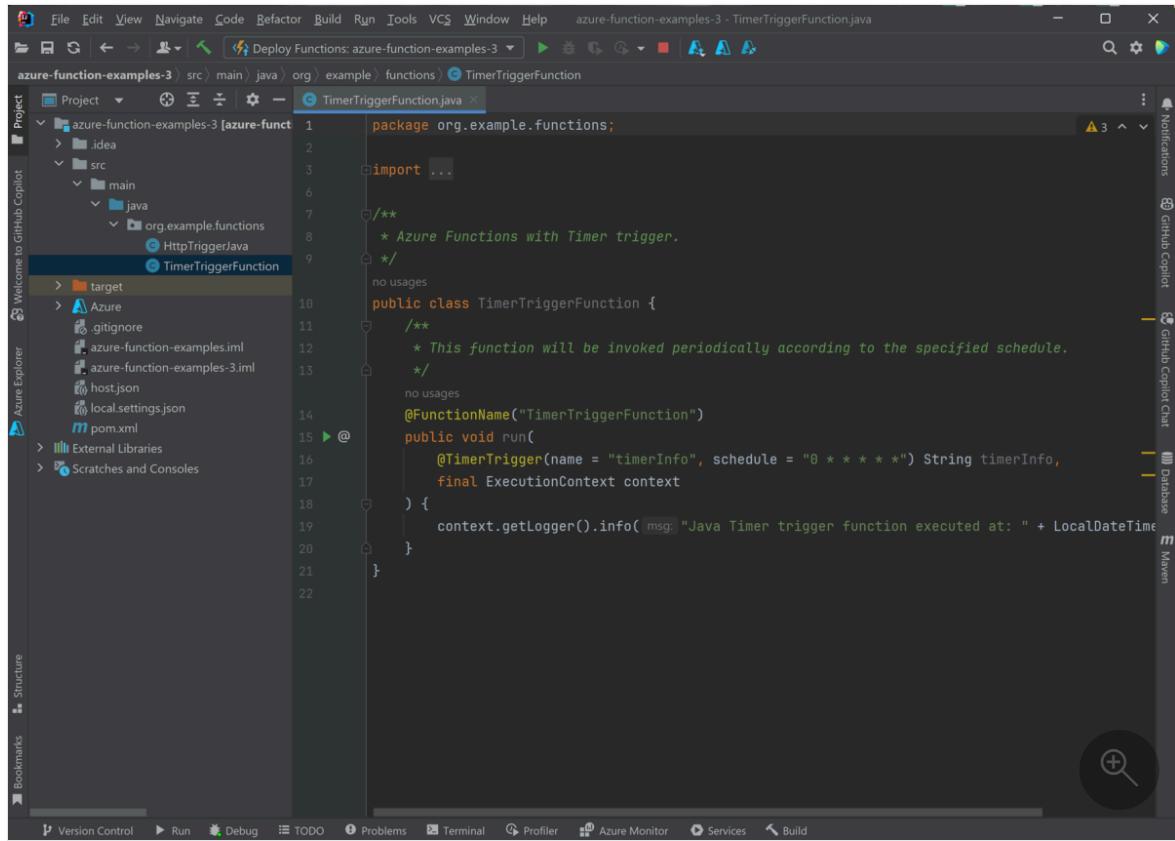

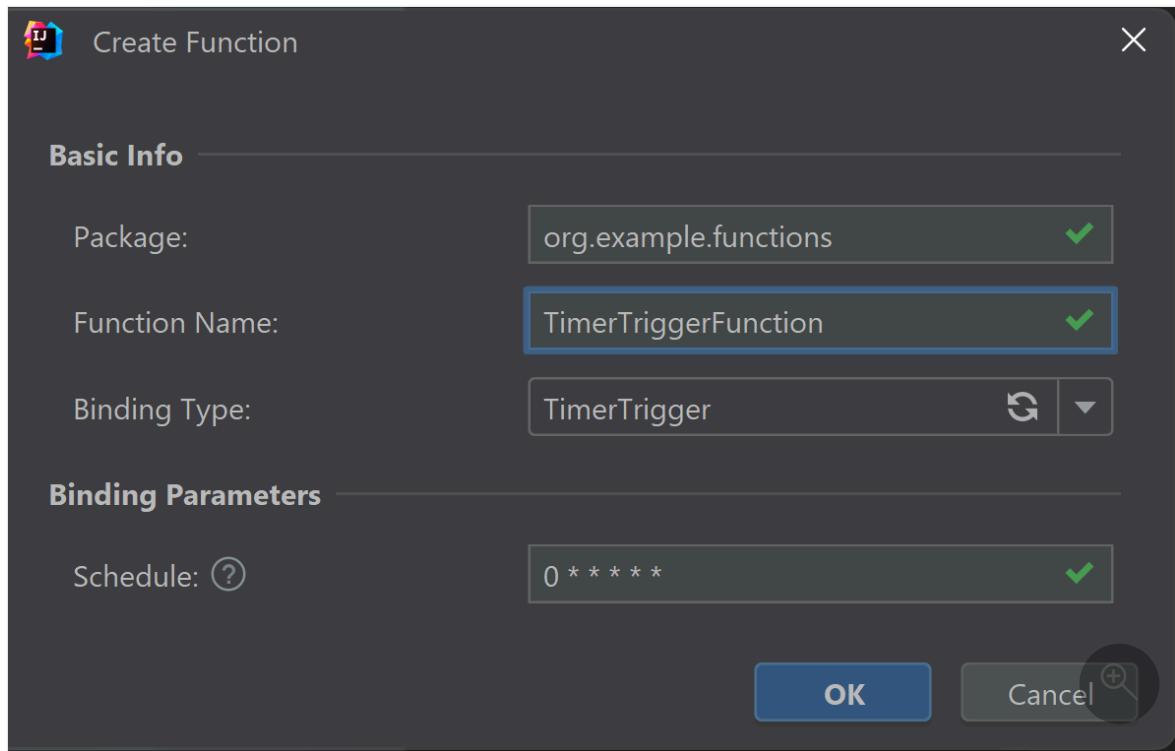

Add more functions to the project

To add more functions to your project, follow these steps:

1. Right-click the package `org.example.functions` and select **New -> Azure Function Class**.

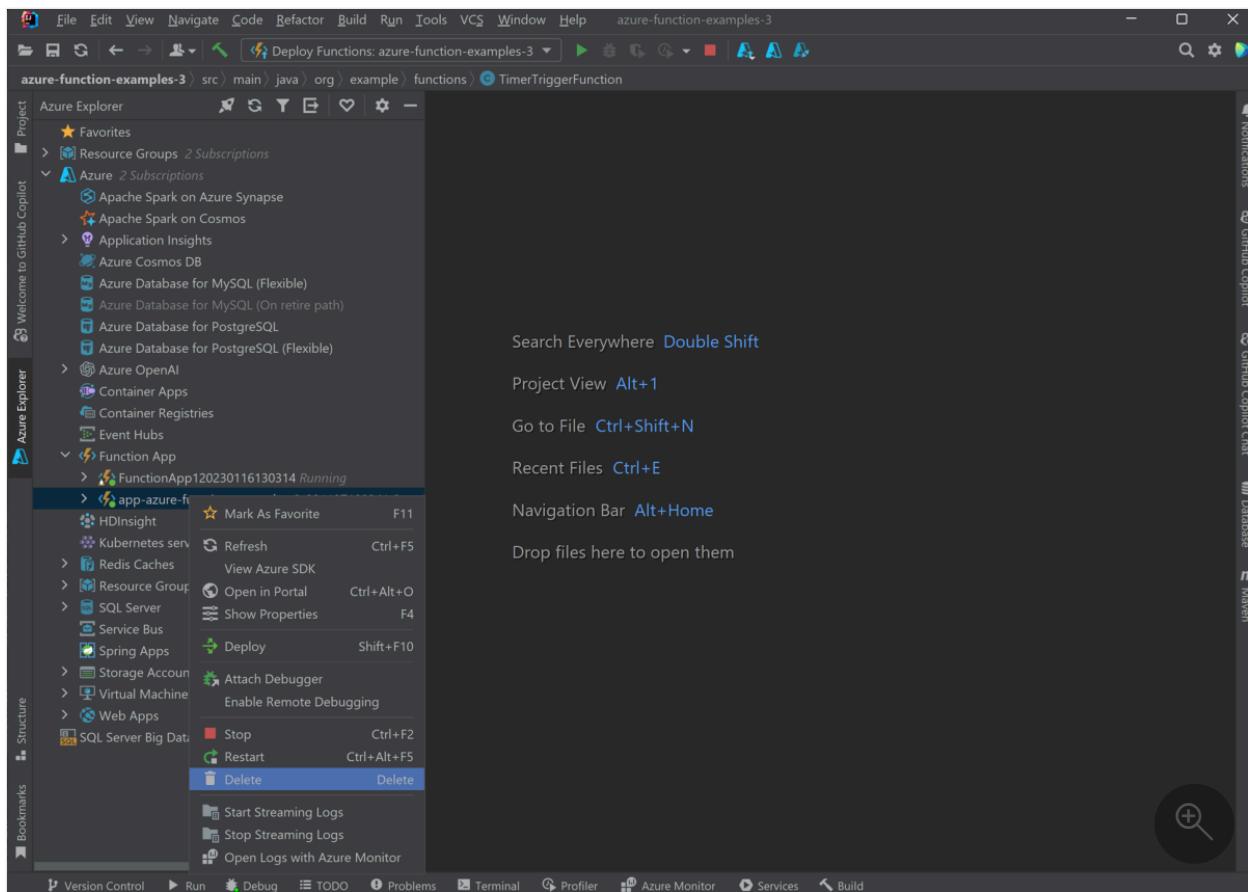

2. Fill in the class name **HttpTest** and select **HttpTrigger** in the create function class wizard, then select **OK** to create. In this way, you can create new functions as you want.

Cleaning up functions

Select one of your function apps using **Azure Explorer** in your IDEA, then right-click and select **Delete**. This command might take several minutes to run. When it's done, the status refreshes in **Azure Explorer**.

Next steps

You've created a Java project with an HTTP triggered function, run it on your local machine, and deployed it to Azure. Now, extend your function by continuing to the following article:

[Adding an Azure Storage queue output binding](#)

Quickstart: Create a Java function in Azure from the command line

Article • 08/24/2023

In this article, you use command-line tools to create a Java function that responds to HTTP requests. After testing the code locally, you deploy it to the serverless environment of Azure Functions.

If Maven isn't your preferred development tool, check out our similar tutorials for Java developers:

- [Gradle](#)
- [IntelliJ IDEA](#)
- [Visual Studio Code](#)

Completing this quickstart incurs a small cost of a few USD cents or less in your Azure account.

Configure your local environment

Before you begin, you must have the following:

- An Azure account with an active subscription. [Create an account for free ↗](#).
- The [Azure CLI](#) version 2.4 or later.
- The [Java Developer Kit](#), version 8 or 11. The `JAVA_HOME` environment variable must be set to the install location of the correct version of the JDK.
- [Apache Maven ↗](#), version 3.0 or above.

Install the Azure Functions Core Tools

The recommended way to install Core Tools depends on the operating system of your local development computer.

Windows

The following steps use a Windows installer (MSI) to install Core Tools v4.x. For more information about other package-based installers, see the [Core Tools readme ↗](#).

Download and run the Core Tools installer, based on your version of Windows:

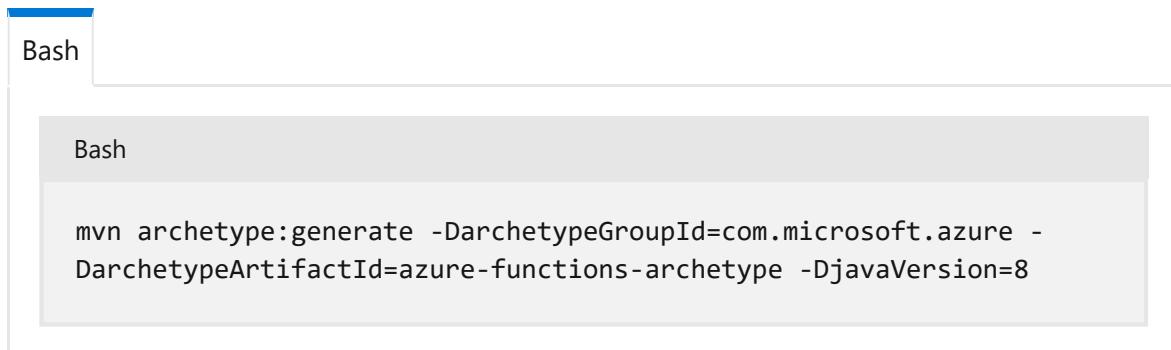

- [v4.x - Windows 64-bit ↗](#) (Recommended. Visual Studio Code debugging requires 64-bit.)
- [v4.x - Windows 32-bit ↗](#)

If you previously used Windows installer (MSI) to install Core Tools on Windows, you should uninstall the old version from Add Remove Programs before installing the latest version.

Create a local function project

In Azure Functions, a function project is a container for one or more individual functions that each responds to a specific trigger. All functions in a project share the same local and hosting configurations. In this section, you create a function project that contains a single function.

1. In an empty folder, run the following command to generate the Functions project from a [Maven archetype ↗](#).

A screenshot of a terminal window titled "Bash". The command `mvn archetype:generate -DarchetypeGroupId=com.microsoft.azure -DarchetypeArtifactId=azure-functions-archetype -DjavaVersion=8` is displayed in the terminal window.

ⓘ Important

- Use `-DjavaVersion=11` if you want your functions to run on Java 11. To learn more, see [Java versions](#).
- The `JAVA_HOME` environment variable must be set to the install location of the correct version of the JDK to complete this article.

2. Maven asks you for values needed to finish generating the project on deployment. Provide the following values when prompted:

Prompt	Value	Description
groupId	com.fabrikam	A value that uniquely identifies your project across all projects, following the package naming rules for Java.
artifactId	fabrikam-functions	A value that is the name of the jar, without a version number.
version	1.0-SNAPSHOT	Choose the default value.
package	com.fabrikam	A value that is the Java package for the generated function code. Use the default.

3. Type `Y` or press Enter to confirm.

Maven creates the project files in a new folder with a name of *artifactId*, which in this example is `fabrikam-functions`.

4. Navigate into the project folder:

```
Console
cd fabrikam-functions
```

This folder contains various files for the project, including configurations files named `local.settings.json` and `host.json`. Because `local.settings.json` can contain secrets downloaded from Azure, the file is excluded from source control by default in the `.gitignore` file.

(Optional) Examine the file contents

If desired, you can skip to [Run the function locally](#) and examine the file contents later.

Function.java

Function.java contains a `run` method that receives request data in the `request` variable is an `HttpRequestMessage` that's decorated with the `HttpTrigger` annotation, which defines the trigger behavior.

```
Java
/**
 * Copyright (c) Microsoft Corporation. All rights reserved.
 * Licensed under the MIT License. See License.txt in the project root for
 * license information.
```

```

*/
package com.functions;

```
* This function listens at endpoint "/api/HttpExampleRetry". The
function is re-executed in case of errors until the maximum number of
retries occur.
 * Retry policies: https://docs.microsoft.com/en-us/azure/azure-
functions/functions-bindings-error-pages?tabs=java
 */
@FunctionName("HttpExampleRetry")
@FixedDelayRetry(maxRetryCount = 3, delayInterval = "00:00:05")
public HttpResponseMessage HttpExampleRetry(
    @HttpTrigger(
        name = "req",
        methods = {HttpMethod.GET, HttpMethod.POST},
        authLevel = AuthorizationLevel.ANONYMOUS)
    HttpRequestMessage<Optional<String>> request,
    final ExecutionContext context) throws Exception {
    context.getLogger().info("Java HTTP trigger processed a request.");
}

if(count<3) {
    count++;
    throw new Exception("error");
}

// Parse query parameter
final String query = request.getQueryParameters().get("name");
final String name = request.getBody().orElse(query);

if (name == null) {
    return
request.createResponseBuilder(HttpStatus.BAD_REQUEST).body("Please pass a
name on the query string or in the request body").build();
} else {
    return
request.createResponseBuilder(HttpStatus.OK).body(name).build();
}

/***
 * This function listens at endpoint "/api/HttpTriggerJavaVersion".
 * It can be used to verify the Java home and java version currently in
use in your Azure function
 */
@FunctionName("HttpTriggerJavaVersion")
public static HttpResponseMessage HttpTriggerJavaVersion(
    @HttpTrigger(
        name = "req",
        methods = {HttpMethod.GET, HttpMethod.POST},
        authLevel = AuthorizationLevel.ANONYMOUS)
    HttpRequestMessage<Optional<String>> request,
    final ExecutionContext context
) {
    context.getLogger().info("Java HTTP trigger processed a request.");
    final String javaVersion = getJavaVersion();
    context.getLogger().info("Function - HttpTriggerJavaVersion" +
javaVersion);
    return
```

```

        request.createResponseBuilder(HttpStatus.OK).body("HttpTriggerJavaVersion").
        build();
    }

    public static String getJavaVersion() {
        return String.join(" - ", System.getProperty("java.home"),
System.getProperty("java.version"));
    }

    /**
     * This function listens at endpoint "/api/StaticWebPage".
     * It can be used to read and serve a static web page.
     * Note: Read the file from the right location for local machine and
     * azure portal usage.
     */
    @FunctionName("StaticWebPage")
    public HttpResponseMessage getStaticWebPage(
        @HttpTrigger(
            name = "req",
            methods = {HttpMethod.GET, HttpMethod.POST},
            authLevel = AuthorizationLevel.ANONYMOUS)
        HttpRequestMessage<Optional<String>> request,
        final ExecutionContext context) {
        context.getLogger().info("Java HTTP trigger processed a request.");

        File htmlFile = new File("index.html");
        try{
            byte[] fileContent = Files.readAllBytes(htmlFile.toPath());
            return
request.createResponseBuilder(HttpStatus.OK).body(fileContent).build();
        }catch (Exception e){
            context.getLogger().info("Error reading file.");
            return
request.createResponseBuilder(HttpStatus.INTERNAL_SERVER_ERROR).build();
        }
    }
}

```

The response message is generated by the [HttpResponseMessage.Builder](#) API.

pom.xml

Settings for the Azure resources created to host your app are defined in the **configuration** element of the plugin with a **groupId** of `com.microsoft.azure` in the generated pom.xml file. For example, the configuration element below instructs a Maven-based deployment to create a function app in the `java-functions-group` resource group in the `westus` region. The function app itself runs on Windows hosted in the `java-functions-app-service-plan` plan, which by default is a serverless Consumption plan.

Java

```
        <encoding>${project.build.sourceEncoding}</encoding>
    </configuration>
</plugin>
<plugin>
    <groupId>com.microsoft.azure</groupId>
    <artifactId>azure-functions-maven-plugin</artifactId>
    <version>${azure.functions.maven.plugin.version}</version>
    <configuration>
        <!-- function app name -->
        <appName>${functionAppName}</appName>
        <!-- function app resource group -->
        <resourceGroup>${functionResourceGroup}</resourceGroup>
        <!-- function app service plan name -->
        <appServicePlanName>${functionServicePlan}</appServicePlanName>
        <!-- function app region-->
        <!-- refers https://github.com/microsoft/azure-maven-
plugins/wiki/Azure-Functions:-Configuration-Details#supported-regions for
all valid values -->
        <region>${functionAppRegion}</region>
        <!-- function pricingTier, default to be consumption if not
specified -->
        <!-- refers https://github.com/microsoft/azure-maven-
plugins/wiki/Azure-Functions:-Configuration-Details#supported-pricing-tiers
for all valid values -->
        <pricingTier>${functionPricingTier}</pricingTier>
        <!-- Whether to disable application insights, default is false -->
        <!-- refers https://github.com/microsoft/azure-maven-
plugins/wiki/Azure-Functions:-Configuration-Details for all valid
configurations for application insights-->
        <!-- <disableAppInsights></disableAppInsights> -->

        <runtime>
            <!-- runtime os, could be windows, linux or docker-->
            <os>windows</os>
            <javaVersion>8</javaVersion>
            <!-- for docker function, please set the following parameters -->
        >
            <!-- <image>[hub-user/]repo-name[:tag]</image> -->
            <!-- <serverId></serverId> -->
            <!-- <registryUrl></registryUrl> -->
        </runtime>
        <appSettings>
            <property>
                <name>FUNCTIONS_EXTENSION_VERSION</name>
                <value>~4</value>
            </property>
        </appSettings>
    </configuration>
    <executions>
        <execution>
            <id>package-functions</id>
            <goals>
```

```
<goal>package</goal>
</goals>
```

You can change these settings to control how resources are created in Azure, such as by changing `runtime.os` from `windows` to `linux` before initial deployment. For a complete list of settings supported by the Maven plug-in, see the [configuration details](#).

FunctionTest.java

The archetype also generates a unit test for your function. When you change your function to add bindings or add new functions to the project, you'll also need to modify the tests in the `FunctionTest.java` file.

Run the function locally

1. Run your function by starting the local Azure Functions runtime host from the `LocalFunctionProj` folder:

```
Console

mvn clean package
mvn azure-functions:run
```

Toward the end of the output, the following lines should appear:

```
...
Now listening on: http://0.0.0.0:7071
Application started. Press Ctrl+C to shut down.

Http Functions:

    HttpExample: [GET,POST] http://localhost:7071/api/HttpExample
...
```

ⓘ Note

If `HttpExample` doesn't appear as shown above, you likely started the host from outside the root folder of the project. In that case, use `Ctrl+C` to stop the

host, navigate to the project's root folder, and run the previous command again.

2. Copy the URL of your `HttpExample` function from this output to a browser and append the query string `?name=<YOUR_NAME>`, making the full URL like `http://localhost:7071/api/HttpExample?name=Functions`. The browser should display a message that echoes back your query string value. The terminal in which you started your project also shows log output as you make requests.
3. When you're done, use `Ctrl+C` and choose `y` to stop the functions host.

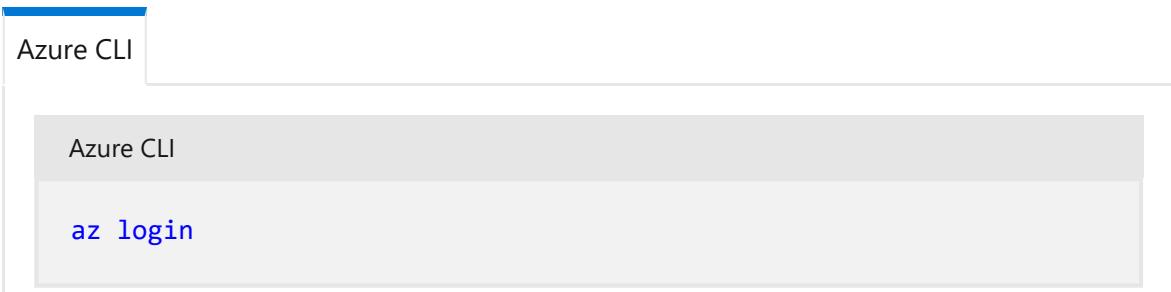

Deploy the function project to Azure

A function app and related resources are created in Azure when you first deploy your functions project. Settings for the Azure resources created to host your app are defined in the [pom.xml file](#). In this article, you'll accept the defaults.

Tip

To create a function app running on Linux instead of Windows, change the `runtime.os` element in the `pom.xml` file from `windows` to `linux`. Running Linux in a consumption plan is supported in [these regions](#). You can't have apps that run on Linux and apps that run on Windows in the same resource group.

1. Before you can deploy, sign in to your Azure subscription using either Azure CLI or Azure PowerShell.

The screenshot shows the Azure CLI interface. A dropdown menu is open, with 'Azure CLI' selected. Below it, the command `az login` is typed into the input field.

The `az login` command signs you into your Azure account.

2. Use the following command to deploy your project to a new function app.

The screenshot shows a Maven console window. The title bar says 'Console'. In the main area, the command `mvn azure-functions:deploy` is visible.

This creates the following resources in Azure:

- Resource group. Named as *java-functions-group*.
- Storage account. Required by Functions. The name is generated randomly based on Storage account name requirements.
- Hosting plan. Serverless hosting for your function app in the *westus* region. The name is *java-functions-app-service-plan*.
- Function app. A function app is the deployment and execution unit for your functions. The name is randomly generated based on your *artifactId*, appended with a randomly generated number.

The deployment packages the project files and deploys them to the new function app using [zip deployment](#). The code runs from the deployment package in Azure.

Important

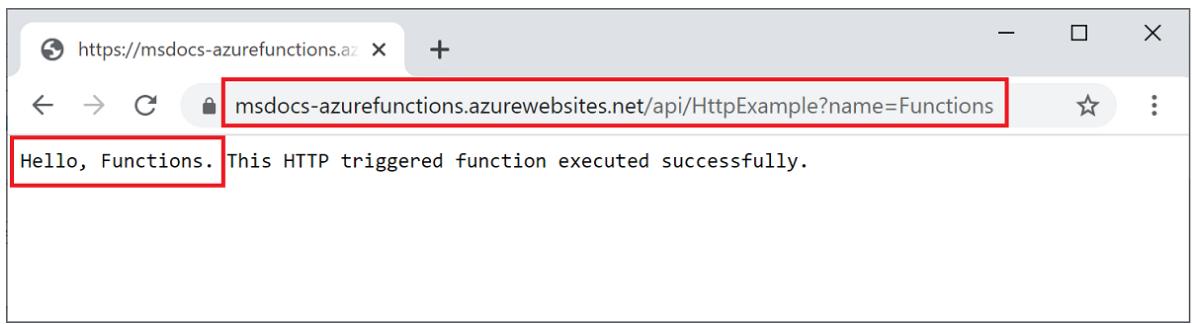

The storage account is used to store important app data, sometimes including the application code itself. You should limit access from other apps and users to the storage account.

Invoke the function on Azure

Because your function uses an HTTP trigger, you invoke it by making an HTTP request to its URL in the browser or with a tool like curl.

Browser

Copy the complete **Invoke URL** shown in the output of the publish command into a browser address bar, appending the query parameter `?name=Functions`. The browser should display similar output as when you ran the function locally.

Hello, Functions. This HTTP triggered function executed successfully.

Run the following command to view near real-time streaming logs:

Console

```
func azure functionapp logstream <APP_NAME>
```

In a separate terminal window or in the browser, call the remote function again. A verbose log of the function execution in Azure is shown in the terminal.

Clean up resources

If you continue to the [next step](#) and add an Azure Storage queue output binding, keep all your resources in place as you'll build on what you've already done.

Otherwise, use the following command to delete the resource group and all its contained resources to avoid incurring further costs.

Azure CLI

Azure CLI

```
az group delete --name java-functions-group
```

Next steps

[Connect to an Azure Storage queue](#)

Deploy serverless Java apps with Quarkus on Azure Functions

Article • 03/17/2023

In this article, you'll develop, build, and deploy a serverless Java app to Azure Functions by using [Quarkus ↗](#). This article uses Quarkus Funqy and its built-in support for the Azure Functions HTTP trigger for Java. Using Quarkus with Azure Functions gives you the power of the Quarkus programming model with the scale and flexibility of Azure Functions. When you finish, you'll run serverless Quarkus applications on Azure Functions and continue to monitor your app on Azure.

Prerequisites

- The [Azure CLI](#) installed on your own computer.
- An [Azure account ↗](#). If you don't have an [Azure subscription](#), create an [Azure free account ↗](#) before you begin.
- [Java JDK 17](#) with `JAVA_HOME` configured appropriately. This article was written with Java 17 in mind, but Azure Functions and Quarkus also support older versions of Java.
- [Apache Maven 3.8.1+ ↗](#).

Create the app project

Use the following command to clone the sample Java project for this article. The sample is on [GitHub ↗](#).

Bash

```
git clone https://github.com/Azure-Samples/quarkus-azure
```

Explore the sample function. Open the *functions-quarkus/src/main/java/io/quarkus/GreetingFunction.java* file.

Run the following command. The `@Funq` annotation makes your method (in this case, `funqyHello`) a serverless function.

Java

```
@Funq  
public String funqyHello() {
```

```
        return "hello funqy";
    }
```

Azure Functions Java has its own set of Azure-specific annotations, but these annotations aren't necessary when you're using Quarkus on Azure Functions in a simple capacity as we're doing here. For more information about Azure Functions Java annotations, see the [Azure Functions Java developer guide](#).

Unless you specify otherwise, the function's name is the same as the method name. You can also use the following command to define the function name with a parameter to the annotation:

Java

```
@Funq("alternateName")
public String funqHello() {
    return "hello funqy";
}
```

The name is important. It becomes a part of the REST URI to invoke the function, as shown later in the article.

Test the function locally

Use `mvn` to run Quarkus dev mode on your local terminal. Running Quarkus in this way enables live reload with background compilation. When you modify your Java files and/or your resource files and refresh your browser, these changes will automatically take effect.

A browser refresh triggers a scan of the workspace. If the scan detects any changes, the Java files are recompiled and the application is redeployed. Your redeployed application services the request. If there are any problems with compilation or deployment, an error page will let you know.

In the following procedure, replace `yourResourceGroupName` with a resource group name. Function app names must be globally unique across all of Azure. Resource group names must be globally unique within a subscription. This article achieves the necessary uniqueness by prepending the resource group name to the function name. Consider prepending a unique identifier to any names you create that must be unique. A useful technique is to use your initials followed by today's date in `mmdd` format.

The resource group is not necessary for this part of the instructions, but it's required later. For simplicity, the Maven project requires you to define the property.

1. Invoke Quarkus dev mode:

Bash

```
cd functions-azure  
mvn -DskipTests -DresourceGroup=<yourResourceGroupName> quarkus:dev
```

The output should look like this:

Output

```
...  
--/ _ \ / / / _ | / _ \ / / / / / _/  
-/ /_ / / / / _ | / , _/ , < / /_ / \ \ /  
--\_\_\_\_\_\_\_/_|/_/_/_/_/_|\_\_\_\_\_\_/_/  
INFO [io.quarkus] (Quarkus Main Thread) quarkus-azure-function 1.0-  
SNAPSHOT on JVM (powered by Quarkus xx.xx.xx.) started in 1.290s.  
Listening on: http://localhost:8080  
  
INFO [io.quarkus] (Quarkus Main Thread) Profile dev activated. Live  
Coding activated.  
INFO [io.quarkus] (Quarkus Main Thread) Installed features: [cdi,  
funqy-http, smallrye-context-propagation, vertx]  
  
--  
Tests paused  
Press [r] to resume testing, [o] Toggle test output, [:] for the  
terminal, [h] for more options>
```

2. Access the function by using the `CURL` command on your local terminal:

Bash

```
curl localhost:8080/api/funqyHello
```

The output should look like this:

Output

```
"hello funqy"
```

Add dependency injection to the function

The open-standard technology Jakarta EE Contexts and Dependency Injection (CDI) provides dependency injection in Quarkus. For a high-level overview of injection in general, and CDI specifically, see the [Jakarta EE tutorial ↗](#).

1. Add a new function that uses dependency injection.

Create a `GreetingService.java` file in the `functions-quarkus/src/main/java/io/quarkus` directory. Use the following code as the source code of the file:

Java

```
package io.quarkus;

import javax.enterprise.context.ApplicationScoped;

@ApplicationScoped
public class GreetingService {

    public String greeting(String name) {
        return "Welcome to build Serverless Java with Quarkus on Azure
Functions, " + name;
    }

}
```

Save the file.

`GreetingService` is an injectable bean that implements a `greeting()` method. The method returns a `Welcome...` string message with a `name` parameter.

2. Open the existing `functions-`

`quarkus/src/main/java/io/quarkus/GreetingFunction.java` file. Replace the class with the following code to add a new `gService` field and the `greeting` method:

Java

```
package io.quarkus;

import javax.inject.Inject;
import io.quarkus.funqy.Funq;

public class GreetingFunction {

    @Inject
    GreetingService gService;

    @Funq
    public String greeting(String name) {
        return gService.greeting(name);
    }

    @Funq
    public String funqyHello() {
        return "hello funqy";
    }
}
```

```
}
```

```
}
```

Save the file.

3. Access the new `greeting` function by using the `curl` command on your local terminal:

Bash

```
curl -d '"Dan"' -X POST localhost:8080/api/greeting
```

The output should look like this:

Output

```
"Welcome to build Serverless Java with Quarkus on Azure Functions, Dan"
```

ⓘ Important

Live Coding (also called dev mode) allows you to run the app and make changes on the fly. Quarkus will automatically recompile and reload the app when changes are made. This is a powerful and efficient style of developing that you'll use throughout this article.

Before you move forward to the next step, stop Quarkus dev mode by selecting **Ctrl+C**.

Deploy the app to Azure

1. If you haven't already, sign in to your Azure subscription by using the following [az login](#) command and follow the on-screen directions:

Azure CLI

```
az login
```

ⓘ Note

If multiple Azure tenants are associated with your Azure credentials, you must specify which tenant you want to sign in to. You can do this by using the `--tenant` option. For example: `az login --tenant contoso.onmicrosoft.com`.

Continue the process in the web browser. If no web browser is available or if the web browser fails to open, use device code flow with `az login --use-device-code`.

After you sign in successfully, the output on your local terminal should look similar to the following:

Output

```
xxxxxxxx-xxxxx-xxxx-xxxx-xxxxxxxxx 'Microsoft'  
[  
  {  
    "cloudName": "AzureCloud",  
    "homeTenantId": "xxxxxxxx-xxxx-xxxx-xxxx-xxxxxxxxx",  
    "id": "xxxxxxxx-xxxx-xxxx-xxxx-xxxxxxxxx",  
    "isDefault": true,  
    "managedByTenants": [],  
    "name": "Contoso account services",  
    "state": "Enabled",  
    "tenantId": "xxxxxxxx-xxxx-xxxx-xxxx-xxxxxxxxxx",  
    "user": {  
      "name": "user@contoso.com",  
      "type": "user"  
    }  
  }  
]
```

2. Build and deploy the functions to Azure.

The `pom.xml` file that you generated in the previous step uses `azure-functions-maven-plugin`. Running `mvn install` generates configuration files and a staging directory that `azure-functions-maven-plugin` requires. For `yourResourceGroupName`, use the value that you used previously.

Bash

```
mvn clean install -DskipTests -DtenantId=<your tenantId from shown  
previously> -DresourceGroup=<yourResourceGroupName> azure-  
functions:deploy
```

3. During deployment, sign in to Azure. The `azure-functions-maven-plugin` plug-in is configured to prompt for Azure sign-in each time the project is deployed. During

the build, output similar to the following appears:

Output

```
[INFO] Auth type: DEVICE_CODE  
To sign in, use a web browser to open the page  
https://microsoft.com/devicelogin and enter the code AXCWTLGMP to  
authenticate.
```

Do as the output says and authenticate to Azure by using the browser and the provided device code. Many other authentication and configuration options are available. The complete reference documentation for [azure-functions-maven-plugin](#) is available at [Azure Functions: Configuration Details ↗](#).

4. After authentication, the build should continue and finish. Make sure that output includes `BUILD SUCCESS` near the end.

Output

```
Successfully deployed the artifact to https://quarkus-demo-  
123451234.azurewebsites.net
```

You can also find the URL to trigger your function on Azure in the output log:

Output

```
[INFO] HTTP TriggerUrls:  
[INFO] quarkus : https://quarkus-azure-functions-http-archetype-  
20220629204040017.azurewebsites.net/api/{*path}
```

It will take a while for the deployment to finish. In the meantime, let's explore Azure Functions in the Azure portal.

Access and monitor the serverless function on Azure

Sign in to [the portal ↗](#) and ensure that you've selected the same tenant and subscription that you used in the Azure CLI.

1. Type **function app** on the search bar at the top of the Azure portal and select the Enter key. Your function app should be deployed and show up with the name `<yourResourceGroupName>-function-quarkus`.

The screenshot shows the Microsoft Azure portal interface. On the left, there's a sidebar with various service icons like Home, Dashboard, All services, Favorites, Resource groups, App Services, Function App, SQL databases, Azure Cosmos DB, Virtual machines, Load balancers, Storage accounts, and Virtual networks. The main area is titled 'Function App' and shows a single item: 'redhat.com'. Below it is a search bar and filter options: 'Subscription equals all', 'Resource group equals all', and 'Add filter'. There are also buttons for 'Create', 'Manage view', 'Refresh', 'Export to CSV', 'Open query', 'Assign tags', 'Start', 'Restart', and more. A table lists the function app details: Name (ejb040110q-functions-quarkus), Status (Running), Location (Central US), Pricing Tier (Dynamic), and App Service Plan (asp-ejb040110q-functions-quarkus). The URL 'https://ejb040110q-functions-quarkus.azurewebsites.net' is shown at the bottom right of the main content area.

2. Select the function app to show detailed information, such as **Location**, **Subscription**, **URL**, **Metrics**, and **App Service Plan**. Then, select the **URL** value.

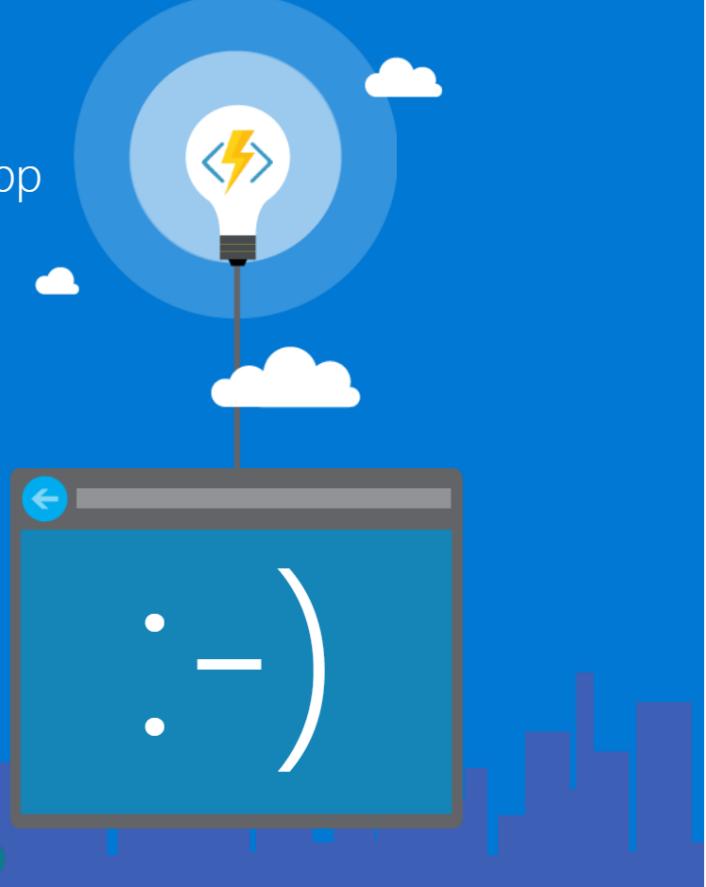

The screenshot shows the 'ejb040110q-functions-quarkus' Function App overview page. On the left, there's a sidebar with links for Overview, Activity log, Access control (IAM), Tags, Diagnose and solve problems, Microsoft Defender for Cloud, Events (preview), Functions (Functions, App keys, App files, Proxies), Deployment (Deployment slots, Deployment Center), and Settings. The main content area has tabs for Overview, Browse, Refresh, Stop, Restart, Swap, Get publish profile, Reset publish profile, Download app content, and more. It displays basic app details: Resource group (ejb040110q), Status (Running), Location (Central US), Subscription (Team (EA Subscription 1)), App Service Plan (asp-ejb040110q-functions-quarkus (Y1: 0)), and Properties (See More). It also shows Runtime version (4.14.0.19631). Below this, there are sections for Metrics (Memory working set: 70MB, 60MB) and Function Execution Count (100, 90, 80). At the bottom, there are links for Tags (edit) and Click here to add tags.

3. Confirm that the welcome page says your function app is "up and running."

Your Functions 4.0 app is up and running

Azure Functions is an event-based serverless compute experience to accelerate your development.

Learn more [\(opens in new tab\)](#)

4. Invoke the `greeting` function by using the following `curl` command on your local terminal.

ⓘ Important

Replace `YOUR_HTTP_TRIGGER_URL` with your own function URL that you find in the Azure portal or output.

Bash

```
curl -d '"Dan on Azure"' -X POST
https://YOUR_HTTP_TRIGGER_URL/api/greeting
```

The output should look similar to the following:

Output

```
"Welcome to build Serverless Java with Quarkus on Azure Functions, Dan
on Azure"
```

You can also access the other function (`funqyHello`) by using the following `curl` command:

Bash

```
curl https://YOUR_HTTP_TRIGGER_URL/api/funqyHello
```

The output should be the same as what you observed earlier:

Output

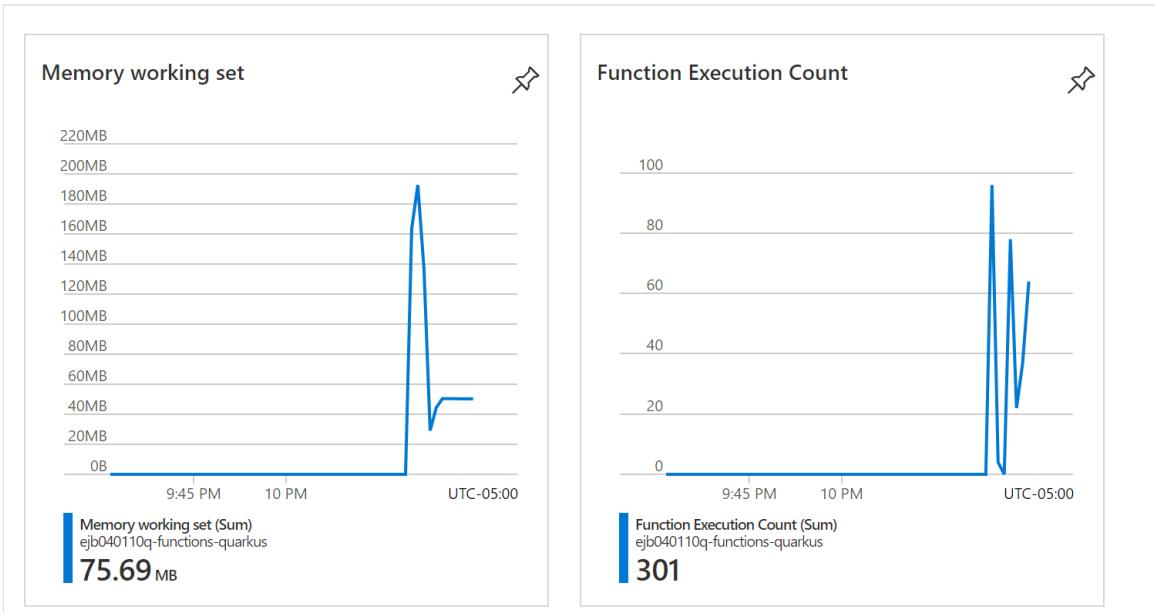

```
"hello funqy"
```

If you want to exercise the basic metrics capability in the Azure portal, try invoking the function within a shell `for` loop:

Bash

```
for i in {1..100}; do curl -d '"Dan on Azure"' -X POST  
https://YOUR_HTTP_TRIGGER_URL/api/greeting; done
```

After a while, you'll see some metrics data in the portal.

Now that you've opened your Azure function in the portal, here are more features that you can access from the portal:

- Monitor the performance of your Azure function. For more information, see [Monitoring Azure Functions](#).
- Explore telemetry. For more information, see [Analyze Azure Functions telemetry in Application Insights](#).
- Set up logging. For more information, see [Enable streaming execution logs in Azure Functions](#).

Clean up resources

If you don't need these resources, you can delete them by running the following command in Azure Cloud Shell or on your local terminal:

Azure CLI

```
az group delete --name <yourResourceGroupName> --yes
```

Next steps

In this article, you learned how to:

- ✓ Run Quarkus dev mode.
- ✓ Deploy a Funqy app to Azure functions by using `azure-functions-maven-plugin`.
- ✓ Examine the performance of the function in the portal.

To learn more about Azure Functions and Quarkus, see the following articles and references:

- [Azure Functions documentation](#)
- [Quarkus guide to deploying on Azure ↗](#)

Spring Cloud Function in Azure

Article • 12/06/2023

This article guides you through using [Spring Cloud Functions](#) to develop a Java function and publish it to Azure Functions. When you're done, your function code runs on the [Consumption Plan](#) in Azure and can be triggered using an HTTP request.

Prerequisites

- An Azure subscription. If you don't have an [Azure subscription](#), create a [free account](#) before you begin.

To develop functions using Java, you must have the following installed:

- [Java Developer Kit](#), version 11
- [Apache Maven](#), version 3.0 or higher
- [Azure CLI](#)
- [Azure Functions Core Tools](#) version 4

ⓘ Important

1. You must set the `JAVA_HOME` environment variable to the install location of the JDK to complete this quickstart.
2. Make sure your core tools version is at least 4.0.5455.

What we're going to build

We're going to build a classical "Hello, World" function that runs on Azure Functions and is configured with Spring Cloud Function.

The function receives a `User` JSON object, which contains a user name, and sends back a `Greeting` object, which contains the welcome message to that user.

The project is available in the [Spring Cloud Function in Azure](#) sample of the [azure-function-java-worker](#) repository on GitHub. You can use that sample directly if you want to see the final work described in this quickstart.

Create a new Maven project

We're going to create an empty Maven project, and configure it with Spring Cloud Function and Azure Functions.

In an empty folder, create a new *pom.xml* file and copy/paste the content from the sample project's [pom.xml](#) file.

ⓘ Note

This file uses Maven dependencies from both Spring Boot and Spring Cloud Function, and it configures the Spring Boot and Azure Functions Maven plugins.

You need to customize a few properties for your application:

- `<functionAppName>` is the name of your Azure Function
- `<functionAppRegion>` is the name of the Azure region where your Function is deployed
- `<functionResourceGroup>` is the name of the Azure resource group you're using

Change those properties directly near the top of the *pom.xml* file, as shown in the following example:

XML

```
<properties>
    <java.version>11</java.version>

    <!-- Spring Boot start class. WARNING: correct class must be set -->
    <start-class>com.example.DemoApplication</start-class>

    <!-- customize those properties. WARNING: the functionAppName should
be unique across Azure -->

<azure.functions.maven.plugin.version>1.29.0</azure.functions.maven.plugin.v
ersion>
    <functionResourceGroup>my-spring-function-resource-
group</functionResourceGroup>
    <functionAppServicePlanName>my-spring-function-service-
plan</functionAppServicePlanName>
    <functionAppName>my-spring-function</functionAppName>
    <functionPricingTier>Y1</functionPricingTier>
    <functionAppRegion>eastus</functionAppRegion>
</properties>
```

Create Azure configuration files

Create a `src/main/resources` folder and add the following Azure Functions configuration files to it.

`host.json`:

```
JSON

{
  "version": "2.0",
  "extensionBundle": {
    "id": "Microsoft.Azure.Functions.ExtensionBundle",
    "version": "[4.*, 5.2.0)"
  },
  "functionTimeout": "00:10:00"
}
```

`local.settings.json`:

```
JSON

{
  "IsEncrypted": false,
  "Values": {
    "AzureWebJobsStorage": "",
    "FUNCTIONS_WORKER_RUNTIME": "java",
    "FUNCTIONS_EXTENSION_VERSION": "~4",
    "AzureWebJobsDashboard": ""
  }
}
```

Create domain objects

Azure Functions can receive and send objects in JSON format. We're now going to create our `User` and `Greeting` objects, which represent our domain model. You can create more complex objects, with more properties, if you want to customize this quickstart and make it more interesting for you.

Create a `src/main/java/com/example/model` folder and add the following two files:

`User.java`:

```
Java

package com.example.model;

public class User {
```

```
private String name;

public User() {
}

public User(String name) {
    this.name = name;
}

public String getName() {
    return name;
}

public void setName(String name) {
    this.name = name;
}
}
```

Greeting.java:

Java

```
package com.example.model;

public class Greeting {

    private String message;

    public Greeting() {
    }

    public Greeting(String message) {
        this.message = message;
    }

    public String getMessage() {
        return message;
    }

    public void setMessage(String message) {
        this.message = message;
    }
}
```

Create the Spring Boot application

This application manages all business logic, and has access to the full Spring Boot ecosystem. This capability gives you two main benefits over a standard Azure Function:

- It doesn't rely on the Azure Functions APIs, so you can easily port it to other systems. For example, you can reuse it in a normal Spring Boot application.
- You can use all the `@Enable` annotations from Spring Boot to add new features.

In the `src/main/java/com/example` folder, create the following file, which is a normal Spring Boot application:

DemoApplication.java:

Java

```
package com.example;

import org.springframework.boot.SpringApplication;
import org.springframework.boot.autoconfigure.SpringBootApplication;

@SpringBootApplication
public class DemoApplication {
    public static void main(String[] args) throws Exception {
        SpringApplication.run(DemoApplication.class, args);
    }
}
```

Now create the following file in the `src/main/java/com/example/hello` folder. This code contains a Spring Boot component that represents the Function we want to run:

Hello.java:

Java

```
package com.example.hello;

import com.example.model.*;
import org.springframework.stereotype.Component;
import java.util.function.Function;

@Component
public class Hello implements Function<User, Greeting> {

    @Override
    public Greeting apply(User user) {
        return new Greeting("Hello, " + user.getName() + "!\n");
    }
}
```

① Note

The `Hello` function is quite specific:

- It is a `java.util.function.Function`. It contains the business logic, and it uses a standard Java API to transform one object into another.
- Because it has the `@Component` annotation, it's a Spring Bean, and by default its name is the same as the class, but starting with a lowercase character: `hello`. Following this naming convention is important if you want to create other functions in your application. The name must match the Azure Functions name we'll create in the next section.

Create the Azure Function

To benefit from the full Azure Functions API, we now code an Azure Function that delegates its execution to the Spring Cloud Function created in the previous step.

In the `src/main/java/com/example/hello` folder, create the following Azure Function class file:

`HelloHandler.java`:

Java

```
package com.example.hello;

import com.microsoft.azure.functions.*;
import com.microsoft.azure.functions.annotation.AuthorizationLevel;
import com.microsoft.azure.functions.annotation.FunctionName;
import com.microsoft.azure.functions.annotation.HttpTrigger;
import com.example.model.*;
import org.springframework.beans.factory.annotation.Autowired;
import org.springframework.stereotype.Component;

import java.util.Optional;

@Component
public class HelloHandler {

    @Autowired
    private Hello hello;

    @FunctionName("hello")
    public HttpResponseMessage execute(
        @HttpTrigger(name = "request", methods = { HttpMethod.GET,
        HttpMethod.POST }, authLevel = AuthorizationLevel.ANONYMOUS)
        HttpRequestMessage<Optional<User>> request, ExecutionContext context) {
        User user = request.getBody()
            .filter(u -> u.getName() != null)
            .orElseGet(() -> new
User(request.getQueryParameters().getOrDefault("name", "world")));
    }
}
```

```
        context.getLogger().info("Greeting user name: " + user.getName());
        return request.createResponseBuilder(HttpStatus.OK)
            .body(hello.apply(user))
            .header("Content-Type", "application/json")
            .build();
    }
}
```

This Java class is an Azure Function, with the following interesting features:

- The class has the `@Component` annotation, so it's a Spring Bean.
- The name of the function, as defined by the `@FunctionName("hello")` annotation, is `hello`.
- The class implements a real Azure Function, so you can use the full Azure Functions API here.

Add unit tests

This step is optional but recommended to validate that the application works correctly.

Create a `src/test/java/com/example` folder and add the following JUnit tests:

HelloTest.java:

```
Java

package com.example;

import com.example.hello.Hello;
import com.example.model.Greeting;
import com.example.model.User;
import org.junit.jupiter.api.Test;

import static org.assertj.core.api.Assertions.assertThat;

public class HelloTest {

    @Test
    public void test() {
        Greeting result = new Hello().apply(new User("foo"));
        assertThat(result.getMessage()).isEqualTo("Hello, foo!\n");
    }
}
```

You can now test your Azure Function using Maven:

```
Bash
```

```
mvn clean test
```

Run the Function locally

Before you deploy your application to Azure Function, let's first test it locally.

First you need to package your application into a Jar file:

Bash

```
mvn package
```

Now that the application is packaged, you can run it using the `azure-functions` Maven plugin:

Bash

```
mvn azure-functions:run
```

The Azure Function should now be available on your localhost, using port 7071. You can test the function by sending it a POST request, with a `User` object in JSON format. For example, using cURL:

Bash

```
curl -X POST http://localhost:7071/api/hello -d "{\"name\":\"Azure\"}"
```

The Function should answer you with a `Greeting` object, still in JSON format:

Output

```
{
  "message": "Hello, Azure!\n"
}
```

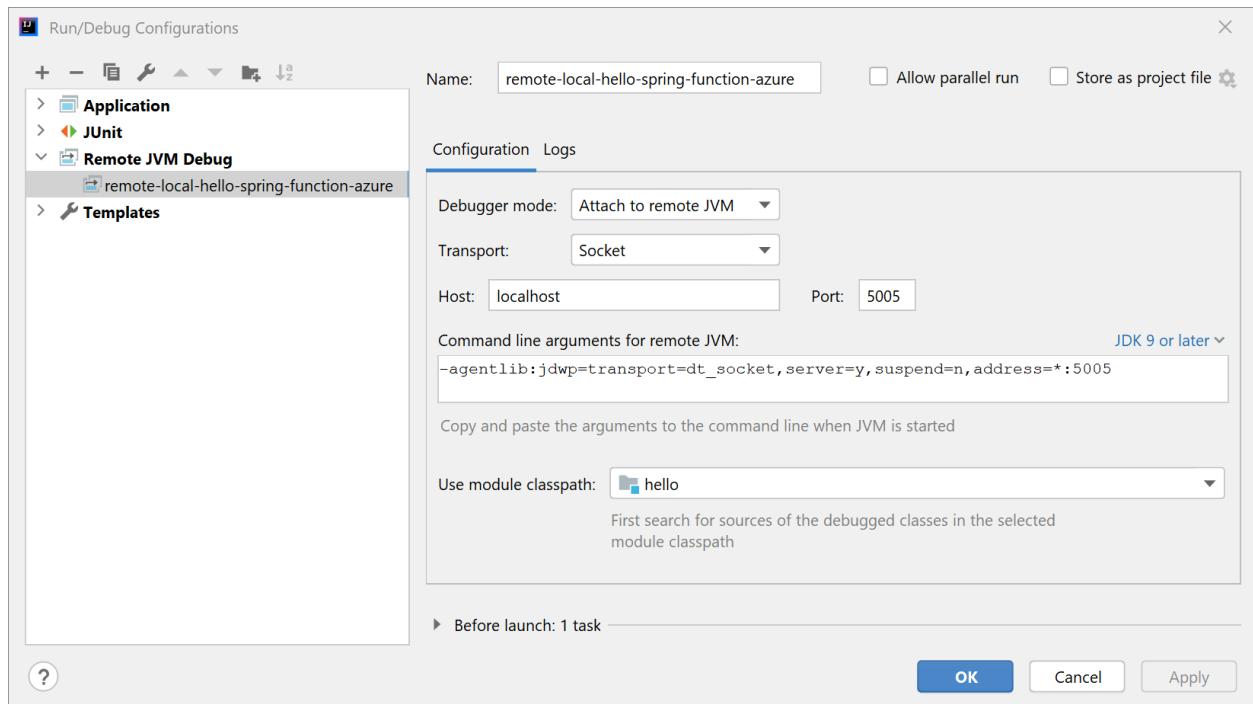

Here's a screenshot of the cURL request on the top of the screen, and the local Azure Function at the bottom:

Debug the Function locally

The following sections describe how to debug the function.

Debug using IntelliJ IDEA

Open the project in IntelliJ IDEA, then create a **Remote JVM Debug** run configuration to attach. For more information, see [Tutorial: Remote debug ↗](#).

Run the application with the following command:

```
Bash
mvn azure-functions:run -DenableDebug
```

When the application starts, you see the following output:

```
Output
Worker process started and initialized.
Listening for transport dt_socket at address: 5005
```

Start project debugging in IntelliJ IDEA. You see the following output:

```
Output
Connected to the target VM, address: 'localhost:5005', transport: 'socket'
```

Mark the breakpoints you want to debug. The IntelliJ IDEA will enter debugging mode after sending a request.

Debug using Visual Studio Code

Open the project in Visual Studio Code, then configure the following *launch.json* file content:

```
JSON
```

```
{  
    "version": "0.2.0",  
    "configurations": [  
        {  
            "type": "java",  
            "name": "Attach to Remote Program",  
            "request": "attach",  
            "hostName": "127.0.0.1",  
            "port": 5005  
        }  
    ]  
}
```

Run the application with the following command:

Bash

```
mvn azure-functions:run -DenableDebug
```

When the application starts, you see the following output:

Output

```
Worker process started and initialized.  
Listening for transport dt_socket at address: 5005
```

Start project debugging in Visual Studio Code, then mark the breakpoints you want to debug. Visual Studio Code will enter debugging mode after sending a request. For more information, see [Running and debugging Java](#).

Deploy the Function to Azure Functions

Now, you're going to publish the Azure Function to production. Remember that the `<functionAppName>`, `<functionAppRegion>`, and `<functionResourceGroup>` properties you've defined in your `pom.xml` file are used to configure your function.

ⓘ Note

The Maven plugin needs to authenticate with Azure. If you have Azure CLI installed, use `az login` before continuing. For more authentication options, see [Authentication](#) in the [azure-maven-plugins](#) repository.

Run Maven to deploy your function automatically:

Bash

```
mvn azure-functions:deploy
```

Now go to the [Azure portal](#) to find the `Function App` that has been created.

Select the function:

- In the function overview, note the function's URL.
- To check your running function, select **Log streaming** on the navigation menu.

Now, as you did in the previous section, use cURL to access the running function, as shown in the following example. Be sure to replace `your-function-name` by your real function name.

Bash

```
curl https://your-function-name.azurewebsites.net/api/hello -d ""  
{"name": "Azure"}
```

Like in the previous section, the Function should answer you with a `Greeting` object, still in JSON format:

Output

```
{  
  "message": "Hello, Azure!\n"  
}
```

Congratulations, you have a Spring Cloud Function running on Azure Functions! For more information and samples of Spring Cloud functions, see the following resources:

- [Spring cloud function blog](#)
- [Spring cloud function reference documents](#)
- [Spring cloud function samples](#)

Quickstart: Create a Java function in Azure using Visual Studio Code

Article • 07/18/2024

In this article, you use Visual Studio Code to create a Java function that responds to HTTP requests. After testing the code locally, you deploy it to the serverless environment of Azure Functions.

If Visual Studio Code isn't your preferred development tool, check out our similar tutorials for Java developers:

- [Gradle](#)
- [IntelliJ IDEA](#)
- [Maven](#)

Completing this quickstart incurs a small cost of a few USD cents or less in your Azure account.

Configure your environment

Before you get started, make sure you have the following requirements in place:

- An Azure account with an active subscription. [Create an account for free](#).
- The [Java Development Kit](#), version 8, 11, 17 or 21(Linux).
- [Apache Maven](#), version 3.0 or above.
- [Visual Studio Code](#) on one of the [supported platforms](#).
- The [Java extension pack](#)
- The [Azure Functions extension](#) for Visual Studio Code.

Install or update Core Tools

The Azure Functions extension for Visual Studio Code integrates with Azure Functions Core Tools so that you can run and debug your functions locally in Visual Studio Code using the Azure Functions runtime. Before getting started, it's a good idea to install Core Tools locally or update an existing installation to use the latest version.

In Visual Studio Code, select F1 to open the command palette, and then search for and run the command **Azure Functions: Install or Update Core Tools**.

This command tries to either start a package-based installation of the latest version of Core Tools or update an existing package-based installation. If you don't have npm or Homebrew installed on your local computer, you must instead [manually install or update Core Tools](#).

Create your local project

In this section, you use Visual Studio Code to create a local Azure Functions project in Java. Later in this article, you'll publish your function code to Azure.

1. In Visual Studio Code, press **F1** to open the command palette and search for and run the command **Azure Functions: Create New Project...**.
2. Choose the directory location for your project workspace and choose **Select**. You should either create a new folder or choose an empty folder for the project workspace. Don't choose a project folder that is already part of a workspace.
3. Provide the following information at the prompts:

[] [Expand table](#)

Prompt	Selection
Select a language	Choose <code>Java</code> .
Select a version of Java	Choose <code>Java 8</code> , <code>Java 11</code> , <code>Java 17</code> or <code>Java 21</code> , the Java version on which your functions run in Azure. Choose a Java version that you've verified locally.
Provide a group ID	Choose <code>com.function</code> .
Provide an artifact ID	Choose <code>myFunction</code> .
Provide a version	Choose <code>1.0-SNAPSHOT</code> .
Provide a package name	Choose <code>com.function</code> .
Provide an app name	Choose <code>myFunction-12345</code> .
Select a template for your project's first function	Choose <code>HTTP trigger</code> .
Select the build tool for Java project	Choose <code>Maven</code> .

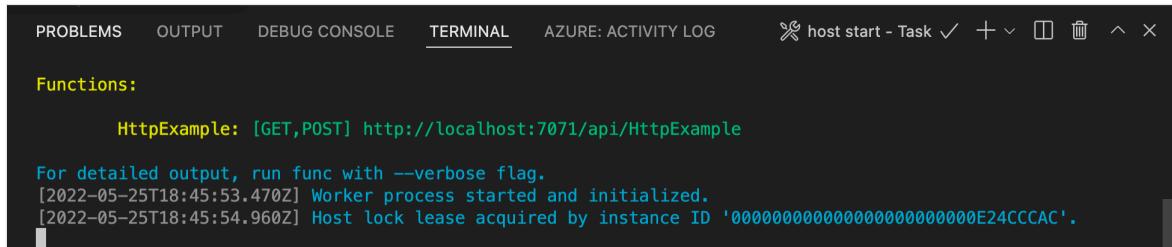

Prompt	Selection
Provide a function name	Enter <code>HttpExample</code> .
Authorization level	Choose <code>Anonymous</code> , which lets anyone call your function endpoint. For more information, see Authorization level .
Select how you would like to open your project	Choose <code>Open in current window</code> .

4. Visual Studio Code uses the provided information and generates an Azure Functions project with an HTTP trigger. You can view the local project files in the Explorer. For more information about the files that are created, see [Generated project files](#).

Run the function locally

Visual Studio Code integrates with [Azure Functions Core tools](#) to let you run this project on your local development computer before you publish to Azure.

- To start the function locally, press `F5` or the Run and Debug icon in the left-hand side Activity bar. The Terminal panel displays the Output from Core Tools. Your app starts in the Terminal panel. You can see the URL endpoint of your HTTP-triggered function running locally.

```

PROBLEMS OUTPUT DEBUG CONSOLE TERMINAL AZURE: ACTIVITY LOG
✖ host start - Task ✓ + ▾ ⌫ ⌄ ×

Functions:

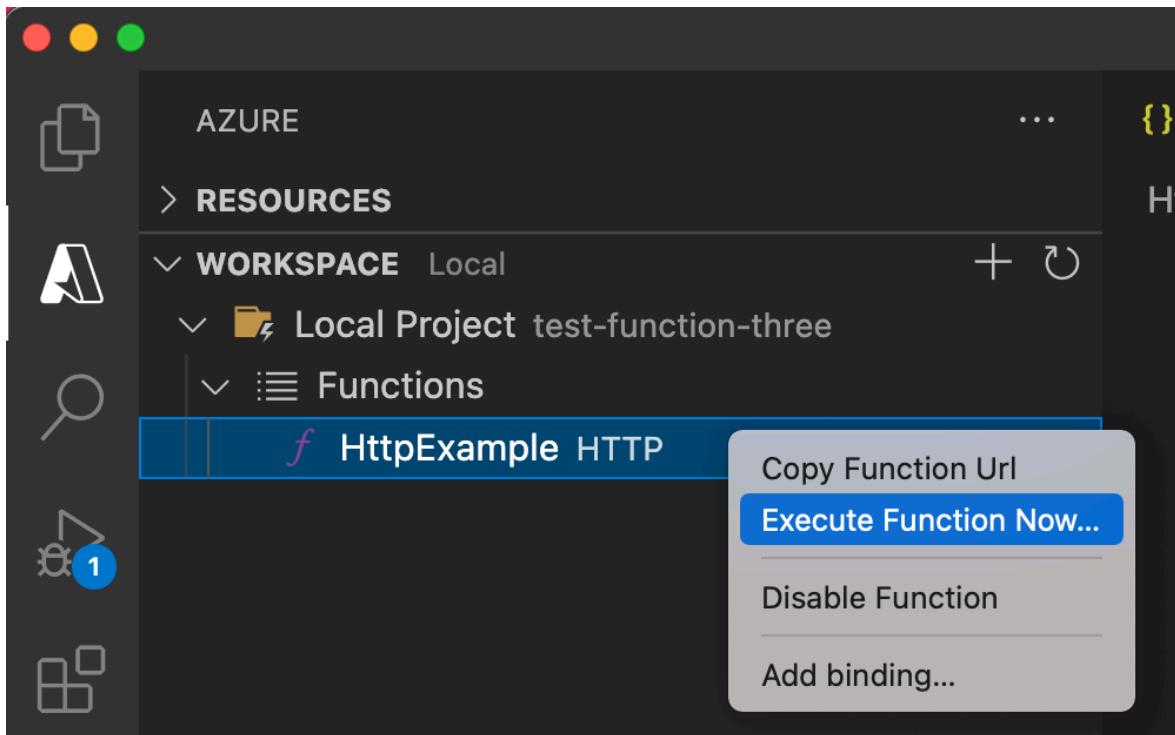

HttpExample: [GET,POST] http://localhost:7071/api/HttpExample

For detailed output, run func with --verbose flag.
[2022-05-25T18:45:53.470Z] Worker process started and initialized.
[2022-05-25T18:45:54.960Z] Host lock lease acquired by instance ID '000000000000000000000000E24CCCAC'.

```

If you have trouble running on Windows, make sure that the default terminal for Visual Studio Code isn't set to **WSL Bash**.

- With Core Tools still running in **Terminal**, choose the Azure icon in the activity bar. In the **Workspace** area, expand **Local Project > Functions**. Right-click (Windows) or `ctrl -` click (macOS) the new function and choose **Execute Function Now....**

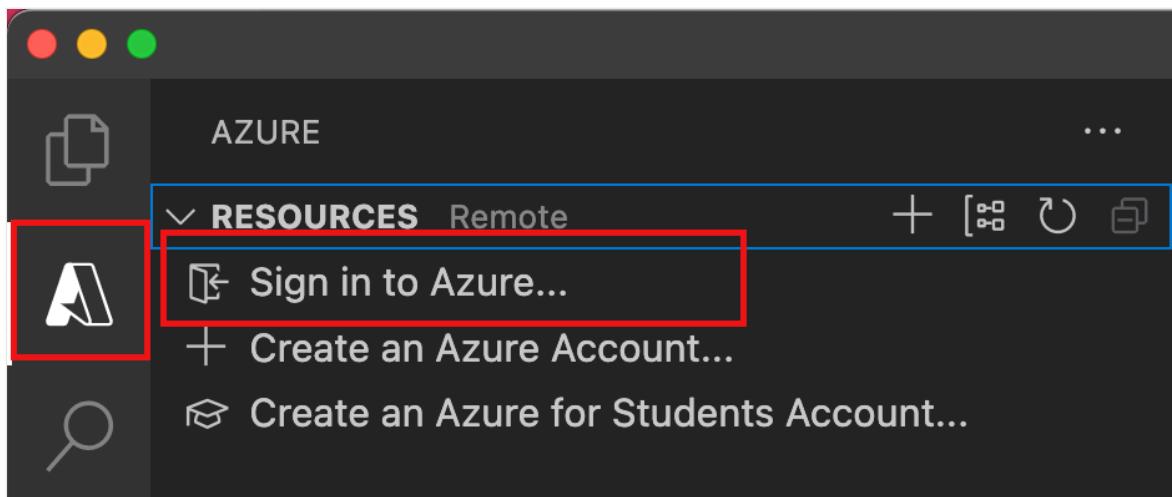

3. In **Enter request body** you see the request message body value of `{ "name": "Azure" }`. Press Enter to send this request message to your function.
4. When the function executes locally and returns a response, a notification is raised in Visual Studio Code. Information about the function execution is shown in **Terminal** panel.
5. With the **Terminal** panel focused, press `Ctrl + C` to stop Core Tools and disconnect the debugger.

After you've verified that the function runs correctly on your local computer, it's time to use Visual Studio Code to publish the project directly to Azure.

Sign in to Azure

Before you can create Azure resources or publish your app, you must sign in to Azure.

1. If you aren't already signed in, in the **Activity bar**, select the Azure icon. Then under **Resources**, select **Sign in to Azure**.

If you're already signed in and can see your existing subscriptions, go to the next section. If you don't yet have an Azure account, select **Create an Azure Account**. Students can select **Create an Azure for Students Account**.

2. When you are prompted in the browser, select your Azure account and sign in by using your Azure account credentials. If you create a new account, you can sign in after your account is created.
3. After you successfully sign in, you can close the new browser window. The subscriptions that belong to your Azure account are displayed in the side bar.

Create the function app in Azure

In this section, you create a function app and related resources in your Azure subscription. Many of the resource creation decisions are made for you based on default behaviors.

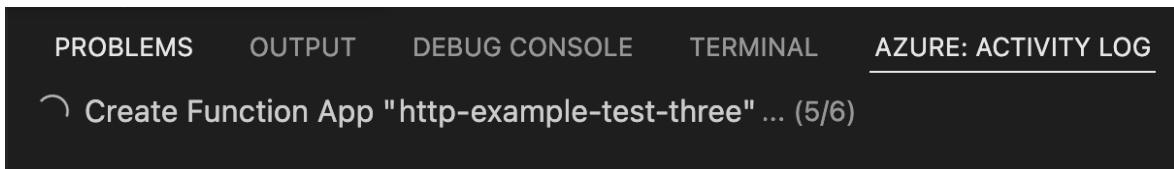

1. In Visual Studio Code, select F1 to open the command palette. At the prompt (>), enter and then select **Azure Functions: Create Function App in Azure**.
2. At the prompts, provide the following information:

[] [Expand table](#)

Prompt	Action
Select subscription	Select the Azure subscription to use. The prompt doesn't appear when you have only one subscription visible under Resources .
Enter a globally unique name for the function app	Enter a name that is valid in a URL path. The name you enter is validated to make sure that it's unique in Azure Functions.

Prompt	Action
Select a runtime stack	Select the language version you currently run locally.
Select a location for new resources	Select an Azure region. For better performance, select a region near you .

In the **Azure: Activity Log** panel, the Azure extension shows the status of individual resources as they're created in Azure.

3. When the function app is created, the following related resources are created in your Azure subscription. The resources are named based on the name you entered for your function app.

- A [resource group](#), which is a logical container for related resources.
- A standard [Azure Storage account](#), which maintains state and other information about your projects.
- A function app, which provides the environment for executing your function code. A function app lets you group functions as a logical unit for easier management, deployment, and sharing of resources within the same hosting plan.
- An Azure App Service plan, which defines the underlying host for your function app.
- An Application Insights instance that's connected to the function app, and which tracks the use of your functions in the app.

A notification is displayed after your function app is created and the deployment package is applied.

💡 Tip

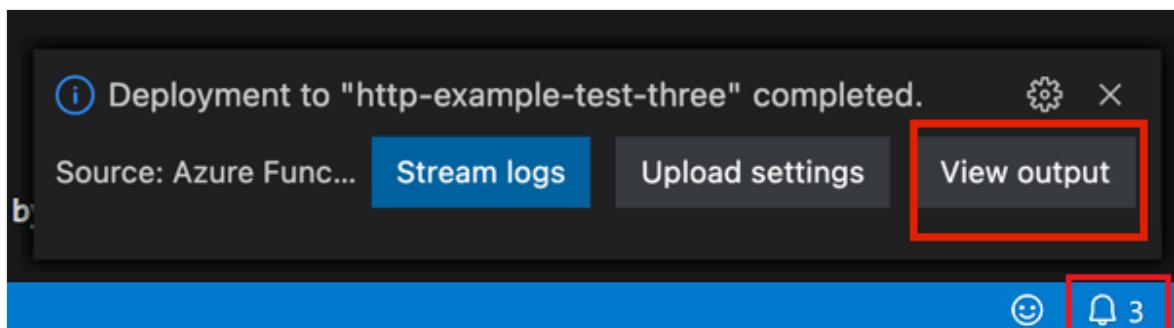

By default, the Azure resources required by your function app are created based on the name you enter for your function app. By default, the resources are created with the function app in the same, new resource group. If you want to customize the names of the associated resources or reuse existing resources, [publish the project with advanced create options](#).

Deploy the project to Azure

ⓘ Important

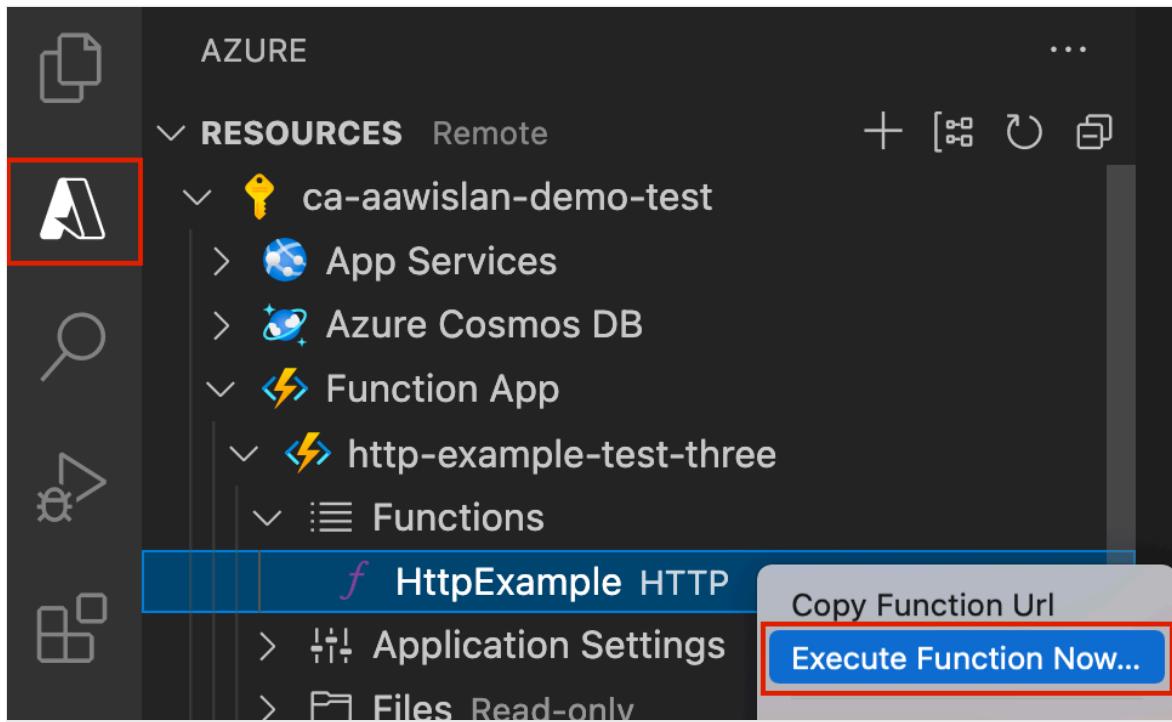

Deploying to an existing function app always overwrites the contents of that app in Azure.

1. In the command palette, enter and then select **Azure Functions: Deploy to Function App**.
2. Select the function app you just created. When prompted about overwriting previous deployments, select **Deploy** to deploy your function code to the new function app resource.
3. When deployment is completed, select **View Output** to view the creation and deployment results, including the Azure resources that you created. If you miss the notification, select the bell icon in the lower-right corner to see it again.

Run the function in Azure

1. Back in the **Resources** area in the side bar, expand your subscription, your new function app, and **Functions**. Right-click (Windows) or **Ctrl** - click (macOS) the `HttpExample` function and choose **Execute Function Now....**

2. In **Enter request body** you see the request message body value of `{ "name": "Azure" }`. Press Enter to send this request message to your function.
3. When the function executes in Azure and returns a response, a notification is raised in Visual Studio Code.

Clean up resources

When you continue to the [next step](#) and add an Azure Storage queue binding to your function, you'll need to keep all your resources in place to build on what you've already done.

Otherwise, you can use the following steps to delete the function app and its related resources to avoid incurring any further costs.

1. In Visual Studio Code, press `F1` to open the command palette. In the command palette, search for and select `Azure: Open in portal`.
2. Choose your function app and press `Enter`. The function app page opens in the Azure portal.
3. In the **Overview** tab, select the named link next to **Resource group**.

The screenshot shows the Azure portal's 'Overview' page for a resource group. The left sidebar lists various options: Activity log, Access control (IAM), Tags, Diagnose and solve problems, Security, Functions (selected), Functions, App keys, App files, and Proxies. The main area shows a card for 'Resource group (change) myResourceGroup'. The card includes fields for Status (Running), Location (Central US), Subscription (Visual Studio Enterprise), and Tags (with a link to 'Click here to add tags'). Below the card, there are navigation tabs: Metrics, Features (8), Notifications (0), and Quickstart.

4. On the **Resource group** page, review the list of included resources, and verify that they're the ones you want to delete.
5. Select **Delete resource group**, and follow the instructions.

Deletion may take a couple of minutes. When it's done, a notification appears for a few seconds. You can also select the bell icon at the top of the page to view the notification.

For more information about Functions costs, see [Estimating Consumption plan costs](#).

Next steps

You have used [Visual Studio Code](#) to create a function app with a simple HTTP-triggered function. In the next article, you expand that function by connecting to Azure Storage. To learn more about connecting to other Azure services, see [Add bindings to an existing function in Azure Functions](#).

[Connect to an Azure Storage queue](#)

Quickstart: Create and deploy functions to Azure Functions using the Azure Developer CLI

Article • 09/09/2024

In this Quickstart, you use Azure Developer command-line tools to create functions that respond to HTTP requests. After testing the code locally, you deploy it to a new serverless function app you create running in a Flex Consumption plan in Azure Functions.

The project source uses the Azure Developer CLI (azd) to simplify deploying your code to Azure. This deployment follows current best practices for secure and scalable Azure Functions deployments.

Important

The [Flex Consumption plan](#) is currently in preview.

By default, the Flex Consumption plan follows a *pay-for-what-you-use* billing model, which means to complete this quickstart incurs a small cost of a few USD cents or less in your Azure account.

Prerequisites

- An Azure account with an active subscription. [Create an account for free ↗](#).
- [Azure Developer CLI](#).
- [Azure Functions Core Tools](#).
- [Java 17 Developer Kit](#)
 - If you use another [supported version of Java](#), you must update the project's pom.xml file.
 - The `JAVA_HOME` environment variable must be set to the install location of the correct version of the JDK.
- [Apache Maven 3.8.x ↗](#)
- A [secure HTTP test tool](#) for sending requests with JSON payloads to your function endpoints. This article uses `curl`.

Initialize the project

You can use the `azd init` command to create a local Azure Functions code project from a template.

1. In your local terminal or command prompt, run this `azd init` command in an empty folder:

```
Console
```

```
azd init --template azure-functions-java-flex-consumption-azd -e flexquickstart-java
```

This command pulls the project files from the [template repository](#) and initializes the project in the current folder. The `-e` flag sets a name for the current environment. In `azd`, the environment is used to maintain a unique deployment context for your app, and you can define more than one. It's also used in the name of the resource group you create in Azure.

2. Run this command to navigate to the `http` app folder:

```
Console
```

```
cd http
```

3. Create a file named `local.settings.json` in the `http` folder that contains this JSON data:

```
JSON
```

```
{  
    "IsEncrypted": false,  
    "Values": {  
        "AzureWebJobsStorage": "UseDevelopmentStorage=true",  
        "FUNCTIONS_WORKER_RUNTIME": "java"  
    }  
}
```

This file is required when running locally.

Run in your local environment

1. Run this command from your app folder in a terminal or command prompt:

Console

```
mvn clean package  
mvn azure-functions:run
```

When the Functions host starts in your local project folder, it writes the URL endpoints of your HTTP triggered functions to the terminal output.

2. In your browser, navigate to the `httpget` endpoint, which should look like this URL:

<http://localhost:7071/api/httpget>

3. From a new terminal or command prompt window, run this `curl` command to send a POST request with a JSON payload to the `httppost` endpoint:

Console

```
curl -i http://localhost:7071/api/httppost -H "Content-Type: text/json"  
-d @testdata.json
```

This command reads JSON payload data from the `testdata.json` project file. You can find examples of both HTTP requests in the `test.http` project file.

4. When you're done, press **Ctrl+C** in the terminal window to stop the `func.exe` host process.

Review the code (optional)

You can review the code that defines the two HTTP trigger function endpoints:

httpget

Java

```
@FunctionName("httpget")  
public HttpResponseMessage run(  
    @HttpTrigger(  
        name = "req",  
        methods = {HttpMethod.GET},  
        authLevel = AuthorizationLevel.FUNCTION)  
    HttpRequestMessage<Optional<String>> request,  
    final ExecutionContext context) {  
    context.getLogger().info("Java HTTP trigger processed a request.");  
  
    // Parse query parameter
```

```
String name =  
Optional.ofNullable(request.getQueryParameters().get("name")).orElse("Wo  
rld");  
  
return request.createResponseBuilder(HttpStatus.OK).body("Hello, " +  
name).build();  
}
```

You can review the complete template project [here](#).

After you verify your functions locally, it's time to publish them to Azure.

Create Azure resources

This project is configured to use the `azd provision` command to create a function app in a Flex Consumption plan, along with other required Azure resources.

ⓘ Note

This project includes a set of Bicep files that `azd` uses to create a secure deployment to a Flex consumption plan that follows best practices.

The `azd up` and `azd deploy` commands aren't currently supported for Java apps.

1. In the root folder of the project, run this command to create the required Azure resources:

Console

```
azd provision
```

The root folder contains the `azure.yaml` definition file required by `azd`.

If you aren't already signed-in, you're asked to authenticate with your Azure account.

2. When prompted, provide these required deployment parameters:

[+] [Expand table](#)

Parameter	Description
<i>Azure subscription</i>	Subscription in which your resources are created.
<i>Azure location</i>	Azure region in which to create the resource group that contains the new Azure resources. Only regions that currently support the Flex Consumption plan are shown.

The `azd provision` command uses your response to these prompts with the Bicep configuration files to create and configure these required Azure resources:

- Flex Consumption plan and function app
- Azure Storage (required) and Application Insights (recommended)
- Access policies and roles for your account
- Service-to-service connections using managed identities (instead of stored connection strings)
- Virtual network to securely run both the function app and the other Azure resources

After the command completes successfully, you can deploy your project code to this new function app in Azure.

Deploy to Azure

You can use Core Tools to package your code and deploy it to Azure from the `target` output folder.

1. Navigate to the app folder equivalent in the `target` output folder:

```
Console
cd http/target/azure-functions/contoso-functions
```

This folder should have a `host.json` file, which indicates that it's the root of your compiled Java function app.

2. Run these commands to deploy your compiled Java code project to the new function app resource in Azure using Core Tools:

```
bash
```

```
Bash
```

```
APP_NAME=$(azd env get-value AZURE_FUNCTION_NAME)
func azure functionapp publish $APP_NAME
```

The `azd env get-value` command gets your function app name from the local environment, which is required for deployment using `func azure functionapp publish`. After publishing completes successfully, you see links to the HTTP trigger endpoints in Azure.

Invoke the function on Azure

You can now invoke your function endpoints in Azure by making HTTP requests to their URLs using your HTTP test tool or from the browser (for GET requests). When your functions run in Azure, access key authorization is enforced, and you must provide a function access key with your request.

You can use the Core Tools to obtain the URL endpoints of your functions running in Azure.

1. In your local terminal or command prompt, run these commands to get the URL endpoint values:

```
bash
```

```
Bash
```

```
SET APP_NAME=(azd env get-value AZURE_FUNCTION_NAME)
func azure functionapp list-functions $APP_NAME --show-keys
```

The `azd env get-value` command gets your function app name from the local environment. Using the `--show-keys` option with `func azure functionapp list-functions` means that the returned **Invoke URL:** value for each endpoint includes a function-level access key.

2. As before, use your HTTP test tool to validate these URLs in your function app running in Azure.

Clean up resources

When you're done working with your function app and related resources, you can use this command to delete the function app and its related resources from Azure and avoid incurring any further costs:

```
Console  
azd down --no-prompt
```

ⓘ Note

The `--no-prompt` option instructs `azd` to delete your resource group without a confirmation from you.

This command doesn't affect your local code project.

Quickstart: Create a JavaScript function in Azure using Visual Studio Code

Article • 07/18/2024

Use Visual Studio Code to create a JavaScript function that responds to HTTP requests. Test the code locally, then deploy it to the serverless environment of Azure Functions.

ⓘ Important

The content of this article changes based on your choice of the Node.js programming model in the selector at the top of the page. The v4 model is generally available and is designed to have a more flexible and intuitive experience for JavaScript and TypeScript developers. Learn more about the differences between v3 and v4 in the [migration guide](#).

Completion of this quickstart incurs a small cost of a few USD cents or less in your Azure account.

There's also a [CLI-based version](#) of this article.

Configure your environment

Before you get started, make sure you have the following requirements in place:

- An Azure account with an active subscription. [Create an account for free](#).
- [Node.js 18.x](#) or above. Use the `node --version` command to check your version.
- [Visual Studio Code](#) on one of the [supported platforms](#).
- The [Azure Functions extension v1.10.4](#) or above for Visual Studio Code. This extension installs [Azure Functions Core Tools](#) for you the first time you locally run your functions. Node.js v4 requires version 4.0.5382, or a later version of Core Tools.

Install or update Core Tools

The Azure Functions extension for Visual Studio Code integrates with Azure Functions Core Tools so that you can run and debug your functions locally in Visual Studio Code

using the Azure Functions runtime. Before getting started, it's a good idea to install Core Tools locally or update an existing installation to use the latest version.

In Visual Studio Code, select F1 to open the command palette, and then search for and run the command **Azure Functions: Install or Update Core Tools**.

This command tries to either start a package-based installation of the latest version of Core Tools or update an existing package-based installation. If you don't have npm or Homebrew installed on your local computer, you must instead [manually install or update Core Tools](#).

Create your local project

In this section, you use Visual Studio Code to create a local Azure Functions project in JavaScript. Later in this article, you publish your function code to Azure.

1. In Visual Studio Code, press **F1** to open the command palette and search for and run the command **Azure Functions: Create New Project....**
2. Choose the directory location for your project workspace and choose **Select**. You should either create a new folder or choose an empty folder for the project workspace. Don't choose a project folder that is already part of a workspace.
3. Provide the following information at the prompts:

[+] Expand table

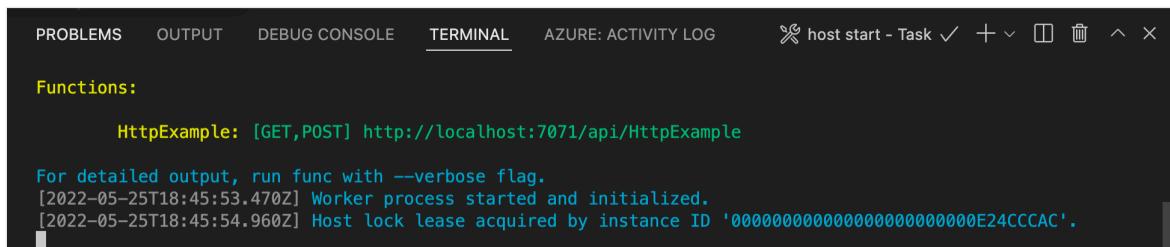

Prompt	Selection
Select a language for your function project	Choose JavaScript .
Select a JavaScript programming model	Choose Model V4
Select a template for your project's first function	Choose HTTP trigger .
Provide a function name	Type HttpExample .
Select how you would like to open your project	Choose Open in current window

Using this information, Visual Studio Code generates an Azure Functions project with an HTTP trigger. You can view the local project files in the Explorer. To learn more about files that are created, see [Azure Functions JavaScript developer guide](#).

Run the function locally

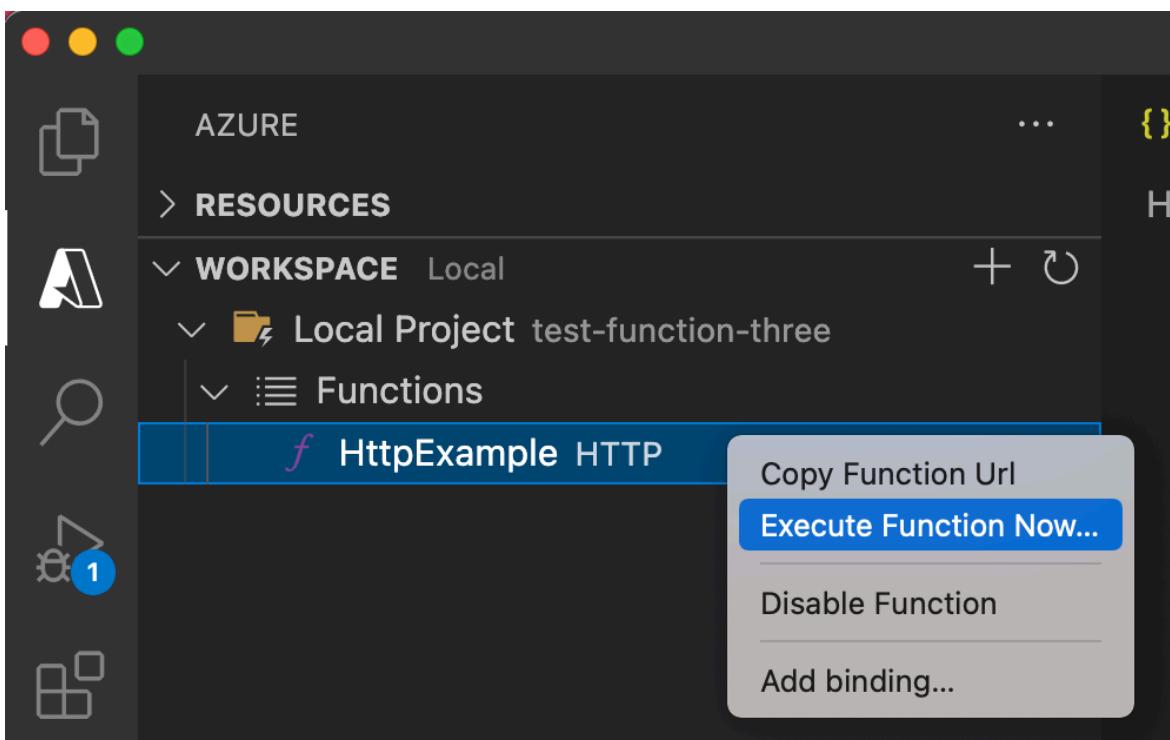

Visual Studio Code integrates with [Azure Functions Core tools](#) to let you run this project on your local development computer before you publish to Azure.

1. To start the function locally, press **F5** or the **Run and Debug** icon in the left-hand side Activity bar. The **Terminal** panel displays the Output from Core Tools. Your app starts in the **Terminal** panel. You can see the URL endpoint of your HTTP-triggered function running locally.

If you have trouble running on Windows, make sure that the default terminal for Visual Studio Code isn't set to **WSL Bash**.

2. With Core Tools still running in **Terminal**, choose the Azure icon in the activity bar. In the **Workspace** area, expand **Local Project > Functions**. Right-click (Windows) or **Ctrl + click** (macOS) the new function and choose **Execute Function Now...**

3. In **Enter request body** you see the request message body value of `{ "name": "Azure" }`. Press Enter to send this request message to your function.
 4. When the function executes locally and returns a response, a notification is raised in Visual Studio Code. Information about the function execution is shown in **Terminal** panel.

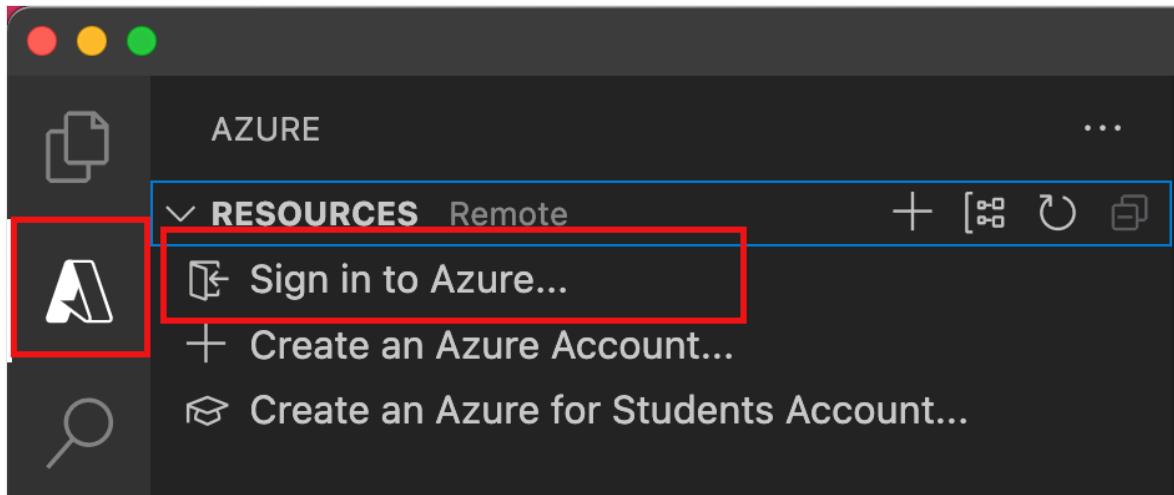

- With the **Terminal** panel focused, press `Ctrl + C` to stop Core Tools and disconnect the debugger.

After you've verified that the function runs correctly on your local computer, it's time to use Visual Studio Code to publish the project directly to Azure.

Sign in to Azure

Before you can create Azure resources or publish your app, you must sign in to Azure.

- If you aren't already signed in, in the **Activity bar**, select the Azure icon. Then under **Resources**, select **Sign in to Azure**.

If you're already signed in and can see your existing subscriptions, go to the next section. If you don't yet have an Azure account, select **Create an Azure Account**. Students can select **Create an Azure for Students Account**.

- When you are prompted in the browser, select your Azure account and sign in by using your Azure account credentials. If you create a new account, you can sign in after your account is created.
- After you successfully sign in, you can close the new browser window. The subscriptions that belong to your Azure account are displayed in the side bar.

Create the function app in Azure

In this section, you create a function app and related resources in your Azure subscription. Many of the resource creation decisions are made for you based on default behaviors.

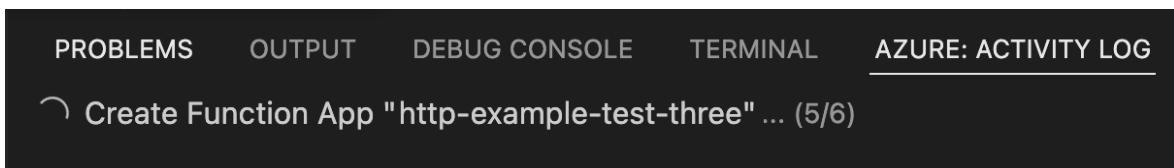

1. In Visual Studio Code, select F1 to open the command palette. At the prompt (>), enter and then select **Azure Functions: Create Function App in Azure**.

2. At the prompts, provide the following information:

[+] [Expand table](#)

Prompt	Action
Select subscription	Select the Azure subscription to use. The prompt doesn't appear when you have only one subscription visible under Resources .
Enter a globally unique name for the function app	Enter a name that is valid in a URL path. The name you enter is validated to make sure that it's unique in Azure Functions.
Select a runtime stack	Select the language version you currently run locally.
Select a location for new resources	Select an Azure region. For better performance, select a region ↗ near you.

In the **Azure: Activity Log** panel, the Azure extension shows the status of individual resources as they're created in Azure.

3. When the function app is created, the following related resources are created in your Azure subscription. The resources are named based on the name you entered for your function app.

- A [resource group](#), which is a logical container for related resources.
- A standard [Azure Storage account](#), which maintains state and other information about your projects.
- A function app, which provides the environment for executing your function code. A function app lets you group functions as a logical unit for easier management, deployment, and sharing of resources within the same hosting plan.
- An Azure App Service plan, which defines the underlying host for your function app.
- An Application Insights instance that's connected to the function app, and which tracks the use of your functions in the app.

A notification is displayed after your function app is created and the deployment package is applied.

💡 Tip

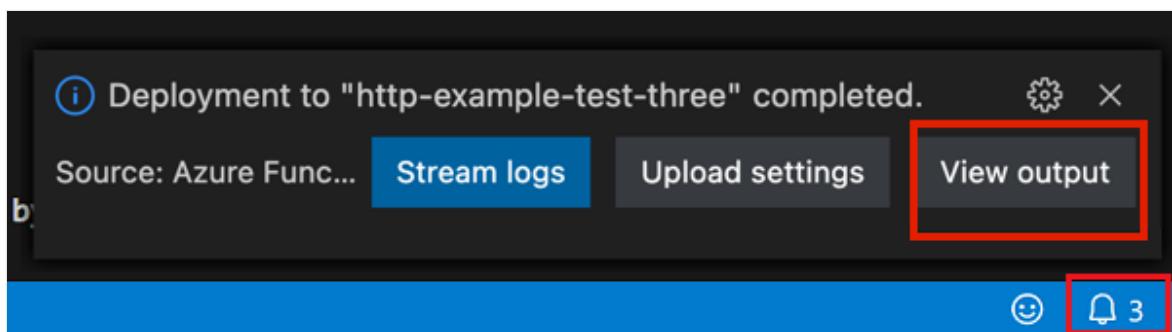

By default, the Azure resources required by your function app are created based on the name you enter for your function app. By default, the resources are created with the function app in the same, new resource group. If you want to customize the names of the associated resources or reuse existing resources, [publish the project with advanced create options](#).

Deploy the project to Azure

ⓘ Important

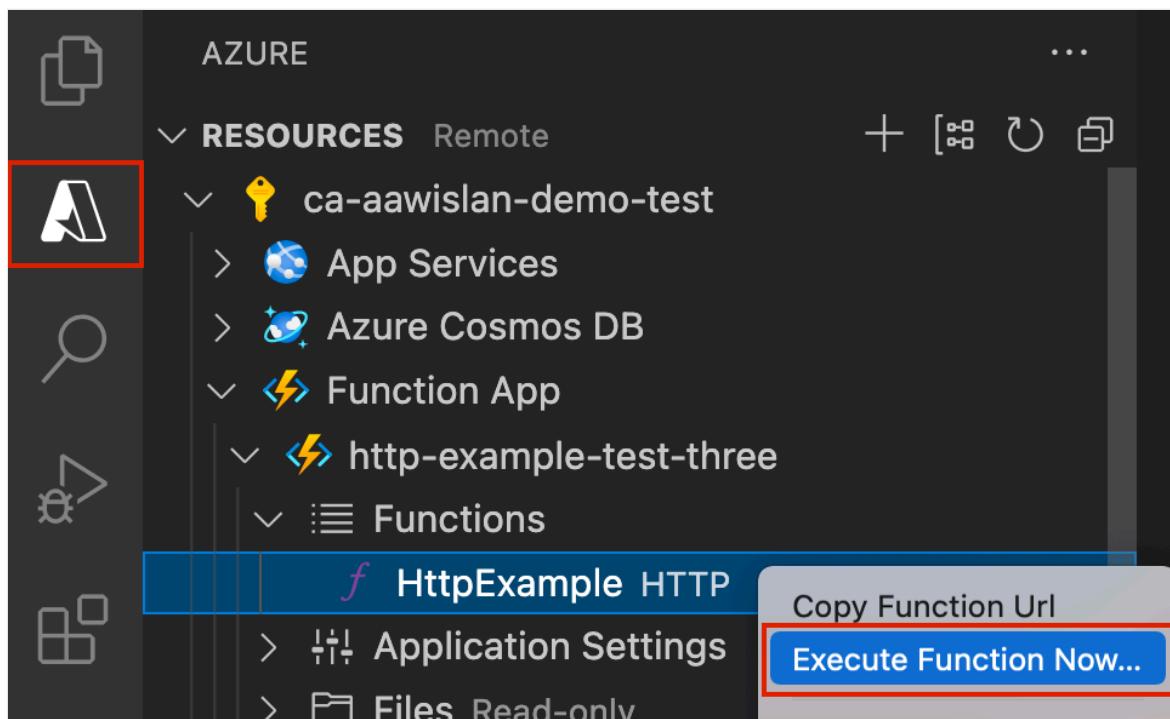

Deploying to an existing function app always overwrites the contents of that app in Azure.

1. In the command palette, enter and then select **Azure Functions: Deploy to Function App**.
2. Select the function app you just created. When prompted about overwriting previous deployments, select **Deploy** to deploy your function code to the new function app resource.
3. When deployment is completed, select **View Output** to view the creation and deployment results, including the Azure resources that you created. If you miss the notification, select the bell icon in the lower-right corner to see it again.

Run the function in Azure

1. Back in the **Resources** area in the side bar, expand your subscription, your new function app, and **Functions**. Right-click (Windows) or **Ctrl - click** (macOS) the `HttpExample` function and choose **Execute Function Now....**

2. In **Enter request body** you see the request message body value of `{ "name": "Azure" }`. Press Enter to send this request message to your function.
3. When the function executes in Azure and returns a response, a notification is raised in Visual Studio Code.

Troubleshooting

Use the following table to resolve the most common issues encountered when using this quickstart.

[] [Expand table](#)

Problem	Solution
Can't create a local function project?	Make sure you have the Azure Functions extension installed.
Can't run the function locally?	Make sure you have the latest version of Azure Functions Core Tools installed . When running on Windows, make sure that the default terminal shell for Visual Studio Code isn't set to WSL Bash.

Problem	Solution
Can't deploy function to Azure?	Review the Output for error information. The bell icon in the lower right corner is another way to view the output. Did you publish to an existing function app? That action overwrites the content of that app in Azure.
Couldn't run the cloud-based Function app?	Remember to use the query string to send in parameters.

Clean up resources

When you continue to the [next step](#) and add an Azure Storage queue binding to your function, you'll need to keep all your resources in place to build on what you've already done.

Otherwise, you can use the following steps to delete the function app and its related resources to avoid incurring any further costs.

1. In Visual Studio Code, select the Azure icon to open the Azure explorer.
2. In the Resource Groups section, find your resource group.
3. Right-click the resource group and select **Delete**.

To learn more about Functions costs, see [Estimating Consumption plan costs](#).

Next steps

You have used [Visual Studio Code](#) to create a function app with a simple HTTP-triggered function.

[Learn more about JavaScript functions](#)

Quickstart: Create a JavaScript function in Azure from the command line

Article • 02/26/2024

In this article, you use command-line tools to create a JavaScript function that responds to HTTP requests. After testing the code locally, you deploy it to the serverless environment of Azure Functions.

ⓘ Important

The content of this article changes based on your choice of the Node.js programming model in the selector at the top of the page. The v4 model is generally available and is designed to have a more flexible and intuitive experience for JavaScript and TypeScript developers. Learn more about the differences between v3 and v4 in the [migration guide](#).

Completion of this quickstart incurs a small cost of a few USD cents or less in your Azure account.

There's also a [Visual Studio Code-based version](#) of this article.

Configure your local environment

Before you begin, you must have the following prerequisites:

- An Azure account with an active subscription. [Create an account for free](#).
- One of the following tools for creating Azure resources:
 - [Azure CLI](#) version 2.4 or later.
 - The Azure [Az PowerShell module](#) version 5.9.0 or later.
- [Node.js](#) version 18 or above.

Install the Azure Functions Core Tools

The recommended way to install Core Tools depends on the operating system of your local development computer.

The following steps use a Windows installer (MSI) to install Core Tools v4.x. For more information about other package-based installers, see the [Core Tools readme](#).

Download and run the Core Tools installer, based on your version of Windows:

- [v4.x - Windows 64-bit](#) (Recommended. Visual Studio Code debugging requires 64-bit.)
- [v4.x - Windows 32-bit](#)

If you previously used Windows installer (MSI) to install Core Tools on Windows, you should uninstall the old version from Add Remove Programs before installing the latest version.

- Make sure you install version v4.0.5382 of the Core Tools, or a later version.

Create a local function project

In Azure Functions, a function project is a container for one or more individual functions that each responds to a specific trigger. All functions in a project share the same local and hosting configurations. In this section, you create a function project that contains a single function.

1. In a suitable folder, run the `func init` command, as follows, to create a JavaScript Node.js v4 project in the current folder:

```
Console  
func init --javascript
```

This folder now contains various files for the project, including configurations files named `local.settings.json` and `host.json`. Because `local.settings.json` can contain secrets downloaded from Azure, the file is excluded from source control by default in the `.gitignore` file. Required npm packages are also installed in `node_modules`.

1. Add a function to your project by using the following command, where the `--name` argument is the unique name of your function (`HttpExample`) and the `--template` argument specifies the function's trigger (HTTP).

```
Console
```

```
func new --name HttpExample --template "HTTP trigger" --authlevel  
"anonymous"

[`func new`](functions-core-tools-reference.md#func-new) creates a file  
named *HttpExample.js* in the *src/functions* directory, which contains  
your function's code.
```

2. Add Azure Storage connection information in *local.settings.json*.

JSON

```
{  
  "Values": {  
    "AzureWebJobsStorage": "<Azure Storage connection  
information>",  
    "FUNCTIONS_WORKER_RUNTIME": "node"  
  }  
}
```

3. (Optional) If you want to learn more about a particular function, say HTTP trigger, you can run the following command:

Console

```
func help httptrigger
```

Run the function locally

1. Run your function by starting the local Azure Functions runtime host from the *LocalFunctionProj* folder.

Console

```
func start
```

Toward the end of the output, the following lines must appear:

```
Azure Functions Core Tools
Core Tools Version:    4.0.5049 Commit hash: N/A  (64-bit)
Function Runtime Version: 4.15.2.20177

[2023-03-17T03:27:12.372Z] Worker process started and initialized.

Functions:

    HttpExample: [GET,POST] http://localhost:7071/api/HttpExample
```

ⓘ Note

If `HttpExample` doesn't appear as shown above, you likely started the host from outside the root folder of the project. In that case, use `Ctrl+C` to stop the host, go to the project's root folder, and run the previous command again.

2. Copy the URL of your HTTP function from this output to a browser and append the query string `?name=<YOUR_NAME>`, making the full URL like `http://localhost:7071/api/HttpExample?name=Functions`. The browser should display a response message that echoes back your query string value. The terminal in which you started your project also shows log output as you make requests.
3. When you're done, press `Ctrl + C` and type `y` to stop the functions host.

Create supporting Azure resources for your function

Before you can deploy your function code to Azure, you need to create three resources:

- A [resource group](#), which is a logical container for related resources.
- A [Storage account](#), which is used to maintain state and other information about your functions.
- A function app, which provides the environment for executing your function code. A function app maps to your local function project and lets you group functions as a logical unit for easier management, deployment, and sharing of resources.

Use the following commands to create these items. Both Azure CLI and PowerShell are supported.

1. If you haven't done so already, sign in to Azure:

Azure CLI

Azure CLI

```
az login
```

The `az login` command signs you into your Azure account.

2. Create a resource group named `AzureFunctionsQuickstart-rg` in your chosen region:

Azure CLI

Azure CLI

```
az group create --name AzureFunctionsQuickstart-rg --location  
<REGION>
```

The `az group create` command creates a resource group. In the above command, replace `<REGION>` with a region near you, using an available region code returned from the `az account list-locations` command.

3. Create a general-purpose storage account in your resource group and region:

Azure CLI

Azure CLI

```
az storage account create --name <STORAGE_NAME> --location <REGION>  
--resource-group AzureFunctionsQuickstart-rg --sku Standard_LRS --  
allow-blob-public-access false
```

The `az storage account create` command creates the storage account.

In the previous example, replace `<STORAGE_NAME>` with a name that is appropriate to you and unique in Azure Storage. Names must contain three to 24 characters numbers and lowercase letters only. `Standard_LRS` specifies a general-purpose account, which is [supported by Functions](#).

ⓘ Important

The storage account is used to store important app data, sometimes including the application code itself. You should limit access from other apps and users to the

storage account.

4. Create the function app in Azure:

```
Azure CLI
```

```
Azure CLI
```

```
az functionapp create --resource-group AzureFunctionsQuickstart-rg  
--consumption-plan-location <REGION> --runtime node --runtime-  
version 18 --functions-version 4 --name <APP_NAME> --storage-  
account <STORAGE_NAME>
```

The `az functionapp create` command creates the function app in Azure. It's recommended that you use the latest LTS version of Node.js, which is currently 18. You can specify the version by setting `--runtime-version` to `18`.

In the previous example, replace `<STORAGE_NAME>` with the name of the account you used in the previous step, and replace `<APP_NAME>` with a globally unique name appropriate to you. The `<APP_NAME>` is also the default DNS domain for the function app.

This command creates a function app running in your specified language runtime under the [Azure Functions Consumption Plan](#), which is free for the amount of usage you incur here. The command also creates an associated Azure Application Insights instance in the same resource group, with which you can monitor your function app and view logs. For more information, see [Monitor Azure Functions](#). The instance incurs no costs until you activate it.

Deploy the function project to Azure

After you've successfully created your function app in Azure, you're now ready to deploy your local functions project by using the `func azure functionapp publish` command.

In the following example, replace `<APP_NAME>` with the name of your app.

```
Console
```

```
func azure functionapp publish <APP_NAME>
```

The publish command shows results similar to the following output (truncated for simplicity):

```
...
Getting site publishing info...
Creating archive for current directory...
Performing remote build for functions project.

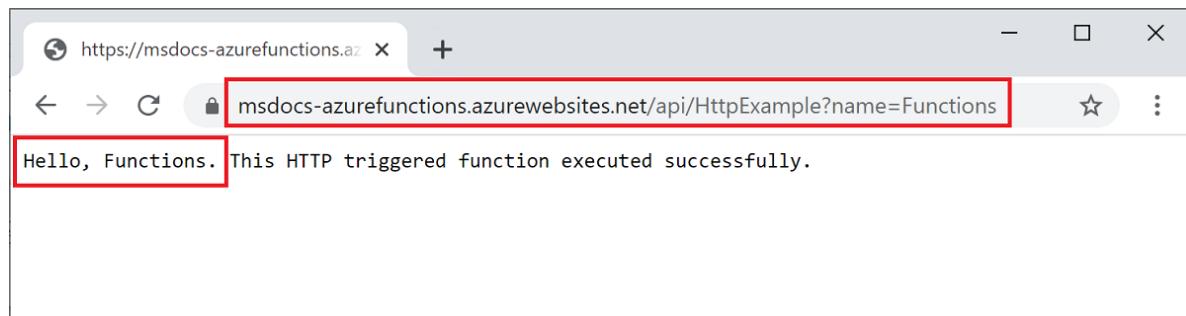

...
Deployment successful.
Remote build succeeded!
Syncing triggers...
Functions in msdocs-azurefunctions-qs:
  HttpExample - [httpTrigger]
    Invoke url: https://msdocs-azurefunctions-qs.azurewebsites.net/api/httpexample
```

Invoke the function on Azure

Because your function uses an HTTP trigger, you invoke it by making an HTTP request to its URL in the browser or with a tool like curl.

Browser

Copy the complete **Invoke URL** shown in the output of the publish command into a browser address bar, appending the query parameter `?name=Functions`. The browser should display similar output as when you ran the function locally.

Run the following command to view near real-time streaming logs:

Console

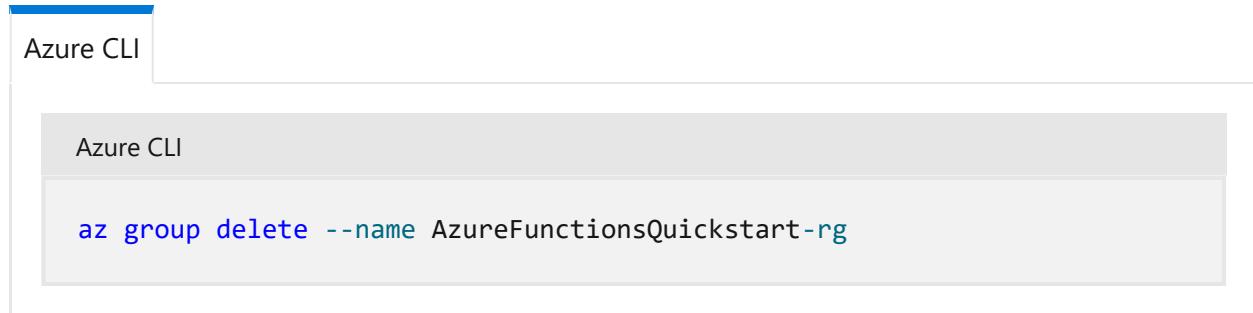

```
func azure functionapp logstream <APP_NAME>
```

In a separate terminal window or in the browser, call the remote function again. A verbose log of the function execution in Azure is shown in the terminal.

Clean up resources

If you continue to the [next step](#) and add an Azure Storage queue output binding, keep all your resources in place as you'll build on what you've already done.

Otherwise, use the following command to delete the resource group and all its contained resources to avoid incurring further costs.

Azure CLI

```
az group delete --name AzureFunctionsQuickstart-rg
```

Next steps

[Learn more about JavaScript functions](#)

Quickstart: Create and deploy functions to Azure Functions using the Azure Developer CLI

Article • 09/09/2024

In this Quickstart, you use Azure Developer command-line tools to create functions that respond to HTTP requests. After testing the code locally, you deploy it to a new serverless function app you create running in a Flex Consumption plan in Azure Functions.

The project source uses the Azure Developer CLI (azd) to simplify deploying your code to Azure. This deployment follows current best practices for secure and scalable Azure Functions deployments.

ⓘ Important

The [Flex Consumption plan](#) is currently in preview.

By default, the Flex Consumption plan follows a *pay-for-what-you-use* billing model, which means to complete this quickstart incurs a small cost of a few USD cents or less in your Azure account.

Prerequisites

- An Azure account with an active subscription. [Create an account for free ↗](#).
- [Azure Developer CLI](#).
- [Azure Functions Core Tools](#).
- [Node.js 20 ↗](#)
- A [secure HTTP test tool](#) for sending requests with JSON payloads to your function endpoints. This article uses `curl`.

Initialize the project

You can use the `azd init` command to create a local Azure Functions code project from a template.

1. In your local terminal or command prompt, run this `azd init` command in an empty folder:

```
Console
```

```
azd init --template functions-quickstart-javascript-azd -e flexquickstart-js
```

This command pulls the project files from the [template repository](#) and initializes the project in the root folder. The `-e` flag sets a name for the current environment. In `azd`, the environment is used to maintain a unique deployment context for your app, and you can define more than one. It's also used in the name of the resource group you create in Azure.

2. Create a file named `local.settings.json` in the root folder that contains this JSON data:

```
JSON
```

```
{  
    "IsEncrypted": false,  
    "Values": {  
        "AzureWebJobsStorage": "UseDevelopmentStorage=true",  
        "FUNCTIONS_WORKER_RUNTIME": "node"  
    }  
}
```

This file is required when running locally.

Run in your local environment

1. Run this command from your app folder in a terminal or command prompt:

```
Console
```

```
func start
```

When the Functions host starts in your local project folder, it writes the URL endpoints of your HTTP triggered functions to the terminal output.

2. In your browser, navigate to the `httpget` endpoint, which should look like this URL:

<http://localhost:7071/api/httpget>

3. From a new terminal or command prompt window, run this `curl` command to send a POST request with a JSON payload to the `httppost` endpoint:

```
Console
```

```
curl -i http://localhost:7071/api/httppost -H "Content-Type: text/json"  
-d @testdata.json
```

This command reads JSON payload data from the `testdata.json` project file. You can find examples of both HTTP requests in the `test.http` project file.

4. When you're done, press `Ctrl+C` in the terminal window to stop the `func.exe` host process.

Review the code (optional)

You can review the code that defines the two HTTP trigger function endpoints:

```
httpget
```

```
JavaScript
```

```
const { app } = require('@azure/functions');

app.http('httpGetFunction', {
    methods: ['GET'],
    authLevel: 'function',
    handler: async (request, context) => {
        context.log(`Http function processed request for url
        "${request.url}"`);

        const name = request.query.get('name') || await request.text()
        || 'world';

        return { body: `Hello, ${name}!` };
    }
});
```

You can review the complete template project [here ↗](#).

After you verify your functions locally, it's time to publish them to Azure.

Deploy to Azure

This project is configured to use the `azd up` command to deploy this project to a new function app in a Flex Consumption plan in Azure.

💡 Tip

This project includes a set of Bicep files that `azd` uses to create a secure deployment to a Flex consumption plan that follows best practices.

1. Run this command to have `azd` create the required Azure resources in Azure and deploy your code project to the new function app:

Console

```
azd up
```

The root folder contains the `azure.yaml` definition file required by `azd`.

If you aren't already signed-in, you're asked to authenticate with your Azure account.

2. When prompted, provide these required deployment parameters:

[\[+\] Expand table](#)

Parameter	Description
<code>Azure subscription</code>	Subscription in which your resources are created.
<code>Azure location</code>	Azure region in which to create the resource group that contains the new Azure resources. Only regions that currently support the Flex Consumption plan are shown.

The `azd up` command uses your response to these prompts with the Bicep configuration files to complete these deployment tasks:

- Create and configure these required Azure resources (equivalent to `azd provision`):
 - Flex Consumption plan and function app
 - Azure Storage (required) and Application Insights (recommended)
 - Access policies and roles for your account
 - Service-to-service connections using managed identities (instead of stored connection strings)

- Virtual network to securely run both the function app and the other Azure resources
- Package and deploy your code to the deployment container (equivalent to `azd deploy`). The app is then started and runs in the deployed package.

After the command completes successfully, you see links to the resources you created.

Invoke the function on Azure

You can now invoke your function endpoints in Azure by making HTTP requests to their URLs using your HTTP test tool or from the browser (for GET requests). When your functions run in Azure, access key authorization is enforced, and you must provide a function access key with your request.

You can use the Core Tools to obtain the URL endpoints of your functions running in Azure.

1. In your local terminal or command prompt, run these commands to get the URL endpoint values:

```
bash
Bash
SET APP_NAME=(azd env get-value AZURE_FUNCTION_NAME)
func azure functionapp list-functions $APP_NAME --show-keys
```

The `azd env get-value` command gets your function app name from the local environment. Using the `--show-keys` option with `func azure functionapp list-functions` means that the returned **Invoke URL:** value for each endpoint includes a function-level access key.

2. As before, use your HTTP test tool to validate these URLs in your function app running in Azure.

Redeploy your code

You can run the `azd up` command as many times as you need to both provision your Azure resources and deploy code updates to your function app.

ⓘ Note

Deployed code files are always overwritten by the latest deployment package.

Your initial responses to `azd` prompts and any environment variables generated by `azd` are stored locally in your named environment. Use the `azd env get-values` command to review all of the variables in your environment that were used when creating Azure resources.

Clean up resources

When you're done working with your function app and related resources, you can use this command to delete the function app and its related resources from Azure and avoid incurring any further costs:

Console

```
azd down --no-prompt
```

ⓘ Note

The `--no-prompt` option instructs `azd` to delete your resource group without a confirmation from you.

This command doesn't affect your local code project.

Quickstart: Create a PowerShell function in Azure using Visual Studio Code

Article • 07/18/2024

In this article, you use Visual Studio Code to create a PowerShell function that responds to HTTP requests. After testing the code locally, you deploy it to the serverless environment of Azure Functions.

Completing this quickstart incurs a small cost of a few USD cents or less in your Azure account.

There's also a [CLI-based version](#) of this article.

Configure your environment

Before you get started, make sure you have the following requirements in place:

- An Azure account with an active subscription. [Create an account for free](#).
- [PowerShell 7.2](#)
- [.NET 6.0 runtime](#)
- [Visual Studio Code](#) on one of the [supported platforms](#).
- The [PowerShell extension for Visual Studio Code](#).
- The [Azure Functions extension](#) for Visual Studio Code.

Install or update Core Tools

The Azure Functions extension for Visual Studio Code integrates with Azure Functions Core Tools so that you can run and debug your functions locally in Visual Studio Code using the Azure Functions runtime. Before getting started, it's a good idea to install Core Tools locally or update an existing installation to use the latest version.

In Visual Studio Code, select F1 to open the command palette, and then search for and run the command **Azure Functions: Install or Update Core Tools**.

This command tries to either start a package-based installation of the latest version of Core Tools or update an existing package-based installation. If you don't have npm or

If Homebrew installed on your local computer, you must instead [manually install or update Core Tools](#).

Create your local project

In this section, you use Visual Studio Code to create a local Azure Functions project in PowerShell. Later in this article, you'll publish your function code to Azure.

1. In Visual Studio Code, press `F1` to open the command palette and search for and run the command `Azure Functions: Create New Project...`.
2. Choose the directory location for your project workspace and choose **Select**. You should either create a new folder or choose an empty folder for the project workspace. Don't choose a project folder that is already part of a workspace.
3. Provide the following information at the prompts:

[+] [Expand table](#)

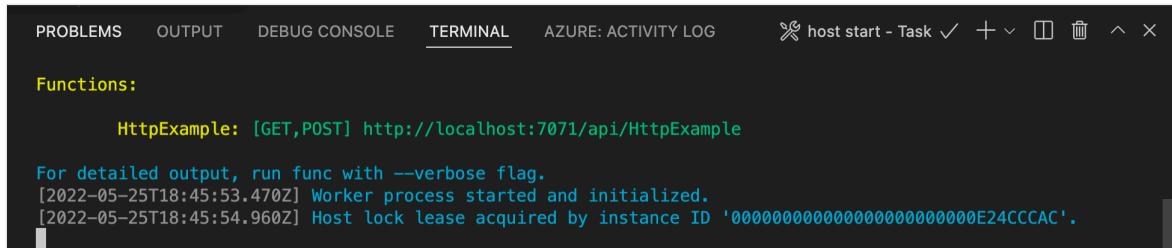

Prompt	Selection
Select a language for your function project	Choose <code>PowerShell</code> .
Select a template for your project's first function	Choose <code>HTTP trigger</code> .
Provide a function name	Type <code>HttpExample</code> .
Authorization level	Choose <code>Anonymous</code> , which enables anyone to call your function endpoint. For more information, see Authorization level .
Select how you would like to open your project	Choose <code>Open in current window</code> .

Using this information, Visual Studio Code generates an Azure Functions project with an HTTP trigger. You can view the local project files in the Explorer. To learn more about files that are created, see [Generated project files](#).

Run the function locally

Visual Studio Code integrates with [Azure Functions Core tools](#) to let you run this project on your local development computer before you publish to Azure.

1. To start the function locally, press `F5` or the **Run and Debug** icon in the left-hand side Activity bar. The **Terminal** panel displays the Output from Core Tools. Your app starts in the **Terminal** panel. You can see the URL endpoint of your HTTP-triggered function running locally.

The screenshot shows the Visual Studio Code interface with the Terminal tab selected. The output window displays the following text:

```
PROBLEMS OUTPUT DEBUG CONSOLE TERMINAL AZURE: ACTIVITY LOG
✖ host start - Task ✓ + □ ⌂ ⌂ ⌂ ×

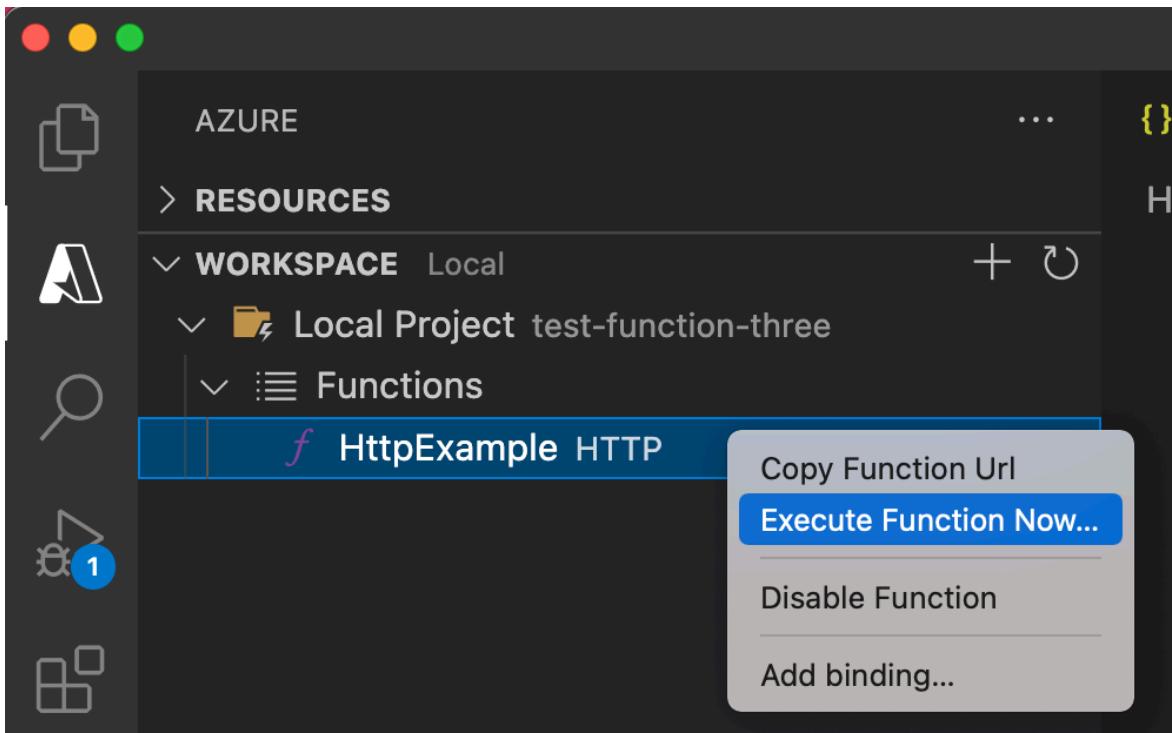

Functions:

HttpExample: [GET,POST] http://localhost:7071/api/HttpExample

For detailed output, run func with --verbose flag.
[2022-05-25T18:45:53.470Z] Worker process started and initialized.
[2022-05-25T18:45:54.960Z] Host lock lease acquired by instance ID '000000000000000000000000E24CCCAC'.
```

If you have trouble running on Windows, make sure that the default terminal for Visual Studio Code isn't set to **WSL Bash**.

2. With Core Tools still running in **Terminal**, choose the Azure icon in the activity bar. In the **Workspace** area, expand **Local Project > Functions**. Right-click (Windows) or `Ctrl + Click` (macOS) the new function and choose **Execute Function Now....**

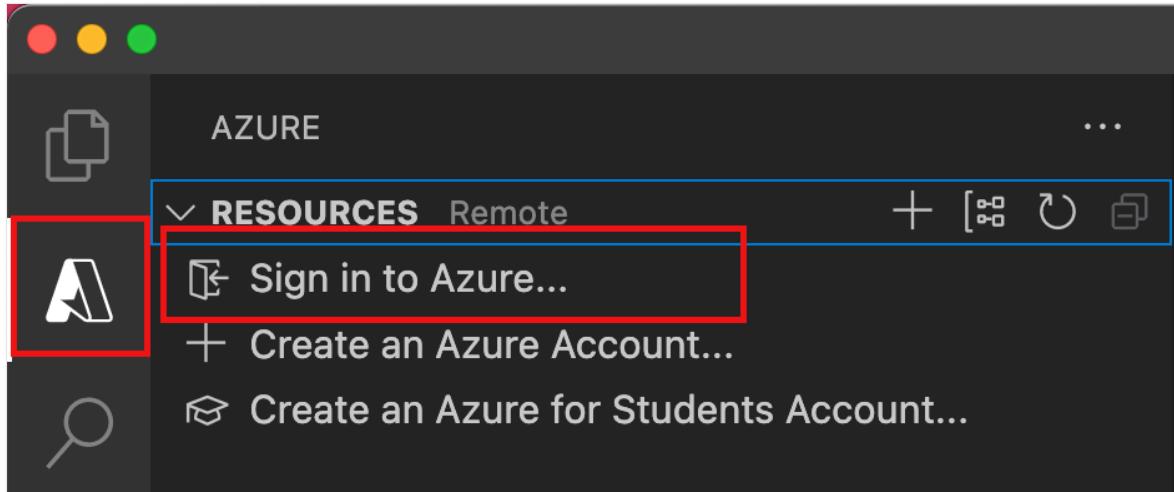

3. In **Enter request body** you see the request message body value of `{ "name": "Azure" }`. Press Enter to send this request message to your function.
4. When the function executes locally and returns a response, a notification is raised in Visual Studio Code. Information about the function execution is shown in **Terminal** panel.
5. With the **Terminal** panel focused, press `Ctrl + C` to stop Core Tools and disconnect the debugger.

After you've verified that the function runs correctly on your local computer, it's time to use Visual Studio Code to publish the project directly to Azure.

Sign in to Azure

Before you can create Azure resources or publish your app, you must sign in to Azure.

1. If you aren't already signed in, in the **Activity bar**, select the Azure icon. Then under **Resources**, select **Sign in to Azure**.

If you're already signed in and can see your existing subscriptions, go to the next section. If you don't yet have an Azure account, select **Create an Azure Account**. Students can select **Create an Azure for Students Account**.

2. When you are prompted in the browser, select your Azure account and sign in by using your Azure account credentials. If you create a new account, you can sign in after your account is created.
3. After you successfully sign in, you can close the new browser window. The subscriptions that belong to your Azure account are displayed in the side bar.

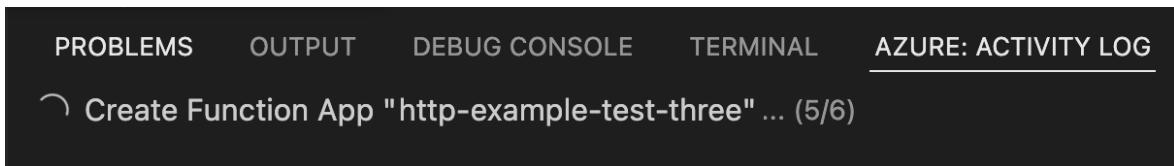

Create the function app in Azure

In this section, you create a function app and related resources in your Azure subscription. Many of the resource creation decisions are made for you based on default behaviors.

1. In Visual Studio Code, select F1 to open the command palette. At the prompt (>), enter and then select **Azure Functions: Create Function App in Azure**.
2. At the prompts, provide the following information:

Prompt	Action
Select subscription	Select the Azure subscription to use. The prompt doesn't appear when you have only one subscription visible under Resources .
Enter a globally unique name for the function app	Enter a name that is valid in a URL path. The name you enter is validated to make sure that it's unique in Azure Functions.
Select a runtime stack	Select the language version you currently run locally.
Select a location for new resources	Select an Azure region. For better performance, select a region ↗ near you.

In the **Azure: Activity Log** panel, the Azure extension shows the status of individual resources as they're created in Azure.

3. When the function app is created, the following related resources are created in your Azure subscription. The resources are named based on the name you entered for your function app.

- A [resource group](#), which is a logical container for related resources.
- A standard [Azure Storage account](#), which maintains state and other information about your projects.
- A function app, which provides the environment for executing your function code. A function app lets you group functions as a logical unit for easier management, deployment, and sharing of resources within the same hosting plan.
- An Azure App Service plan, which defines the underlying host for your function app.
- An Application Insights instance that's connected to the function app, and which tracks the use of your functions in the app.

A notification is displayed after your function app is created and the deployment package is applied.

Tip

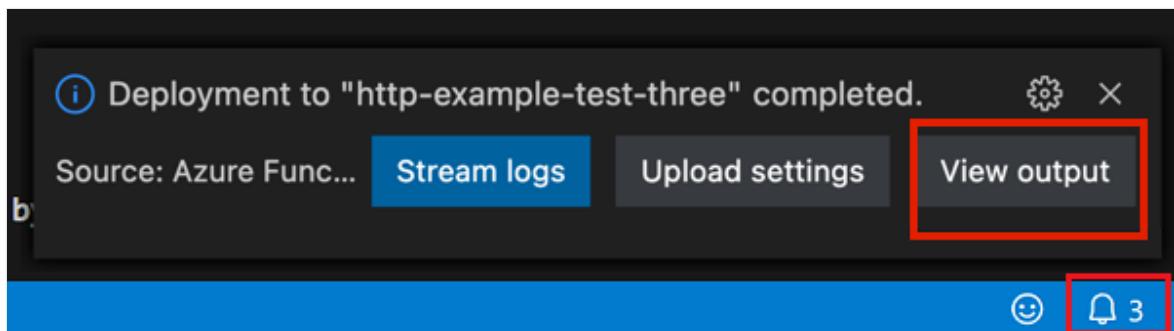

By default, the Azure resources required by your function app are created based on the name you enter for your function app. By default, the resources are created with the function app in the same, new resource group. If you want to customize the names of the associated resources or reuse existing resources, [publish the project with advanced create options](#).

Deploy the project to Azure

ⓘ Important

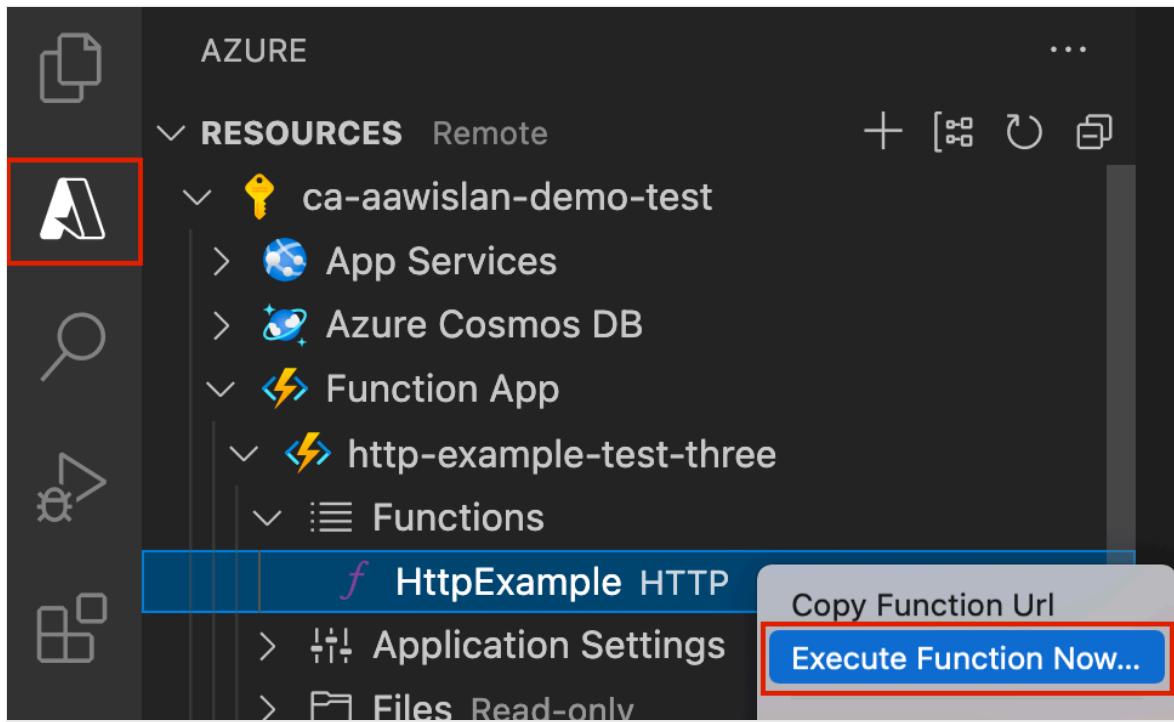

Deploying to an existing function app always overwrites the contents of that app in Azure.

1. In the command palette, enter and then select **Azure Functions: Deploy to Function App**.
2. Select the function app you just created. When prompted about overwriting previous deployments, select **Deploy** to deploy your function code to the new function app resource.
3. When deployment is completed, select **View Output** to view the creation and deployment results, including the Azure resources that you created. If you miss the notification, select the bell icon in the lower-right corner to see it again.

Run the function in Azure

1. Back in the **Resources** area in the side bar, expand your subscription, your new function app, and **Functions**. Right-click (Windows) or **Ctrl -** click (macOS) the `HttpExample` function and choose **Execute Function Now....**

2. In **Enter request body** you see the request message body value of `{ "name": "Azure" }`. Press Enter to send this request message to your function.
3. When the function executes in Azure and returns a response, a notification is raised in Visual Studio Code.

Clean up resources

When you continue to the [next step](#) and add an Azure Storage queue binding to your function, you'll need to keep all your resources in place to build on what you've already done.

Otherwise, you can use the following steps to delete the function app and its related resources to avoid incurring any further costs.

1. In Visual Studio Code, press `F1` to open the command palette. In the command palette, search for and select `Azure: Open in portal`.
2. Choose your function app and press `Enter`. The function app page opens in the Azure portal.
3. In the **Overview** tab, select the named link next to **Resource group**.

The screenshot shows the Azure portal's 'Overview' page for a function app named 'myfunctionapp'. The 'Resource group (change)' section is highlighted with a red box. Key details shown include:

- Status: Running
- Location: Central US
- Subscription: Visual Studio Enterprise
- Runtime version: 3.0.13139.0

The left sidebar lists various navigation options, and the bottom of the page has tabs for Metrics, Features (8), Notifications (0), and Quickstart.

4. On the **Resource group** page, review the list of included resources, and verify that they're the ones you want to delete.

5. Select **Delete resource group**, and follow the instructions.

Deletion may take a couple of minutes. When it's done, a notification appears for a few seconds. You can also select the bell icon at the top of the page to view the notification.

For more information about Functions costs, see [Estimating Consumption plan costs](#).

Next steps

You have used [Visual Studio Code](#) to create a function app with a simple HTTP-triggered function. In the next article, you expand that function by connecting to Azure Storage. To learn more about connecting to other Azure services, see [Add bindings to an existing function in Azure Functions](#).

[Connect to an Azure Storage queue](#)

Quickstart: Create a PowerShell function in Azure from the command line

Article • 08/24/2023

In this article, you use command-line tools to create a PowerShell function that responds to HTTP requests. After testing the code locally, you deploy it to the serverless environment of Azure Functions.

Completing this quickstart incurs a small cost of a few USD cents or less in your Azure account.

There is also a [Visual Studio Code-based version](#) of this article.

Configure your local environment

Before you begin, you must have the following:

- An Azure account with an active subscription. [Create an account for free ↗](#).
- One of the following tools for creating Azure resources:
 - The Azure [Az PowerShell module](#) version 9.4.0 or later.
 - [Azure CLI](#) version 2.4 or later.
- The [.NET 6.0 SDK ↗](#)
- [PowerShell 7.2](#)

Install the Azure Functions Core Tools

The recommended way to install Core Tools depends on the operating system of your local development computer.

Windows

The following steps use a Windows installer (MSI) to install Core Tools v4.x. For more information about other package-based installers, see the [Core Tools readme ↗](#).

Download and run the Core Tools installer, based on your version of Windows:

- [v4.x - Windows 64-bit](#) (Recommended. [Visual Studio Code debugging](#) requires 64-bit.)
- [v4.x - Windows 32-bit](#)

If you previously used Windows installer (MSI) to install Core Tools on Windows, you should uninstall the old version from Add Remove Programs before installing the latest version.

Create a local function project

In Azure Functions, a function project is a container for one or more individual functions that each responds to a specific trigger. All functions in a project share the same local and hosting configurations. In this section, you create a function project that contains a single function.

1. Run the `func init` command, as follows, to create a functions project in a folder named *LocalFunctionProj* with the specified runtime:

```
Console  
func init LocalFunctionProj --powershell
```

2. Navigate into the project folder:

```
Console  
cd LocalFunctionProj
```

This folder contains various files for the project, including configurations files named `local.settings.json` and `host.json`. Because `local.settings.json` can contain secrets downloaded from Azure, the file is excluded from source control by default in the `.gitignore` file.

3. Add a function to your project by using the following command, where the `--name` argument is the unique name of your function (`HttpExample`) and the `--template` argument specifies the function's trigger (HTTP).

```
Console  
func new --name HttpExample --template "HTTP trigger" --authlevel  
"anonymous"
```

`func new` creates a subfolder matching the function name that contains a code file appropriate to the project's chosen language and a configuration file named *function.json*.

(Optional) Examine the file contents

If desired, you can skip to [Run the function locally](#) and examine the file contents later.

run.ps1

run.ps1 defines a function script that's triggered according to the configuration in *function.json*.

```
PowerShell

using namespace System.Net

# Input bindings are passed in via param block.
param($Request, $TriggerMetadata)

# Write to the Azure Functions log stream.
Write-Host "PowerShell HTTP trigger function processed a request."

# Interact with query parameters or the body of the request.
$name = $Request.Query.Name
if (-not $name) {
    $name = $Request.Body.Name
}

$body = "This HTTP triggered function executed successfully. Pass a name in
the query string or in the request body for a personalized response.

if ($name) {
    $body = "Hello, $name. This HTTP triggered function executed
successfully."
}

# Associate values to output bindings by calling 'Push-OutputBinding'.
Push-OutputBinding -Name Response -Value ([HttpResponseContext]@{
    StatusCode = [HttpStatusCode]::OK
    Body = $body
})
```

For an HTTP trigger, the function receives request data passed to the `$Request` param defined in *function.json*. The return object, defined as `Response` in *function.json*, is passed to the `Push-OutputBinding` cmdlet as the response.

function.json

function.json is a configuration file that defines the input and output `bindings` for the function, including the trigger type.

```
JSON

{
  "bindings": [
    {
      "authLevel": "function",
      "type": "httpTrigger",
      "direction": "in",
      "name": "Request",
      "methods": [
        "get",
        "post"
      ]
    },
    {
      "type": "http",
      "direction": "out",
      "name": "Response"
    }
  ]
}
```

Each binding requires a direction, a type, and a unique name. The HTTP trigger has an input binding of type `httpTrigger` and output binding of type `http`.

Run the function locally

1. Run your function by starting the local Azure Functions runtime host from the *LocalFunctionProj* folder.

```
Console
func start
```

Toward the end of the output, the following lines must appear:

```
Azure Functions Core Tools
Core Tools Version:    4.0.5049 Commit hash: N/A  (64-bit)
Function Runtime Version: 4.15.2.20177

[2023-03-17T03:27:12.372Z] Worker process started and initialized.

Functions:

    HttpExample: [GET,POST] http://localhost:7071/api/HttpExample
```

ⓘ Note

If `HttpExample` doesn't appear as shown above, you likely started the host from outside the root folder of the project. In that case, use `Ctrl+C` to stop the host, go to the project's root folder, and run the previous command again.

2. Copy the URL of your HTTP function from this output to a browser and append the query string `?name=<YOUR_NAME>`, making the full URL like `http://localhost:7071/api/HttpExample?name=Functions`. The browser should display a response message that echoes back your query string value. The terminal in which you started your project also shows log output as you make requests.
3. When you're done, press `Ctrl + C` and type `y` to stop the functions host.

Create supporting Azure resources for your function

Before you can deploy your function code to Azure, you need to create three resources:

- A [resource group](#), which is a logical container for related resources.
- A [Storage account](#), which is used to maintain state and other information about your functions.
- A function app, which provides the environment for executing your function code. A function app maps to your local function project and lets you group functions as a logical unit for easier management, deployment, and sharing of resources.

Use the following commands to create these items. Both Azure CLI and PowerShell are supported.

1. If you haven't done so already, sign in to Azure:

Azure CLI

Azure CLI

```
az login
```

The [az login](#) command signs you into your Azure account.

2. Create a resource group named `AzureFunctionsQuickstart-rg` in your chosen region:

Azure CLI

Azure CLI

```
az group create --name AzureFunctionsQuickstart-rg --location  
<REGION>
```

The [az group create](#) command creates a resource group. In the above command, replace `<REGION>` with a region near you, using an available region code returned from the [az account list-locations](#) command.

3. Create a general-purpose storage account in your resource group and region:

Azure CLI

Azure CLI

```
az storage account create --name <STORAGE_NAME> --location <REGION>  
--resource-group AzureFunctionsQuickstart-rg --sku Standard_LRS --  
allow-blob-public-access false
```

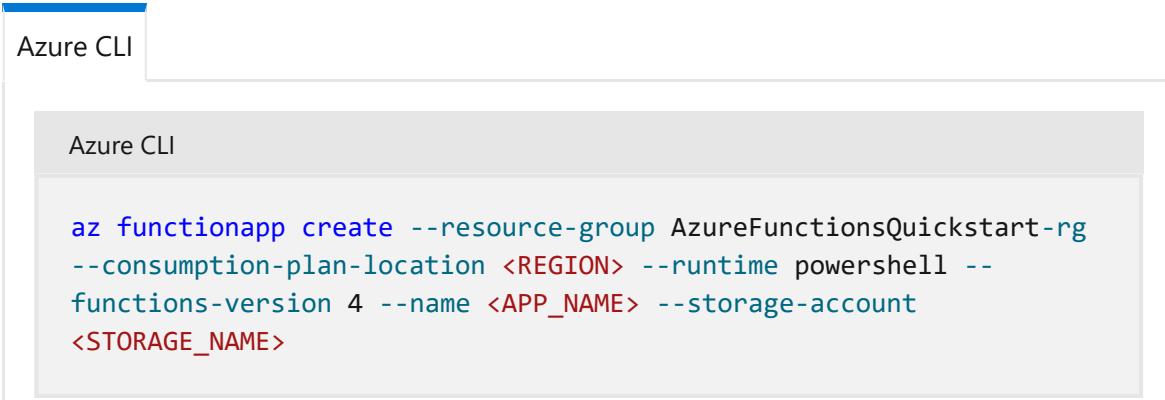

The [az storage account create](#) command creates the storage account.

In the previous example, replace `<STORAGE_NAME>` with a name that is appropriate to you and unique in Azure Storage. Names must contain three to 24 characters numbers and lowercase letters only. `Standard_LRS` specifies a general-purpose account, which is [supported by Functions](#).

 **Important**

The storage account is used to store important app data, sometimes including the application code itself. You should limit access from other apps and users to the storage account.

4. Create the function app in Azure:

Azure CLI

```
az functionapp create --resource-group AzureFunctionsQuickstart-rg --consumption-plan-location <REGION> --runtime powershell --functions-version 4 --name <APP_NAME> --storage-account <STORAGE_NAME>
```

The `az functionapp create` command creates the function app in Azure.

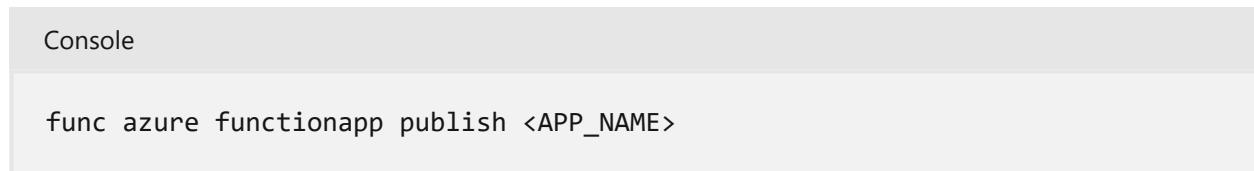

In the previous example, replace `<STORAGE_NAME>` with the name of the account you used in the previous step, and replace `<APP_NAME>` with a globally unique name appropriate to you. The `<APP_NAME>` is also the default DNS domain for the function app.

This command creates a function app running in your specified language runtime under the [Azure Functions Consumption Plan](#), which is free for the amount of usage you incur here. The command also provisions an associated Azure Application Insights instance in the same resource group, with which you can monitor your function app and view logs. For more information, see [Monitor Azure Functions](#). The instance incurs no costs until you activate it.

Deploy the function project to Azure

After you've successfully created your function app in Azure, you're now ready to deploy your local functions project by using the `func azure functionapp publish` command.

In the following example, replace `<APP_NAME>` with the name of your app.

Console

```
func azure functionapp publish <APP_NAME>
```

The publish command shows results similar to the following output (truncated for simplicity):

```
...
Getting site publishing info...
Creating archive for current directory...
Performing remote build for functions project.

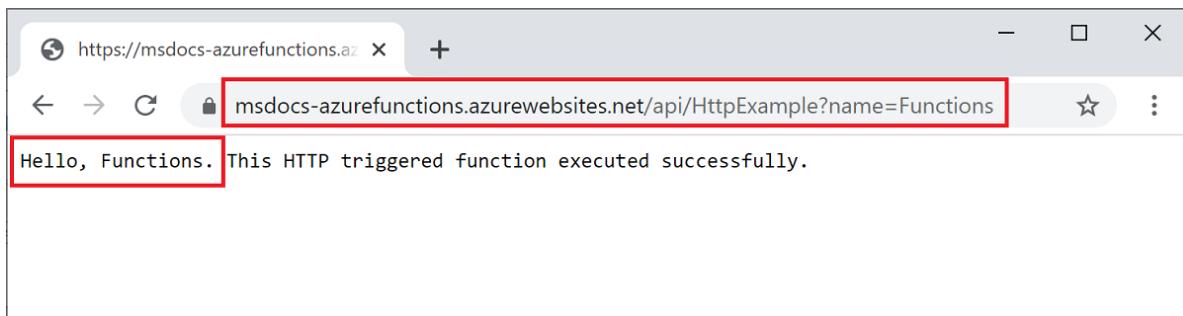

...
Deployment successful.
Remote build succeeded!
Syncing triggers...
Functions in msdocs-azurefunctions-qs:
  HttpExample - [httpTrigger]
    Invoke url: https://msdocs-azurefunctions-
qs.azurewebsites.net/api/httpexample
```

Invoke the function on Azure

Because your function uses an HTTP trigger, you invoke it by making an HTTP request to its URL in the browser or with a tool like curl.

Browser

Copy the complete **Invoke URL** shown in the output of the publish command into a browser address bar, appending the query parameter `?name=Functions`. The browser should display similar output as when you ran the function locally.

Run the following command to view near real-time streaming logs:

Console

```
func azure functionapp logstream <APP_NAME>
```

In a separate terminal window or in the browser, call the remote function again. A verbose log of the function execution in Azure is shown in the terminal.

Clean up resources

If you continue to the [next step](#) and add an Azure Storage queue output binding, keep all your resources in place as you'll build on what you've already done.

Otherwise, use the following command to delete the resource group and all its contained resources to avoid incurring further costs.

```
Azure CLI
az group delete --name AzureFunctionsQuickstart-rg
```

Next steps

[Connect to an Azure Storage queue](#)

Quickstart: Create and deploy functions to Azure Functions using the Azure Developer CLI

Article • 09/09/2024

In this Quickstart, you use Azure Developer command-line tools to create functions that respond to HTTP requests. After testing the code locally, you deploy it to a new serverless function app you create running in a Flex Consumption plan in Azure Functions.

The project source uses the Azure Developer CLI (azd) to simplify deploying your code to Azure. This deployment follows current best practices for secure and scalable Azure Functions deployments.

ⓘ Important

The [Flex Consumption plan](#) is currently in preview.

By default, the Flex Consumption plan follows a *pay-for-what-you-use* billing model, which means to complete this quickstart incurs a small cost of a few USD cents or less in your Azure account.

Prerequisites

- An Azure account with an active subscription. [Create an account for free ↗](#).
- [Azure Developer CLI](#).
- [Azure Functions Core Tools](#).
- [PowerShell 7.2](#)
- [.NET 6.0 SDK ↗](#)
- A [secure HTTP test tool](#) for sending requests with JSON payloads to your function endpoints. This article uses `curl`.

Initialize the project

You can use the `azd init` command to create a local Azure Functions code project from a template.

1. In your local terminal or command prompt, run this `azd init` command in an empty folder:

```
Console
```

```
azd init --template functions-quickstart-powershell-azd -e flexquickstart-ps
```

This command pulls the project files from the [template repository](#) and initializes the project in the root folder. The `-e` flag sets a name for the current environment. In `azd`, the environment is used to maintain a unique deployment context for your app, and you can define more than one. It's also used in the name of the resource group you create in Azure.

2. Run this command to navigate to the `src` app folder:

```
Console
```

```
cd src
```

3. Create a file named `local.settings.json` in the `src` folder that contains this JSON data:

```
JSON
```

```
{  
    "IsEncrypted": false,  
    "Values": {  
        "AzureWebJobsStorage": "UseDevelopmentStorage=true",  
        "FUNCTIONS_WORKER_RUNTIME": "powershell",  
        "FUNCTIONS_WORKER_RUNTIME_VERSION": "7.2"  
    }  
}
```

This file is required when running locally.

Run in your local environment

1. Run this command from your app folder in a terminal or command prompt:

```
Console
```

```
func start
```

When the Functions host starts in your local project folder, it writes the URL endpoints of your HTTP triggered functions to the terminal output.

2. In your browser, navigate to the `httpget` endpoint, which should look like this URL:

<http://localhost:7071/api/httpget>

3. From a new terminal or command prompt window, run this `curl` command to send a POST request with a JSON payload to the `httppost` endpoint:

Console

```
curl -i http://localhost:7071/api/httppost -H "Content-Type: text/json"  
-d @testdata.json
```

This command reads JSON payload data from the `testdata.json` project file. You can find examples of both HTTP requests in the `test.http` project file.

4. When you're done, press **Ctrl+C** in the terminal window to stop the `func.exe` host process.

Review the code (optional)

You can review the code that defines the two HTTP trigger function endpoints:

httpget

This `function.json` file defines the `httpget` function:

JSON

```
{  
  "bindings": [  
    {  
      "authLevel": "function",  
      "type": "httpTrigger",  
      "direction": "in",  
      "name": "Request",  
      "methods": [  
        "get"  
      ]  
    },  
  ],  
  "disabled": false  
}
```

```
{  
    "type": "http",  
    "direction": "out",  
    "name": "Response"  
}  
]  
}
```

This `run.ps1` file implements the function code:

PowerShell

```
using namespace System.Net  
  
# Input bindings are passed in via param block.  
param($Request, $TriggerMetadata)  
  
# Write to the Azure Functions log stream.  
Write-Host "PowerShell HTTP trigger function processed a request."  
  
# Interact with query parameters  
$name = $Request.Query.name  
  
$body = "This HTTP triggered function executed successfully. Pass a name  
in the query string for a personalized response."  
  
if ($name) {  
    $body = "Hello, $name. This HTTP triggered function executed  
successfully."  
}  
  
# Associate values to output bindings by calling 'Push-OutputBinding'.  
Push-OutputBinding -Name Response -Value ([HttpResponseContext]@{  
    StatusCode = [ HttpStatusCode ]::OK  
    Body = $body  
})
```

You can review the complete template project [here ↗](#).

After you verify your functions locally, it's time to publish them to Azure.

Deploy to Azure

This project is configured to use the `azd up` command to deploy this project to a new function app in a Flex Consumption plan in Azure.

 Tip

This project includes a set of Bicep files that `azd` uses to create a secure deployment to a Flex consumption plan that follows best practices.

1. Run this command to have `azd` create the required Azure resources in Azure and deploy your code project to the new function app:

```
Console
```

```
azd up
```

The root folder contains the `azure.yaml` definition file required by `azd`.

If you aren't already signed-in, you're asked to authenticate with your Azure account.

2. When prompted, provide these required deployment parameters:

[\[+\] Expand table](#)

Parameter	Description
<code>Azure subscription</code>	Subscription in which your resources are created.
<code>Azure location</code>	Azure region in which to create the resource group that contains the new Azure resources. Only regions that currently support the Flex Consumption plan are shown.

The `azd up` command uses your response to these prompts with the Bicep configuration files to complete these deployment tasks:

- Create and configure these required Azure resources (equivalent to `azd provision`):
 - Flex Consumption plan and function app
 - Azure Storage (required) and Application Insights (recommended)
 - Access policies and roles for your account
 - Service-to-service connections using managed identities (instead of stored connection strings)
 - Virtual network to securely run both the function app and the other Azure resources
- Package and deploy your code to the deployment container (equivalent to `azd deploy`). The app is then started and runs in the deployed package.

After the command completes successfully, you see links to the resources you created.

Invoke the function on Azure

You can now invoke your function endpoints in Azure by making HTTP requests to their URLs using your HTTP test tool or from the browser (for GET requests). When your functions run in Azure, access key authorization is enforced, and you must provide a function access key with your request.

You can use the Core Tools to obtain the URL endpoints of your functions running in Azure.

1. In your local terminal or command prompt, run these commands to get the URL endpoint values:

PowerShell

PowerShell

```
$APP_NAME = azd env get-value AZURE_FUNCTION_NAME  
func azure functionapp list-functions $APP_NAME --show-keys
```

The `azd env get-value` command gets your function app name from the local environment. Using the `--show-keys` option with `func azure functionapp list-functions` means that the returned **Invoke URL:** value for each endpoint includes a function-level access key.

2. As before, use your HTTP test tool to validate these URLs in your function app running in Azure.

Redeploy your code

You can run the `azd up` command as many times as you need to both provision your Azure resources and deploy code updates to your function app.

 **Note**

Deployed code files are always overwritten by the latest deployment package.

Your initial responses to `azd` prompts and any environment variables generated by `azd` are stored locally in your named environment. Use the `azd env get-values` command to review all of the variables in your environment that were used when creating Azure resources.

Clean up resources

When you're done working with your function app and related resources, you can use this command to delete the function app and its related resources from Azure and avoid incurring any further costs:

Console

```
azd down --no-prompt
```

Note

The `--no-prompt` option instructs `azd` to delete your resource group without a confirmation from you.

This command doesn't affect your local code project.

Quickstart: Create a function in Azure with Python using Visual Studio Code

Article • 09/10/2024

In this article, you use Visual Studio Code to create a Python function that responds to HTTP requests. After testing the code locally, you deploy it to the serverless environment of Azure Functions.

This article uses the Python v2 programming model for Azure Functions, which provides a decorator-based approach for creating functions. To learn more about the Python v2 programming model, see the [Developer Reference Guide](#)

Completing this quickstart incurs a small cost of a few USD cents or less in your Azure account.

There's also a [CLI-based version](#) of this article.

This video shows you how to create a Python function in Azure using Visual Studio Code.

[https://learn-video.azurefd.net/vod/player?id=a1e10f96-2940-489c-bc53-da2b915c8fc2&locale=en-us&embedUrl=%2Fazure%2Fazure-functions%2Fcreate-first-function-vs-code-python ↗](https://learn-video.azurefd.net/vod/player?id=a1e10f96-2940-489c-bc53-da2b915c8fc2&locale=en-us&embedUrl=%2Fazure%2Fazure-functions%2Fcreate-first-function-vs-code-python)

The steps in the video are also described in the following sections.

Configure your environment

Before you begin, make sure that you have the following requirements in place:

- An Azure account with an active subscription. [Create an account for free ↗](#).
- A Python version that is [supported by Azure Functions](#). For more information, see [How to install Python ↗](#).
- [Visual Studio Code ↗](#) on one of the [supported platforms ↗](#).
- The [Python extension ↗](#) for Visual Studio Code.
- The [Azure Functions extension ↗](#) for Visual Studio Code, version 1.8.1 or later.
- The [Azurite V3 extension ↗](#) local storage emulator. While you can also use an actual Azure storage account, this article assumes you're using the Azurite emulator.

Install or update Core Tools

The Azure Functions extension for Visual Studio Code integrates with Azure Functions Core Tools so that you can run and debug your functions locally in Visual Studio Code using the Azure Functions runtime. Before getting started, it's a good idea to install Core Tools locally or update an existing installation to use the latest version.

In Visual Studio Code, select F1 to open the command palette, and then search for and run the command **Azure Functions: Install or Update Core Tools**.

This command tries to either start a package-based installation of the latest version of Core Tools or update an existing package-based installation. If you don't have npm or Homebrew installed on your local computer, you must instead [manually install or update Core Tools](#).

Create your local project

In this section, you use Visual Studio Code to create a local Azure Functions project in Python. Later in this article, you publish your function code to Azure.

1. In Visual Studio Code, press `F1` to open the command palette and search for and run the command `Azure Functions: Create New Project...`.
2. Choose the directory location for your project workspace and choose **Select**. You should either create a new folder or choose an empty folder for the project workspace. Don't choose a project folder that is already part of a workspace.
3. Provide the following information at the prompts:

[] [Expand table](#)

Prompt	Selection
Select a language	Choose <code>Python (Programming Model V2)</code> .
Select a Python interpreter to create a virtual environment	Choose your preferred Python interpreter. If an option isn't shown, type in the full path to your Python binary.
Select a template for your project's first function	Choose <code>HTTP trigger</code> .
Name of the function you want to create	Enter <code>HttpExample</code> .

Prompt	Selection
Authorization level	Choose <code>ANONYMOUS</code> , which lets anyone call your function endpoint. For more information, see Authorization level .
Select how you would like to open your project	Choose <code>Open in current window</code> .

- Visual Studio Code uses the provided information and generates an Azure Functions project with an HTTP trigger. You can view the local project files in the Explorer. The generated `function_app.py` project file contains your functions.
- In the `local.settings.json` file, update the `AzureWebJobsStorage` setting as in the following example:

JSON

```
"AzureWebJobsStorage": "UseDevelopmentStorage=true",
```

This tells the local Functions host to use the storage emulator for the storage connection required by the Python v2 model. When you publish your project to Azure, this setting uses the default storage account instead. If you're using an Azure Storage account during local development, set your storage account connection string here.

Start the emulator

- In Visual Studio Code, press `F1` to open the command palette. In the command palette, search for and select `Azurite: Start`.
- Check the bottom bar and verify that Azurite emulation services are running. If so, you can now run your function locally.

Run the function locally

Visual Studio Code integrates with [Azure Functions Core tools](#) to let you run this project on your local development computer before you publish to Azure.

- To start the function locally, press `F5` or the Run and Debug icon in the left-hand side Activity bar. The Terminal panel displays the Output from Core Tools. Your app starts in the Terminal panel. You can see the URL endpoint of your HTTP-triggered function running locally.

The screenshot shows the Visual Studio Code interface with the Terminal tab selected. The output window displays the following text:

```
PROBLEMS OUTPUT DEBUG CONSOLE TERMINAL AZURE: ACTIVITY LOG host start - Task ✓ + × ↻ ↺ ↺ ×

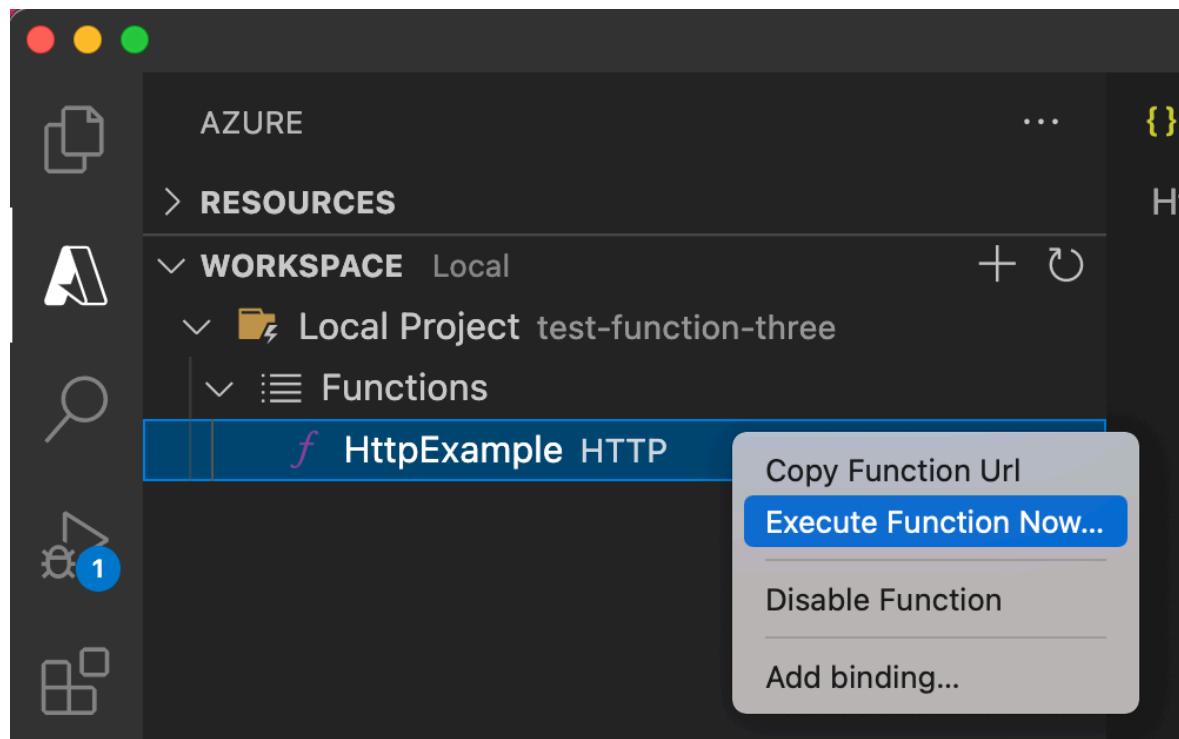

Functions:

HttpExample: [GET,POST] http://localhost:7071/api/HttpExample

For detailed output, run func with --verbose flag.
[2022-05-25T18:45:53.470Z] Worker process started and initialized.
[2022-05-25T18:45:54.960Z] Host lock lease acquired by instance ID '000000000000000000000000E24CCCAC'.
```

If you have trouble running on Windows, make sure that the default terminal for Visual Studio Code isn't set to **WSL Bash**.

- With Core Tools still running in **Terminal**, choose the Azure icon in the activity bar. In the **Workspace** area, expand **Local Project > Functions**. Right-click (Windows) or **Ctrl + click** (macOS) the new function and choose **Execute Function Now....**

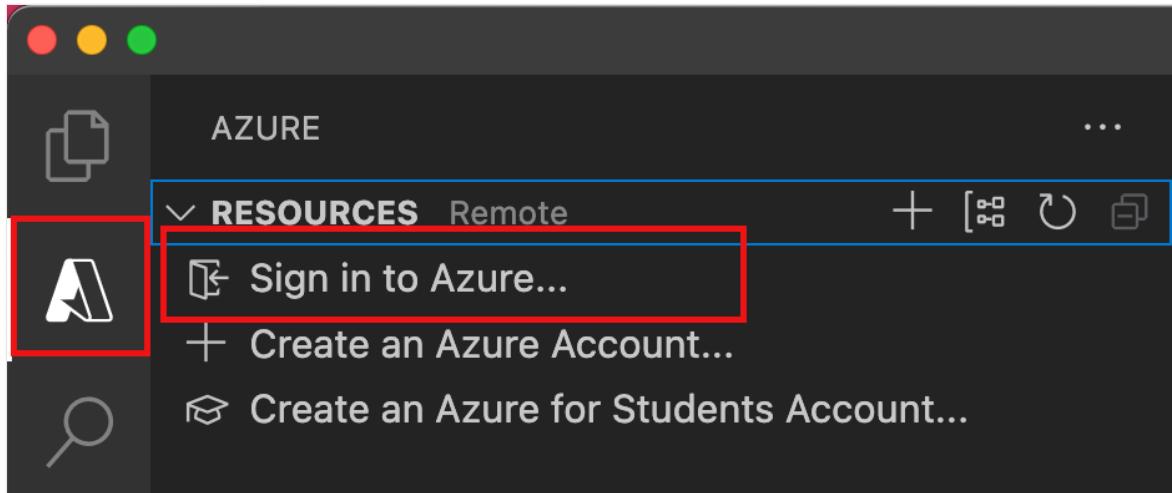

- In **Enter request body** you see the request message body value of `{ "name": "Azure" }`. Press Enter to send this request message to your function.
- When the function executes locally and returns a response, a notification is raised in Visual Studio Code. Information about the function execution is shown in **Terminal** panel.
- With the **Terminal** panel focused, press **Ctrl + C** to stop Core Tools and disconnect the debugger.

After you verify that the function runs correctly on your local computer, it's time to use Visual Studio Code to publish the project directly to Azure.

Sign in to Azure

Before you can create Azure resources or publish your app, you must sign in to Azure.

1. If you aren't already signed in, in the **Activity bar**, select the Azure icon. Then under **Resources**, select **Sign in to Azure**.

If you're already signed in and can see your existing subscriptions, go to the next section. If you don't yet have an Azure account, select **Create an Azure Account**. Students can select **Create an Azure for Students Account**.

2. When you are prompted in the browser, select your Azure account and sign in by using your Azure account credentials. If you create a new account, you can sign in after your account is created.
3. After you successfully sign in, you can close the new browser window. The subscriptions that belong to your Azure account are displayed in the side bar.

Create the function app in Azure

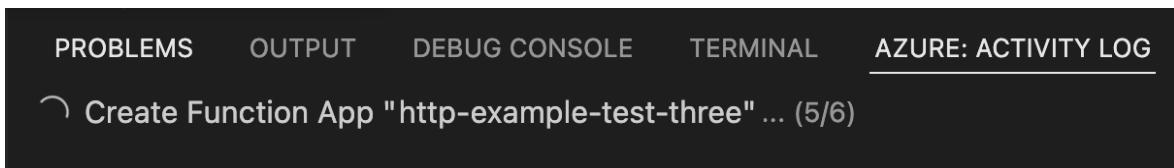

In this section, you create a function app and related resources in your Azure subscription. Many of the resource creation decisions are made for you based on default behaviors. For more control over the created resources, you must instead [create your function app with advanced options](#).

1. In Visual Studio Code, select F1 to open the command palette. At the prompt (>), enter and then select **Azure Functions: Create Function App in Azure**.
2. At the prompts, provide the following information:

[] [Expand table](#)

Prompt	Action
Select subscription	Select the Azure subscription to use. The prompt doesn't appear when you have only one subscription visible under Resources .
Enter a globally unique name for the function app	Enter a name that is valid in a URL path. The name you enter is validated to make sure that it's unique in Azure Functions.
Select a runtime stack	Select the language version you currently run locally.
Select a location for new resources	Select an Azure region. For better performance, select a region near you.

In the **Azure: Activity Log** panel, the Azure extension shows the status of individual resources as they're created in Azure.

- When the function app is created, the following related resources are created in your Azure subscription. The resources are named based on the name you entered for your function app.

- A [resource group](#), which is a logical container for related resources.
- A standard [Azure Storage account](#), which maintains state and other information about your projects.
- A function app, which provides the environment for executing your function code. A function app lets you group functions as a logical unit for easier management, deployment, and sharing of resources within the same hosting plan.
- An Azure App Service plan, which defines the underlying host for your function app.
- An Application Insights instance that's connected to the function app, and which tracks the use of your functions in the app.

A notification is displayed after your function app is created and the deployment package is applied.

Tip

By default, the Azure resources required by your function app are created based on the name you enter for your function app. By default, the resources

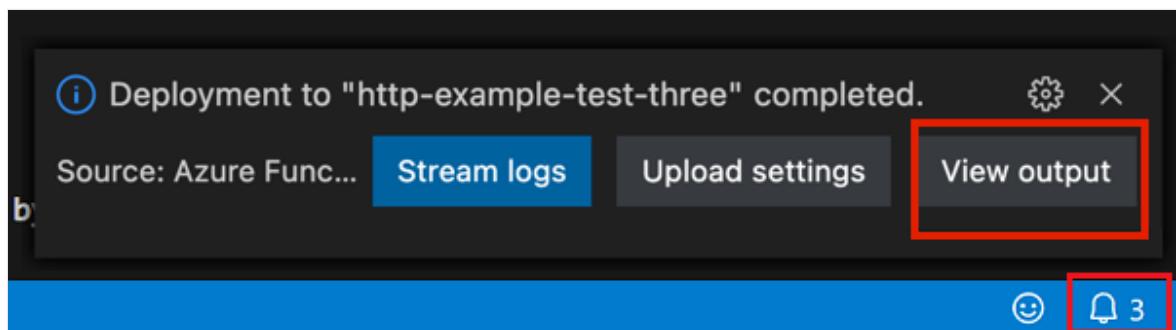

are created with the function app in the same, new resource group. If you want to customize the names of the associated resources or reuse existing resources, [publish the project with advanced create options](#).

Deploy the project to Azure

ⓘ Important

Deploying to an existing function app always overwrites the contents of that app in Azure.

1. In the command palette, enter and then select **Azure Functions: Deploy to Function App**.
2. Select the function app you just created. When prompted about overwriting previous deployments, select **Deploy** to deploy your function code to the new function app resource.
3. When deployment is completed, select **View Output** to view the creation and deployment results, including the Azure resources that you created. If you miss the notification, select the bell icon in the lower-right corner to see it again.

Run the function in Azure

1. Press **F1** to display the command palette, then search for and run the command **Azure Functions:Execute Function Now....**. If prompted, select your subscription.
2. Select your new function app resource and **HttpExample** as your function.
3. In **Enter request body** type `{ "name": "Azure" }`, then press Enter to send this request message to your function.

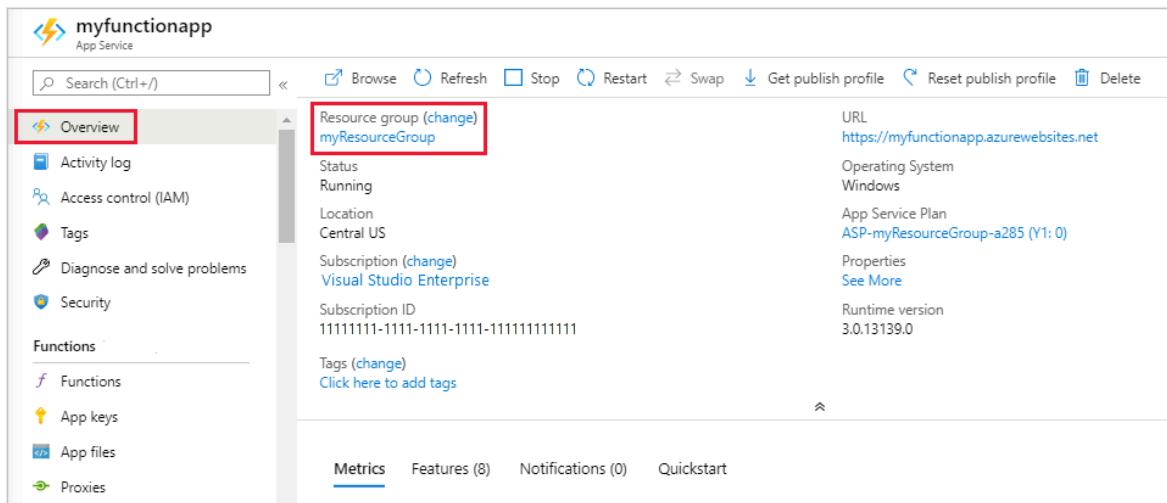

- When the function executes in Azure, the response is displayed in the notification area. Expand the notification to review the full response.

Clean up resources

When you continue to the [next step](#) and add an Azure Storage queue binding to your function, you'll need to keep all your resources in place to build on what you've already done.

Otherwise, you can use the following steps to delete the function app and its related resources to avoid incurring any further costs.

- In Visual Studio Code, press `F1` to open the command palette. In the command palette, search for and select `Azure: Open in portal`.
- Choose your function app and press `Enter`. The function app page opens in the Azure portal.
- In the **Overview** tab, select the named link next to **Resource group**.

- On the **Resource group** page, review the list of included resources, and verify that they're the ones you want to delete.
- Select **Delete resource group**, and follow the instructions.

Deletion may take a couple of minutes. When it's done, a notification appears for a few seconds. You can also select the bell icon at the top of the page to view the notification.

For more information about Functions costs, see [Estimating Consumption plan costs](#).

Next steps

You created and deployed a function app with a simple HTTP-triggered function. In the next articles, you expand that function by connecting to a storage service in Azure. To learn more about connecting to other Azure services, see [Add bindings to an existing function in Azure Functions](#).

Quickstart: Create a Python function in Azure from the command line

Article • 03/05/2024

In this article, you use command-line tools to create a Python function that responds to HTTP requests. After testing the code locally, you deploy it to the serverless environment of Azure Functions.

This article uses the Python v2 programming model for Azure Functions, which provides a decorator-based approach for creating functions. To learn more about the Python v2 programming model, see the [Developer Reference Guide](#)

Completing this quickstart incurs a small cost of a few USD cents or less in your Azure account.

There's also a [Visual Studio Code-based version](#) of this article.

Configure your local environment

Before you begin, you must have the following requirements in place:

- An Azure account with an active subscription. [Create an account for free](#).
- One of the following tools for creating Azure resources:
 - [Azure CLI](#) version 2.4 or later.
 - The Azure [Az PowerShell module](#) version 5.9.0 or later.
- A Python version supported by Azure Functions.
- The [Azurite storage emulator](#). While you can also use an actual Azure Storage account, the article assumes you're using this emulator.

Install the Azure Functions Core Tools

The recommended way to install Core Tools depends on the operating system of your local development computer.

Windows

The following steps use a Windows installer (MSI) to install Core Tools v4.x. For more information about other package-based installers, see the [Core Tools readme](#).

Download and run the Core Tools installer, based on your version of Windows:

- [v4.x - Windows 64-bit](#) (Recommended. Visual Studio Code debugging requires 64-bit.)
- [v4.x - Windows 32-bit](#)

If you previously used Windows installer (MSI) to install Core Tools on Windows, you should uninstall the old version from Add Remove Programs before installing the latest version.

Use the `func --version` command to make sure your version of Core Tools is at least [4.0.5530](#).

Create and activate a virtual environment

In a suitable folder, run the following commands to create and activate a virtual environment named `.venv`. Make sure that you're using a [version of Python supported by Azure Functions](#).

```
bash
```

```
Bash
```

```
python -m venv .venv
```

```
Bash
```

```
source .venv/bin/activate
```

If Python didn't install the `venv` package on your Linux distribution, run the following command:

```
Bash
```

```
sudo apt-get install python3-venv
```

You run all subsequent commands in this activated virtual environment.

Create a local function

In Azure Functions, a function project is a container for one or more individual functions that each responds to a specific trigger. All functions in a project share the same local and hosting configurations.

In this section, you create a function project and add an HTTP triggered function.

1. Run the `func init` command as follows to create a Python v2 functions project in the virtual environment.

```
Console  
func init --python
```

The environment now contains various files for the project, including configuration files named `local.settings.json` and `host.json`. Because `local.settings.json` can contain secrets downloaded from Azure, the file is excluded from source control by default in the `.gitignore` file.

2. Add a function to your project by using the following command, where the `--name` argument is the unique name of your function (`HttpExample`) and the `--template` argument specifies the function's trigger (HTTP).

```
Console  
func new --name HttpExample --template "HTTP trigger" --authlevel  
"anonymous"
```

If prompted, choose the **ANONYMOUS** option. `func new` adds an HTTP trigger endpoint named `HttpExample` to the `function_app.py` file, which is accessible without authentication.

Run the function locally

1. Run your function by starting the local Azure Functions runtime host from the `LocalFunctionProj` folder.

```
Console
```

```
func start
```

Toward the end of the output, the following lines must appear:

```
Azure Functions Core Tools
Core Tools Version:        4.0.5049 Commit hash: N/A  (64-bit)
Function Runtime Version: 4.15.2.20177

[2023-03-17T03:27:12.372Z] Worker process started and initialized.

Functions:

    HttpExample: [GET,POST] http://localhost:7071/api/HttpExample
```

ⓘ Note

If `HttpExample` doesn't appear as shown above, you likely started the host from outside the root folder of the project. In that case, use `Ctrl+C` to stop the host, go to the project's root folder, and run the previous command again.

2. Copy the URL of your HTTP function from this output to a browser and append the query string `?name=<YOUR_NAME>`, making the full URL like `http://localhost:7071/api/HttpExample?name=Functions`. The browser should display a response message that echoes back your query string value. The terminal in which you started your project also shows log output as you make requests.
3. When you're done, press `Ctrl + C` and type `y` to stop the functions host.

Create supporting Azure resources for your function

Before you can deploy your function code to Azure, you need to create three resources:

- A resource group, which is a logical container for related resources.
- A storage account, which maintains the state and other information about your projects.
- A function app, which provides the environment for executing your function code. A function app maps to your local function project and lets you group functions as a logical unit for easier management, deployment, and sharing of resources.

Use the following commands to create these items. Both Azure CLI and PowerShell are supported.

1. If needed, sign in to Azure.

```
Azure CLI
```

```
Azure CLI
```

```
az login
```

The `az login` command signs you into your Azure account.

2. Create a resource group named `AzureFunctionsQuickstart-rg` in your chosen region.

```
Azure CLI
```

```
Azure CLI
```

```
az group create --name AzureFunctionsQuickstart-rg --location  
<REGION>
```

The `az group create` command creates a resource group. In the above command, replace `<REGION>` with a region near you, using an available region code returned from the [az account list-locations](#) command.

ⓘ Note

You can't host Linux and Windows apps in the same resource group. If you have an existing resource group named `AzureFunctionsQuickstart-rg` with a Windows function app or web app, you must use a different resource group.

3. Create a general-purpose storage account in your resource group and region.

```
Azure CLI
```

```
Azure CLI
```

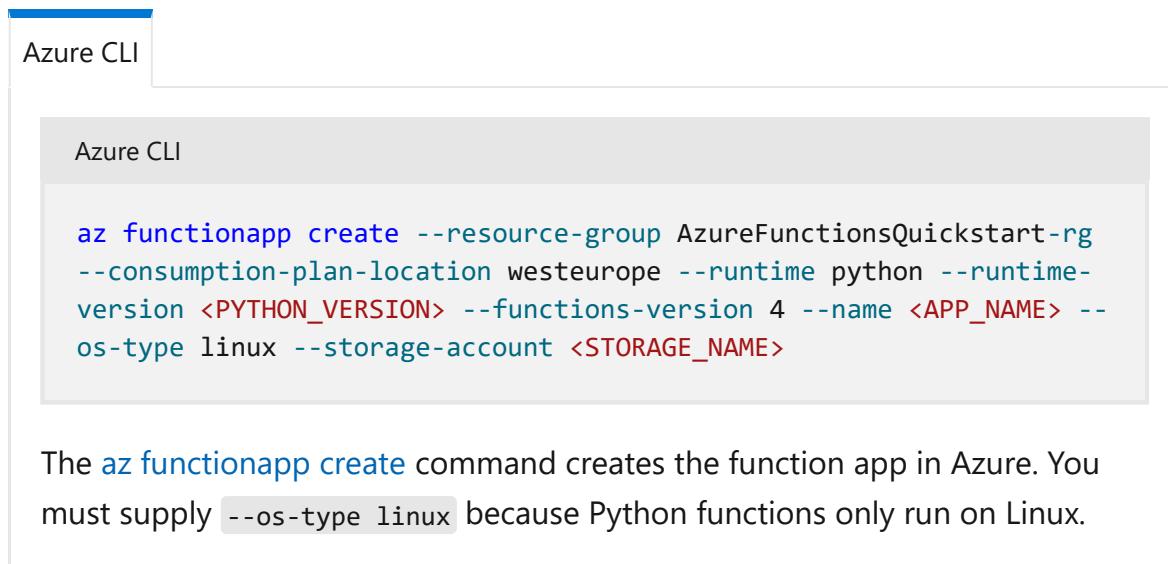

```
az storage account create --name <STORAGE_NAME> --location <REGION>  
--resource-group AzureFunctionsQuickstart-rg --sku Standard_LRS
```

The `az storage account create` command creates the storage account.

In the previous example, replace `<STORAGE_NAME>` with a name that's appropriate to you and unique in Azure Storage. Names must contain 3 to 24 characters numbers and lowercase letters only. `Standard_LRS` specifies a general-purpose account supported by Functions.

The storage account incurs only a few cents (USD) for this quickstart.

4. Create the function app in Azure.

Azure CLI

```
az functionapp create --resource-group AzureFunctionsQuickstart-rg --consumption-plan-location westeurope --runtime python --runtime-version <PYTHON_VERSION> --functions-version 4 --name <APP_NAME> --os-type linux --storage-account <STORAGE_NAME>
```

The `az functionapp create` command creates the function app in Azure. You must supply `--os-type linux` because Python functions only run on Linux.

In the previous example, replace `<APP_NAME>` with a globally unique name appropriate to you. The `<APP_NAME>` is also the default subdomain for the function app. Make sure that the value you set for `<PYTHON_VERSION>` is a version supported by Functions and is the same version you used during local development.

This command creates a function app running in your specified language runtime under the [Azure Functions Consumption Plan](#), which is free for the amount of usage you incur here. The command also creates an associated Azure Application Insights instance in the same resource group, with which you can monitor your function app and view logs. For more information, see [Monitor Azure Functions](#). The instance incurs no costs until you activate it.

Deploy the function project to Azure

After you've successfully created your function app in Azure, you're now ready to deploy your local functions project by using the `func azure functionapp publish` command.

In the following example, replace `<APP_NAME>` with the name of your app.

Console

```
func azure functionapp publish <APP_NAME>
```

The publish command shows results similar to the following output (truncated for simplicity):

```
...
Getting site publishing info...
Creating archive for current directory...
Performing remote build for functions project.

...
Deployment successful.
Remote build succeeded!
Syncing triggers...
Functions in msdocs-azurefunctions-qs:
  HttpExample - [httpTrigger]
    Invoke url: https://msdocs-azurefunctions-
qs.azurewebsites.net/api/httpexample
```

Invoke the function on Azure

Because your function uses an HTTP trigger, you invoke it by making an HTTP request to its URL in the browser or with a tool like curl.

Browser

Copy the complete **Invoke URL** shown in the output of the `publish` command into a browser address bar, appending the query parameter `?name=Functions`. The browser should display similar output as when you ran the function locally.

Clean up resources

If you continue to the [next step](#) and add an Azure Storage queue output binding, keep all your resources in place as you'll build on what you've already done.

Otherwise, use the following command to delete the resource group and all its contained resources to avoid incurring further costs.

Azure CLI

Azure CLI

```
az group delete --name AzureFunctionsQuickstart-rg
```

Next steps

Quickstart: Create and deploy functions to Azure Functions using the Azure Developer CLI

Article • 09/09/2024

In this Quickstart, you use Azure Developer command-line tools to create functions that respond to HTTP requests. After testing the code locally, you deploy it to a new serverless function app you create running in a Flex Consumption plan in Azure Functions.

The project source uses the Azure Developer CLI (azd) to simplify deploying your code to Azure. This deployment follows current best practices for secure and scalable Azure Functions deployments.

ⓘ Important

The [Flex Consumption plan](#) is currently in preview.

By default, the Flex Consumption plan follows a *pay-for-what-you-use* billing model, which means to complete this quickstart incurs a small cost of a few USD cents or less in your Azure account.

Prerequisites

- An Azure account with an active subscription. [Create an account for free ↗](#).
- [Azure Developer CLI](#).
- [Azure Functions Core Tools](#).
- [Python 3.11 ↗](#).
- A [secure HTTP test tool](#) for sending requests with JSON payloads to your function endpoints. This article uses `curl`.

Initialize the project

You can use the `azd init` command to create a local Azure Functions code project from a template.

1. In your local terminal or command prompt, run this `azd init` command in an empty folder:

```
Console
```

```
azd init --template functions-quickstart-python-http-azd -e flexquickstart-py
```

This command pulls the project files from the [template repository](#) and initializes the project in the root folder. The `-e` flag sets a name for the current environment. In `azd`, the environment is used to maintain a unique deployment context for your app, and you can define more than one. It's also used in the name of the resource group you create in Azure.

2. Create a file named `local.settings.json` in the root folder that contains this JSON data:

```
JSON
```

```
{  
    "IsEncrypted": false,  
    "Values": {  
        "AzureWebJobsStorage": "UseDevelopmentStorage=true",  
        "FUNCTIONS_WORKER_RUNTIME": "python"  
    }  
}
```

This file is required when running locally.

Create and activate a virtual environment

In the root folder, run these commands to create and activate a virtual environment named `.venv`:

Linux/macOS

Bash

```
python3 -m venv .venv  
source .venv/bin/activate
```

If Python didn't install the `venv` package on your Linux distribution, run the following command:

Bash

```
sudo apt-get install python3-venv
```

Run in your local environment

1. Run this command from your app folder in a terminal or command prompt:

Console

```
func start
```

When the Functions host starts in your local project folder, it writes the URL endpoints of your HTTP triggered functions to the terminal output.

2. In your browser, navigate to the `httpget` endpoint, which should look like this URL:

<http://localhost:7071/api/httpget>

3. From a new terminal or command prompt window, run this `curl` command to send a POST request with a JSON payload to the `httppost` endpoint:

Console

```
curl -i http://localhost:7071/api/httppost -H "Content-Type: text/json"  
-d @testdata.json
```

This command reads JSON payload data from the `testdata.json` project file. You can find examples of both HTTP requests in the `test.http` project file.

4. When you're done, press **Ctrl+C** in the terminal window to stop the `func.exe` host process.

5. Run `deactivate` to shut down the virtual environment.

Review the code (optional)

You can review the code that defines the two HTTP trigger function endpoints:

httpget

Python

```
@app.route(route="httpget", methods=["GET"])
def http_get(req: func.HttpRequest) -> func.HttpResponse:
    name = req.params.get("name", "World")

    logging.info(f"Processing GET request. Name: {name}")

    return func.HttpResponse(f"Hello, {name}!")
```

You can review the complete template project [here ↗](#).

After you verify your functions locally, it's time to publish them to Azure.

Deploy to Azure

This project is configured to use the `azd up` command to deploy this project to a new function app in a Flex Consumption plan in Azure.

💡 Tip

This project includes a set of Bicep files that `azd` uses to create a secure deployment to a Flex consumption plan that follows best practices.

1. Run this command to have `azd` create the required Azure resources in Azure and deploy your code project to the new function app:

Console

```
azd up
```

The root folder contains the `azure.yaml` definition file required by `azd`.

If you aren't already signed-in, you're asked to authenticate with your Azure account.

2. When prompted, provide these required deployment parameters:

[+] Expand table

Parameter	Description
<i>Azure subscription</i>	Subscription in which your resources are created.
<i>Azure location</i>	Azure region in which to create the resource group that contains the new Azure resources. Only regions that currently support the Flex Consumption plan are shown.

The `azd up` command uses your response to these prompts with the Bicep configuration files to complete these deployment tasks:

- Create and configure these required Azure resources (equivalent to `azd provision`):
 - Flex Consumption plan and function app
 - Azure Storage (required) and Application Insights (recommended)
 - Access policies and roles for your account
 - Service-to-service connections using managed identities (instead of stored connection strings)
 - Virtual network to securely run both the function app and the other Azure resources
- Package and deploy your code to the deployment container (equivalent to `azd deploy`). The app is then started and runs in the deployed package.

After the command completes successfully, you see links to the resources you created.

Invoke the function on Azure

You can now invoke your function endpoints in Azure by making HTTP requests to their URLs using your HTTP test tool or from the browser (for GET requests). When your functions run in Azure, access key authorization is enforced, and you must provide a function access key with your request.

You can use the Core Tools to obtain the URL endpoints of your functions running in Azure.

1. In your local terminal or command prompt, run these commands to get the URL endpoint values:

```
bash
```

Bash

```
SET APP_NAME=(azd env get-value AZURE_FUNCTION_NAME)
func azure functionapp list-functions $APP_NAME --show-keys
```

The `azd env get-value` command gets your function app name from the local environment. Using the `--show-keys` option with `func azure functionapp list-functions` means that the returned **Invoke URL:** value for each endpoint includes a function-level access key.

2. As before, use your HTTP test tool to validate these URLs in your function app running in Azure.

Redeploy your code

You can run the `azd up` command as many times as you need to both provision your Azure resources and deploy code updates to your function app.

 Note

Deployed code files are always overwritten by the latest deployment package.

Your initial responses to `azd` prompts and any environment variables generated by `azd` are stored locally in your named environment. Use the `azd env get-values` command to review all of the variables in your environment that were used when creating Azure resources.

Clean up resources

When you're done working with your function app and related resources, you can use this command to delete the function app and its related resources from Azure and avoid incurring any further costs:

Console

```
azd down --no-prompt
```

 Note

The `--no-prompt` option instructs `azd` to delete your resource group without a confirmation from you.

This command doesn't affect your local code project.

Quickstart: Create a function in Azure with TypeScript using Visual Studio Code

Article • 07/18/2024

In this article, you use Visual Studio Code to create a TypeScript function that responds to HTTP requests. After testing the code locally, you deploy it to the serverless environment of Azure Functions.

ⓘ Important

The content of this article changes based on your choice of the Node.js programming model in the selector at the top of the page. The v4 model is generally available and is designed to have a more flexible and intuitive experience for JavaScript and TypeScript developers. Learn more about the differences between v3 and v4 in the [migration guide](#).

Completion of this quickstart incurs a small cost of a few USD cents or less in your Azure account.

There's also a [CLI-based version](#) of this article.

Configure your environment

Before you get started, make sure you have the following requirements in place:

- An Azure account with an active subscription. [Create an account for free](#).
- [Node.js 18.x](#) or above. Use the `node --version` command to check your version.
- [TypeScript 4.x](#). Use the `tsc -v` command to check your version.
- [Visual Studio Code](#) on one of the [supported platforms](#).
- The [Azure Functions extension v1.10.4](#) or above for Visual Studio Code.
- [Azure Functions Core Tools v4.0.5382](#) or above.

Create your local project

In this section, you use Visual Studio Code to create a local Azure Functions project in TypeScript. Later in this article, you publish your function code to Azure.

1. In Visual Studio Code, press **F1** to open the command palette and search for and run the command **Azure Functions: Create New Project...**.
2. Choose the directory location for your project workspace and choose **Select**. You should either create a new folder or choose an empty folder for the project workspace. Don't choose a project folder that is already part of a workspace.
3. Provide the following information at the prompts:

[+] Expand table

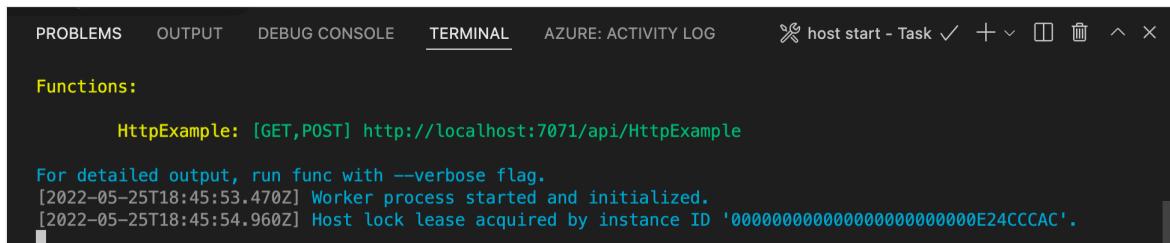

Prompt	Selection
Select a language for your function project	Choose TypeScript .
Select a TypeScript programming model	Choose Model V4
Select a template for your project's first function	Choose HTTP trigger .
Provide a function name	Type HttpExample .
Select how you would like to open your project	Choose Open in current window

Using this information, Visual Studio Code generates an Azure Functions project with an HTTP trigger. You can view the local project files in the Explorer. To learn more about files that are created, see [Azure Functions TypeScript developer guide](#).

Run the function locally

Visual Studio Code integrates with [Azure Functions Core tools](#) to let you run this project on your local development computer before you publish to Azure.

1. To start the function locally, press **F5** or the **Run and Debug** icon in the left-hand side Activity bar. The **Terminal** panel displays the Output from Core Tools. Your app starts in the **Terminal** panel. You can see the URL endpoint of your HTTP-triggered function running locally.

The screenshot shows the Visual Studio Code interface with the Terminal tab selected. The output window displays the following text:

```
PROBLEMS OUTPUT DEBUG CONSOLE TERMINAL AZURE: ACTIVITY LOG
✖ host start - Task ✓ + ×

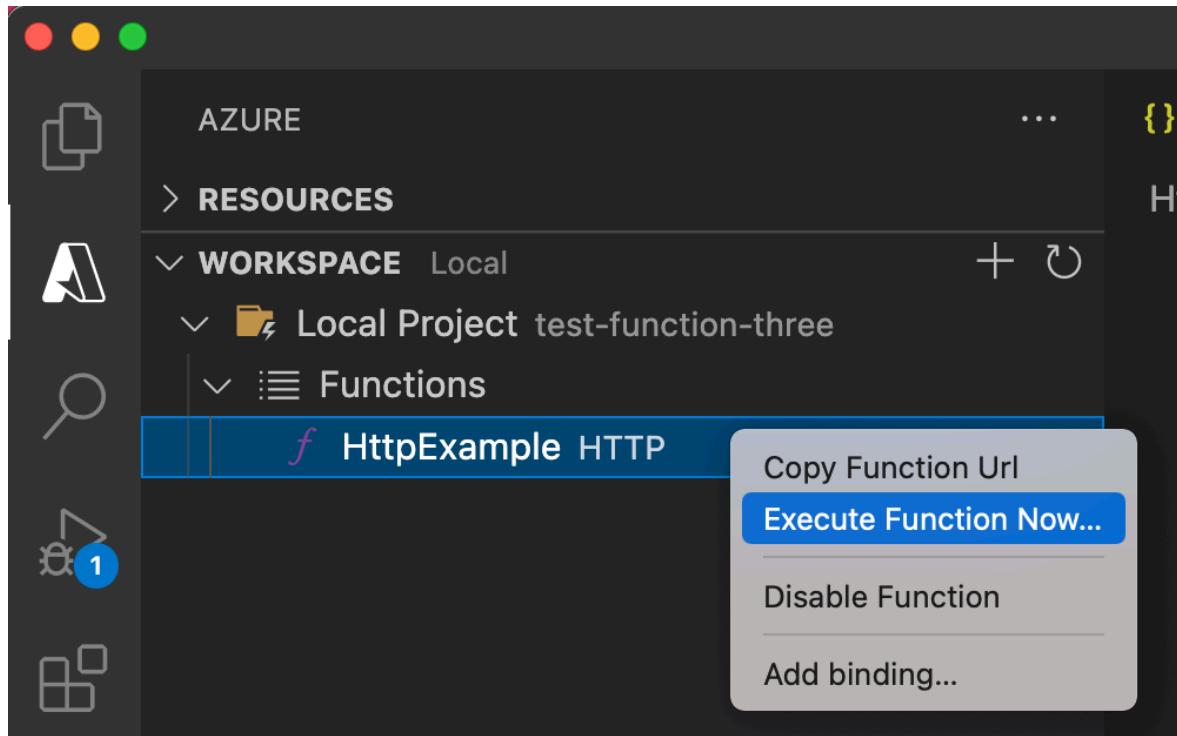

Functions:

HttpExample: [GET,POST] http://localhost:7071/api/HttpExample

For detailed output, run func with --verbose flag.
[2022-05-25T18:45:53.470Z] Worker process started and initialized.
[2022-05-25T18:45:54.960Z] Host lock lease acquired by instance ID '000000000000000000000000E24CCCAC'.
```

If you have trouble running on Windows, make sure that the default terminal for Visual Studio Code isn't set to **WSL Bash**.

2. With Core Tools still running in **Terminal**, choose the Azure icon in the activity bar. In the **Workspace** area, expand **Local Project > Functions**. Right-click (Windows) or **Ctrl + click** (macOS) the new function and choose **Execute Function Now...**

3. In **Enter request body** you see the request message body value of `{ "name": "Azure" }`. Press Enter to send this request message to your function.

4. When the function executes locally and returns a response, a notification is raised in Visual Studio Code. Information about the function execution is shown in **Terminal** panel.

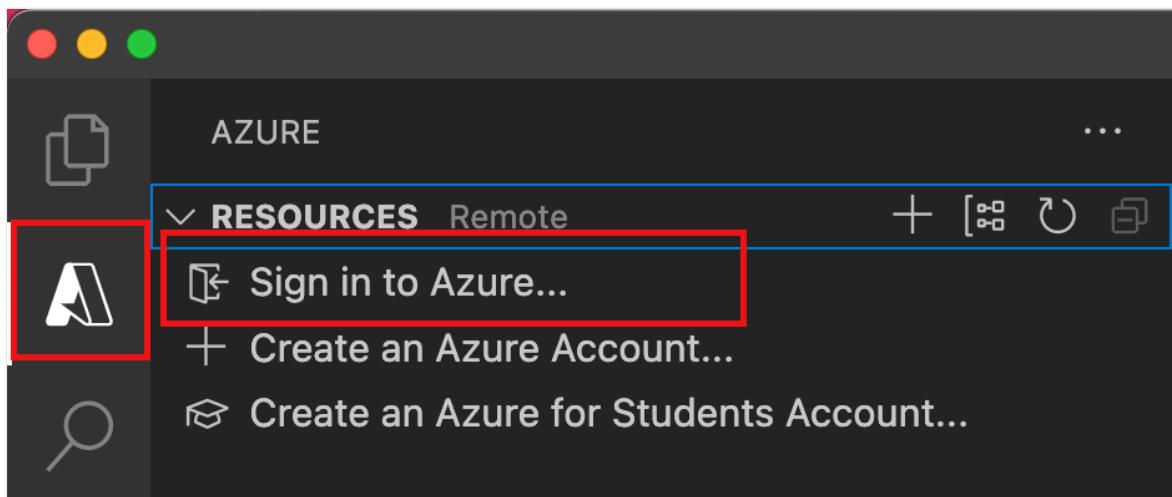

5. With the **Terminal** panel focused, press **Ctrl + c** to stop Core Tools and disconnect the debugger.

After you've verified that the function runs correctly on your local computer, it's time to use Visual Studio Code to publish the project directly to Azure.

Sign in to Azure

Before you can create Azure resources or publish your app, you must sign in to Azure.

1. If you aren't already signed in, in the **Activity bar**, select the Azure icon. Then under **Resources**, select **Sign in to Azure**.

If you're already signed in and can see your existing subscriptions, go to the next section. If you don't yet have an Azure account, select **Create an Azure Account**. Students can select **Create an Azure for Students Account**.

2. When you are prompted in the browser, select your Azure account and sign in by using your Azure account credentials. If you create a new account, you can sign in after your account is created.
3. After you successfully sign in, you can close the new browser window. The subscriptions that belong to your Azure account are displayed in the side bar.

Create the function app in Azure

In this section, you create a function app and related resources in your Azure subscription. Many of the resource creation decisions are made for you based on default behaviors.

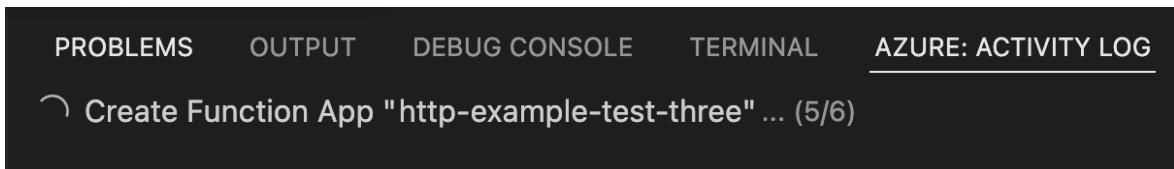

1. In Visual Studio Code, select F1 to open the command palette. At the prompt (>), enter and then select **Azure Functions: Create Function App in Azure**.
2. At the prompts, provide the following information:

[] [Expand table](#)

Prompt	Action
Select subscription	Select the Azure subscription to use. The prompt doesn't appear when you have only one subscription visible under Resources .
Enter a globally unique name for the function app	Enter a name that is valid in a URL path. The name you enter is validated to make sure that it's unique in Azure Functions.

Prompt	Action
Select a runtime stack	Select the language version you currently run locally.
Select a location for new resources	Select an Azure region. For better performance, select a region near you .

In the **Azure: Activity Log** panel, the Azure extension shows the status of individual resources as they're created in Azure.

3. When the function app is created, the following related resources are created in your Azure subscription. The resources are named based on the name you entered for your function app.

- A [resource group](#), which is a logical container for related resources.
- A standard [Azure Storage account](#), which maintains state and other information about your projects.
- A function app, which provides the environment for executing your function code. A function app lets you group functions as a logical unit for easier management, deployment, and sharing of resources within the same hosting plan.
- An Azure App Service plan, which defines the underlying host for your function app.
- An Application Insights instance that's connected to the function app, and which tracks the use of your functions in the app.

A notification is displayed after your function app is created and the deployment package is applied.

💡 Tip

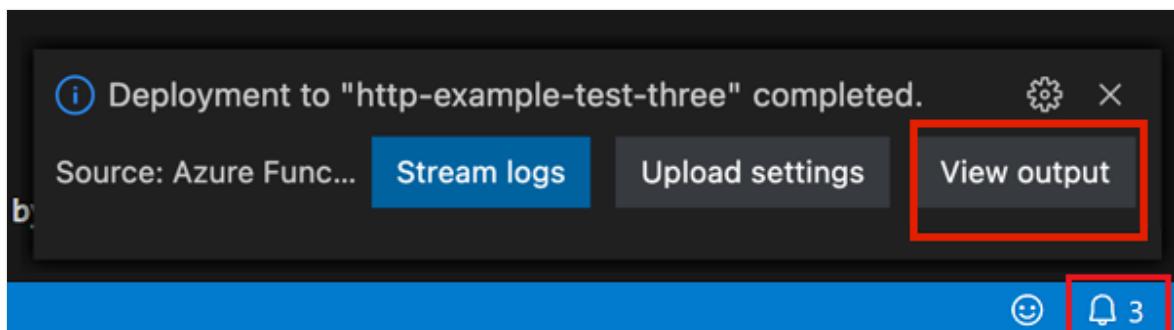

By default, the Azure resources required by your function app are created based on the name you enter for your function app. By default, the resources are created with the function app in the same, new resource group. If you want to customize the names of the associated resources or reuse existing resources, [publish the project with advanced create options](#).

Deploy the project to Azure

ⓘ Important

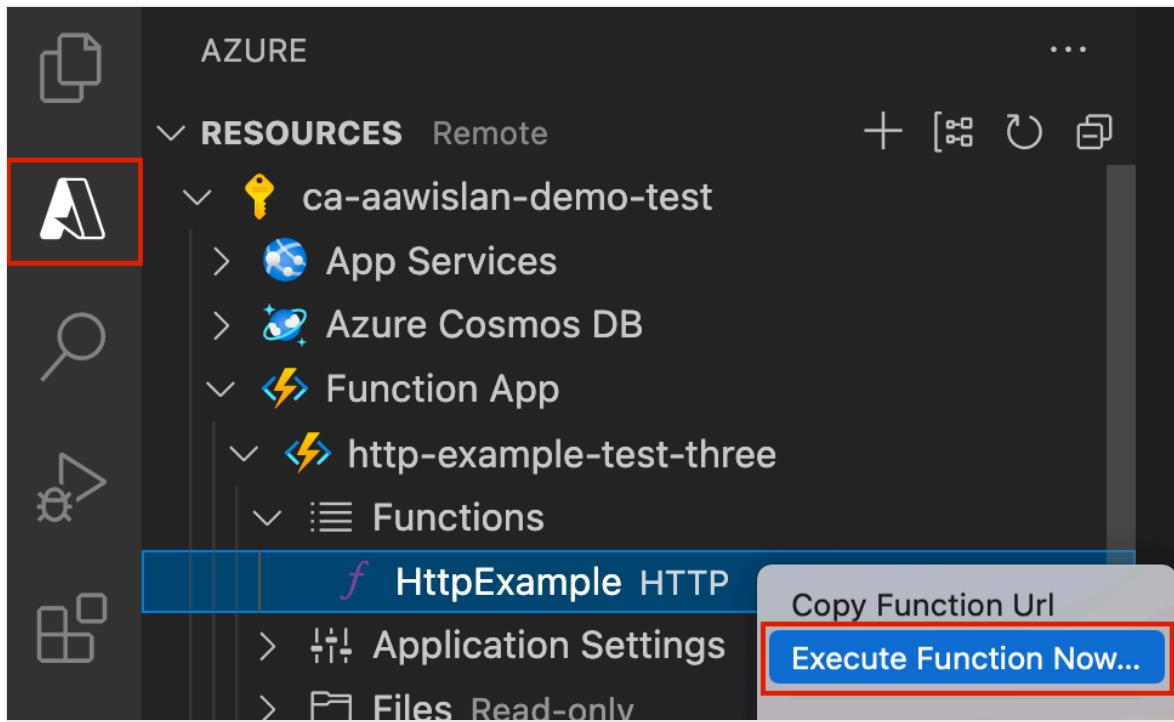

Deploying to an existing function app always overwrites the contents of that app in Azure.

1. In the command palette, enter and then select **Azure Functions: Deploy to Function App**.
2. Select the function app you just created. When prompted about overwriting previous deployments, select **Deploy** to deploy your function code to the new function app resource.
3. When deployment is completed, select **View Output** to view the creation and deployment results, including the Azure resources that you created. If you miss the notification, select the bell icon in the lower-right corner to see it again.

Run the function in Azure

1. Back in the **Resources** area in the side bar, expand your subscription, your new function app, and **Functions**. Right-click (Windows) or **Ctrl -** click (macOS) the `HttpExample` function and choose **Execute Function Now....**

2. In **Enter request body** you see the request message body value of `{ "name": "Azure" }`. Press Enter to send this request message to your function.
3. When the function executes in Azure and returns a response, a notification is raised in Visual Studio Code.

Clean up resources

When you continue to the [next step](#) and add an Azure Storage queue binding to your function, you'll need to keep all your resources in place to build on what you've already done.

Otherwise, you can use the following steps to delete the function app and its related resources to avoid incurring any further costs.

1. In Visual Studio Code, press `F1` to open the command palette. In the command palette, search for and select `Azure: Open in portal`.
2. Choose your function app and press `Enter`. The function app page opens in the Azure portal.
3. In the **Overview** tab, select the named link next to **Resource group**.

The screenshot shows the Azure portal's 'Overview' page for a function app named 'myfunctionapp'. The 'Resource group (change)' section is highlighted with a red box. Key details shown include:

- Status: Running
- Location: Central US
- Subscription: Visual Studio Enterprise
- Runtime version: 3.0.13139.0

The left sidebar lists various navigation options, and the bottom of the page has tabs for Metrics, Features (8), Notifications (0), and Quickstart.

4. On the **Resource group** page, review the list of included resources, and verify that they're the ones you want to delete.

5. Select **Delete resource group**, and follow the instructions.

Deletion may take a couple of minutes. When it's done, a notification appears for a few seconds. You can also select the bell icon at the top of the page to view the notification.

For more information about Functions costs, see [Estimating Consumption plan costs](#).

Next steps

You have used [Visual Studio Code](#) to create a function app with a simple HTTP-triggered function. In the next article, you expand that function by connecting to Azure Storage. To learn more about connecting to other Azure services, see [Add bindings to an existing function in Azure Functions](#).

[Connect to an Azure Storage queue](#)

Quickstart: Create a TypeScript function in Azure from the command line

Article • 12/19/2023

In this article, you use command-line tools to create a TypeScript function that responds to HTTP requests. After testing the code locally, you deploy it to the serverless environment of Azure Functions.

ⓘ Important

The content of this article changes based on your choice of the Node.js programming model in the selector at the top of the page. The v4 model is generally available and is designed to have a more flexible and intuitive experience for JavaScript and TypeScript developers. Learn more about the differences between v3 and v4 in the [migration guide](#).

Completion of this quickstart incurs a small cost of a few USD cents or less in your Azure account.

There's also a [Visual Studio Code-based version](#) of this article.

Configure your local environment

Before you begin, you must have the following prerequisites:

- An Azure account with an active subscription. [Create an account for free](#).
- One of the following tools for creating Azure resources:
 - [Azure CLI](#) version 2.4 or later.
 - The Azure [Az PowerShell module](#) version 5.9.0 or later.
- [Node.js](#) version 18 or above.
- [TypeScript](#) version 4+.

Install the Azure Functions Core Tools

The recommended way to install Core Tools depends on the operating system of your local development computer.

The following steps use a Windows installer (MSI) to install Core Tools v4.x. For more information about other package-based installers, see the [Core Tools readme](#).

Download and run the Core Tools installer, based on your version of Windows:

- [v4.x - Windows 64-bit](#) (Recommended. Visual Studio Code debugging requires 64-bit.)
- [v4.x - Windows 32-bit](#)

If you previously used Windows installer (MSI) to install Core Tools on Windows, you should uninstall the old version from Add Remove Programs before installing the latest version.

- Make sure you install version v4.0.5382 of the Core Tools, or a later version.

Create a local function project

In Azure Functions, a function project is a container for one or more individual functions that each responds to a specific trigger. All functions in a project share the same local and hosting configurations. In this section, you create a function project that contains a single function.

1. In a suitable folder, run the `func init` command, as follows, to create a TypeScript Node.js v4 project in the current folder:

```
Console  
func init --typescript
```

This folder now contains various files for the project, including configurations files named `local.settings.json` and `host.json`. Because `local.settings.json` can contain secrets downloaded from Azure, the file is excluded from source control by default in the `.gitignore` file. Required npm packages are also installed in `node_modules`.

2. Add a function to your project by using the following command, where the `--name` argument is the unique name of your function (HttpExample) and the `--template` argument specifies the function's trigger (HTTP).

```
Console
```

```
func new --name HttpExample --template "HTTP trigger" --authlevel  
"anonymous"
```

`func new` creates a file named *HttpExample.ts* in the *src/functions* directory, which contains your function's code.

3. Add Azure Storage connection information in *local.settings.json*.

JSON

```
{  
  "Values": {  
    "AzureWebJobsStorage": "<Azure Storage connection  
information>",  
    "FUNCTIONS_WORKER_RUNTIME": "node"  
  }  
}
```

4. (Optional) If you want to learn more about a particular function, say HTTP trigger, you can run the following command:

Console

```
func help httptrigger
```

Run the function locally

1. Run your function by starting the local Azure Functions runtime host from the *LocalFunctionProj* folder:

Console

```
npm start
```

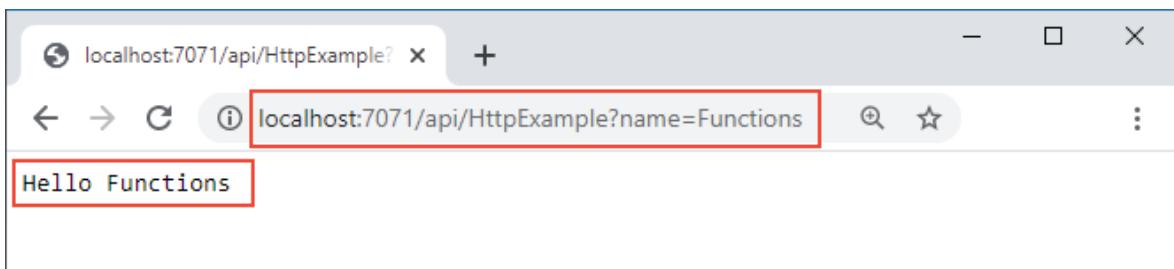

Toward the end of the output, the following logs should appear:

```
Azure Functions Core Tools  
Core Tools Version: 4.0.5049 Commit hash: N/A (64-bit)  
Function Runtime Version: 4.15.2.20177  
  
[2023-03-17T03:27:12.372Z] Worker process started and initialized.  
  
Functions:  
  
  HttpExample: [GET,POST] http://localhost:7071/api/HttpExample
```

(!) Note

If `HttpExample` doesn't appear as shown in the logs, you likely started the host from outside the root folder of the project. In that case, use `Ctrl + C` to stop the host, navigate to the project's root folder, and run the previous command again.

2. Copy the URL of your `HttpExample` function from this output to a browser and append the query string `?name=<your-name>`, making the full URL like `http://localhost:7071/api/HttpExample?name=Functions`. The browser should display a message like `Hello Functions`:

The terminal in which you started your project also shows log output as you make requests.

3. When you're ready, use `Ctrl + C` and choose `y` to stop the functions host.

Create supporting Azure resources for your function

Before you can deploy your function code to Azure, you need to create three resources:

- A [resource group](#), which is a logical container for related resources.
- A [Storage account](#), which is used to maintain state and other information about your functions.
- A function app, which provides the environment for executing your function code. A function app maps to your local function project and lets you group functions as a logical unit for easier management, deployment, and sharing of resources.

Use the following commands to create these items. Both Azure CLI and PowerShell are supported.

1. If you haven't done so already, sign in to Azure:

Azure CLI

Azure CLI

```
az login
```

The `az login` command signs you into your Azure account.

2. Create a resource group named `AzureFunctionsQuickstart-rg` in your chosen region:

Azure CLI

Azure CLI

```
az group create --name AzureFunctionsQuickstart-rg --location  
<REGION>
```

The `az group create` command creates a resource group. In the above command, replace `<REGION>` with a region near you, using an available region code returned from the `az account list-locations` command.

3. Create a general-purpose storage account in your resource group and region:

Azure CLI

Azure CLI

```
az storage account create --name <STORAGE_NAME> --location <REGION>  
--resource-group AzureFunctionsQuickstart-rg --sku Standard_LRS --  
allow-blob-public-access false
```

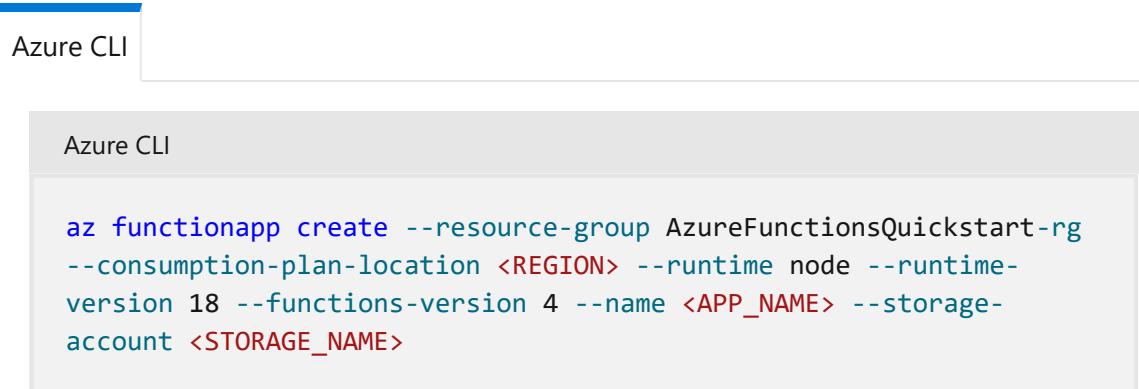

The `az storage account create` command creates the storage account.

In the previous example, replace `<STORAGE_NAME>` with a name that is appropriate to you and unique in Azure Storage. Names must contain three to 24 characters numbers and lowercase letters only. `Standard_LRS` specifies a general-purpose account, which is [supported by Functions](#).

 **Important**

The storage account is used to store important app data, sometimes including the application code itself. You should limit access from other apps and users to the storage account.

4. Create the function app in Azure:

```
Azure CLI
az functionapp create --resource-group AzureFunctionsQuickstart-rg
--consumption-plan-location <REGION> --runtime node --runtime-
version 18 --functions-version 4 --name <APP_NAME> --storage-
account <STORAGE_NAME>
```

The `az functionapp create` command creates the function app in Azure. It's recommended that you use the latest version of Node.js, which is currently 18. You can specify the version by setting `--runtime-version` to 18.

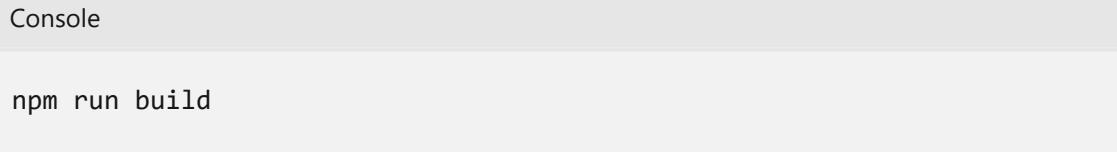

In the previous example, replace `<STORAGE_NAME>` with the name of the account you used in the previous step, and replace `<APP_NAME>` with a globally unique name appropriate to you. The `<APP_NAME>` is also the default DNS domain for the function app.

This command creates a function app running in your specified language runtime under the [Azure Functions Consumption Plan](#), which is free for the amount of usage you incur here. The command also creates an associated Azure Application Insights instance in the same resource group, with which you can monitor your function app and view logs. For more information, see [Monitor Azure Functions](#). The instance incurs no costs until you activate it.

Deploy the function project to Azure

Before you use Core Tools to deploy your project to Azure, you create a production-ready build of JavaScript files from the TypeScript source files.

1. Use the following command to prepare your TypeScript project for deployment:

```
Console
npm run build
```

2. With the necessary resources in place, you're now ready to deploy your local functions project to the function app in Azure by using the [publish](#) command. In the following example, replace `<APP_NAME>` with the name of your app.

Console

```
func azure functionapp publish <APP_NAME>
```

If you see the error, "Can't find app with name ...", wait a few seconds and try again, as Azure may not have fully initialized the app after the previous `az functionapp create` command.

The publish command shows results similar to the following output (truncated for simplicity):

```
...
Getting site publishing info...
Creating archive for current directory...
Performing remote build for functions project.

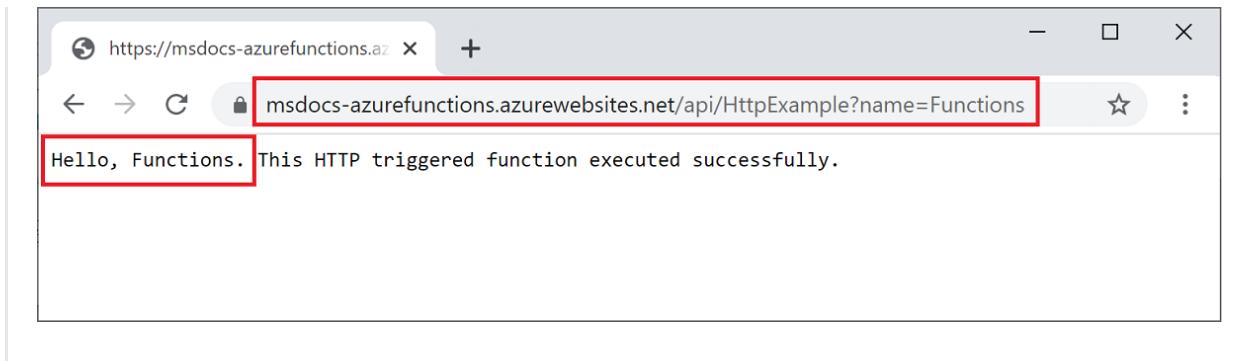

...
Deployment successful.
Remote build succeeded!
Syncing triggers...
Functions in msdocs-azurefunctions-qs:
    HttpExample - [httpTrigger]
        Invoke url: https://msdocs-azurefunctions-
qs.azurewebsites.net/api/httpexample?
code=KYHrydo4GFe9y0000000qRgRJ8NdLFKpkakGJQfC3izYVidzzDN4gQ==
```

Invoke the function on Azure

Because your function uses an HTTP trigger, you invoke it by making an HTTP request to its URL in the browser or with a tool like curl.

Browser

Copy the complete **Invoke URL** shown in the output of the publish command into a browser address bar, appending the query parameter `?name=Functions`. The browser should display similar output as when you ran the function locally.

Run the following command to view near real-time streaming logs:

```
Console  
  
func azure functionapp logstream <APP_NAME>
```

In a separate terminal window or in the browser, call the remote function again. A verbose log of the function execution in Azure is shown in the terminal.

Clean up resources

If you continue to the [next step](#) and add an Azure Storage queue output binding, keep all your resources in place as you'll build on what you've already done.

Otherwise, use the following command to delete the resource group and all its contained resources to avoid incurring further costs.

```
Azure CLI  
  
az group delete --name AzureFunctionsQuickstart-rg
```

Next steps

[Connect to an Azure Storage queue](#)

Quickstart: Create and deploy functions to Azure Functions using the Azure Developer CLI

Article • 09/09/2024

In this Quickstart, you use Azure Developer command-line tools to create functions that respond to HTTP requests. After testing the code locally, you deploy it to a new serverless function app you create running in a Flex Consumption plan in Azure Functions.

The project source uses the Azure Developer CLI (azd) to simplify deploying your code to Azure. This deployment follows current best practices for secure and scalable Azure Functions deployments.

Important

The [Flex Consumption plan](#) is currently in preview.

By default, the Flex Consumption plan follows a *pay-for-what-you-use* billing model, which means to complete this quickstart incurs a small cost of a few USD cents or less in your Azure account.

Prerequisites

- An Azure account with an active subscription. [Create an account for free](#).
- [Azure Developer CLI](#).
- [Azure Functions Core Tools](#).
- [.NET 8.0 SDK](#)
- [Azurite storage emulator](#)
- [Java 17 Developer Kit](#)
 - If you use another [supported version of Java](#), you must update the project's pom.xml file.
 - The `JAVA_HOME` environment variable must be set to the install location of the correct version of the JDK.
- [Apache Maven 3.8.x](#)

- [Node.js 20](#)
- [PowerShell 7.2](#)
- [.NET 6.0 SDK](#)
- [Python 3.11](#).
- A [secure HTTP test tool](#) for sending requests with JSON payloads to your function endpoints. This article uses `curl`.

Initialize the project

You can use the `azd init` command to create a local Azure Functions code project from a template.

1. In your local terminal or command prompt, run this `azd init` command in an empty folder:

```
Console  
  
azd init --template functions-quickstart-dotnet-azd -e flexquickstart-dotnet
```

This command pulls the project files from the [template repository](#) and initializes the project in the current folder. The `-e` flag sets a name for the current environment. In `azd`, the environment is used to maintain a unique deployment context for your app, and you can define more than one. It's also used in the name of the resource group you create in Azure.

2. Run this command to navigate to the `http` app folder:

```
Console  
  
cd http
```

3. Create a file named `local.settings.json` in the `http` folder that contains this JSON data:

```
JSON  
  
{  
    "IsEncrypted": false,  
    "Values": {
```

```
        "AzureWebJobsStorage": "UseDevelopmentStorage=true",
        "FUNCTIONS_WORKER_RUNTIME": "dotnet-isolated"
    }
}
```

This file is required when running locally.

1. In your local terminal or command prompt, run this `azd init` command in an empty folder:

Console

```
azd init --template azure-functions-java-flex-consumption-azd -e
flexquickstart-java
```

This command pulls the project files from the [template repository](#) and initializes the project in the current folder. The `-e` flag sets a name for the current environment. In `azd`, the environment is used to maintain a unique deployment context for your app, and you can define more than one. It's also used in the name of the resource group you create in Azure.

2. Run this command to navigate to the `http` app folder:

Console

```
cd http
```

3. Create a file named `local.settings.json` in the `http` folder that contains this JSON data:

JSON

```
{
    "IsEncrypted": false,
    "Values": {
        "AzureWebJobsStorage": "UseDevelopmentStorage=true",
        "FUNCTIONS_WORKER_RUNTIME": "java"
    }
}
```

This file is required when running locally.

1. In your local terminal or command prompt, run this `azd init` command in an empty folder:

Console

```
azd init --template functions-quickstart-javascript-azd -e flexquickstart-js
```

This command pulls the project files from the [template repository](#) and initializes the project in the root folder. The `-e` flag sets a name for the current environment. In `azd`, the environment is used to maintain a unique deployment context for your app, and you can define more than one. It's also used in the name of the resource group you create in Azure.

2. Create a file named `local.settings.json` in the root folder that contains this JSON data:

JSON

```
{  
    "IsEncrypted": false,  
    "Values": {  
        "AzureWebJobsStorage": "UseDevelopmentStorage=true",  
        "FUNCTIONS_WORKER_RUNTIME": "node"  
    }  
}
```

This file is required when running locally.

1. In your local terminal or command prompt, run this `azd init` command in an empty folder:

Console

```
azd init --template functions-quickstart-powershell-azd -e flexquickstart-ps
```

This command pulls the project files from the [template repository](#) and initializes the project in the root folder. The `-e` flag sets a name for the current environment. In `azd`, the environment is used to maintain a unique deployment context for your app, and you can define more than one. It's also used in the name of the resource group you create in Azure.

2. Run this command to navigate to the `src` app folder:

Console

```
cd src
```

3. Create a file named `local.settings.json` in the `src` folder that contains this JSON data:

JSON

```
{  
    "IsEncrypted": false,  
    "Values": {  
        "AzureWebJobsStorage": "UseDevelopmentStorage=true",  
        "FUNCTIONS_WORKER_RUNTIME": "powershell",  
        "FUNCTIONS_WORKER_RUNTIME_VERSION": "7.2"  
    }  
}
```

This file is required when running locally.

1. In your local terminal or command prompt, run this `azd init` command in an empty folder:

Console

```
azd init --template functions-quickstart-typescript-azd -e  
flexquickstart-ts
```

This command pulls the project files from the [template repository](#) and initializes the project in the root folder. The `-e` flag sets a name for the current environment. In `azd`, the environment is used to maintain a unique deployment context for your app, and you can define more than one. It's also used in the name of the resource group you create in Azure.

2. Create a file named `local.settings.json` in the root folder that contains this JSON data:

JSON

```
{  
    "IsEncrypted": false,  
    "Values": {  
        "AzureWebJobsStorage": "UseDevelopmentStorage=true",  
        "FUNCTIONS_WORKER_RUNTIME": "node"  
    }  
}
```

This file is required when running locally.

1. In your local terminal or command prompt, run this `azd init` command in an empty folder:

Console

```
azd init --template functions-quickstart-python-http-azd -e flexquickstart-py
```

This command pulls the project files from the [template repository](#) and initializes the project in the root folder. The `-e` flag sets a name for the current environment. In `azd`, the environment is used to maintain a unique deployment context for your app, and you can define more than one. It's also used in the name of the resource group you create in Azure.

2. Create a file named `local.settings.json` in the root folder that contains this JSON data:

JSON

```
{
  "IsEncrypted": false,
  "Values": {
    "AzureWebJobsStorage": "UseDevelopmentStorage=true",
    "FUNCTIONS_WORKER_RUNTIME": "python"
  }
}
```

This file is required when running locally.

Create and activate a virtual environment

In the root folder, run these commands to create and activate a virtual environment named `.venv`:

Linux/macOS

Bash

```
python3 -m venv .venv
source .venv/bin/activate
```

If Python didn't install the `venv` package on your Linux distribution, run the following command:

```
Bash
```

```
sudo apt-get install python3-venv
```

Run in your local environment

1. Run this command from your app folder in a terminal or command prompt:

```
Console
```

```
func start
```

```
Console
```

```
mvn clean package  
mvn azure-functions:run
```

```
Console
```

```
npm start
```

When the Functions host starts in your local project folder, it writes the URL endpoints of your HTTP triggered functions to the terminal output.

2. In your browser, navigate to the `httpget` endpoint, which should look like this URL:

<http://localhost:7071/api/httpget>

3. From a new terminal or command prompt window, run this `curl` command to send a POST request with a JSON payload to the `httppost` endpoint:

```
Console
```

```
curl -i http://localhost:7071/api/httppost -H "Content-Type: text/json"  
-d @testdata.json
```

This command reads JSON payload data from the `testdata.json` project file. You can find examples of both HTTP requests in the `test.http` project file.

4. When you're done, press Ctrl+C in the terminal window to stop the `func.exe` host process.

5. Run `deactivate` to shut down the virtual environment.

Review the code (optional)

You can review the code that defines the two HTTP trigger function endpoints:

httpget

C#

```
[Function("httpget")]
    public IActionResult
Run([HttpTrigger(AuthorizationLevel.Function, "get")]
    HttpRequest req,
    string name)
{
    var returnValue = string.IsNullOrEmpty(name)
        ? "Hello, World."
        : $"Hello, {name}.";

    _logger.LogInformation($"C# HTTP trigger function processed
a request for {returnValue}.");

    return new OkObjectResult(returnValue);
}
```

Java

```
@FunctionName("httpget")
public HttpResponseMessage run(
    @HttpTrigger(
        name = "req",
        methods = {HttpMethod.GET},
        authLevel = AuthorizationLevel.FUNCTION)
    HttpRequestMessage<Optional<String>> request,
    final ExecutionContext context) {
    context.getLogger().info("Java HTTP trigger processed a request.");

    // Parse query parameter
    String name =
Optional.ofNullable(request.getQueryParameters().get("name")).orElse("Wo
rld");

    return request.createResponseBuilder(HttpStatus.OK).body("Hello, " +
```

```
name).build();
}
```

JavaScript

```
const { app } = require('@azure/functions');

app.http('httpGetFunction', {
    methods: ['GET'],
    authLevel: 'function',
    handler: async (request, context) => {
        context.log(`Http function processed request for url
"${request.url}"`);

        const name = request.query.get('name') || await request.text()
        || 'world';

        return { body: `Hello, ${name}!` };
    }
});
```

TypeScript

```
import { app, HttpRequest, HttpResponseInit, InvocationContext } from
"@azure/functions";

export async function httpGetFunction(request: HttpRequest, context:
InvocationContext): Promise<HttpResponseInit> {
    context.log(`Http function processed request for url
"${request.url}"`);

    const name = request.query.get('name') || await request.text() ||
    'world';

    return { body: `Hello, ${name}!` };
}

app.http('httpget', {
    methods: ['GET'],
    authLevel: 'function',
    handler: httpGetFunction
});
```

This `function.json` file defines the `httpget` function:

JSON

```
{
    "bindings": [
        {
```

```
    "authLevel": "function",
    "type": "httpTrigger",
    "direction": "in",
    "name": "Request",
    "methods": [
        "get"
    ],
},
{
    "type": "http",
    "direction": "out",
    "name": "Response"
}
]
```

This `run.ps1` file implements the function code:

PowerShell

```
using namespace System.Net

# Input bindings are passed in via param block.
param($Request, $TriggerMetadata)

# Write to the Azure Functions log stream.
Write-Host "PowerShell HTTP trigger function processed a request."

# Interact with query parameters
$name = $Request.Query.name

$body = "This HTTP triggered function executed successfully. Pass a name
in the query string for a personalized response."

if ($name) {
    $body = "Hello, $name. This HTTP triggered function executed
successfully."
}

# Associate values to output bindings by calling 'Push-OutputBinding'.
Push-OutputBinding -Name Response -Value ([HttpResponseContext]@{
    StatusCode = [HttpStatusCode]::OK
    Body = $body
})
```

Python

```
@app.route(route="httpget", methods=["GET"])
def http_get(req: func.HttpRequest) -> func.HttpResponse:
    name = req.params.get("name", "World")

    logging.info(f"Processing GET request. Name: {name}")
```

```
return func.HttpResponse(f"Hello, {name}!")
```

After you verify your functions locally, it's time to publish them to Azure.

Create Azure resources

This project is configured to use the `azd provision` command to create a function app in a Flex Consumption plan, along with other required Azure resources.

ⓘ Note

This project includes a set of Bicep files that `azd` uses to create a secure deployment to a Flex consumption plan that follows best practices.

The `azd up` and `azd deploy` commands aren't currently supported for Java apps.

1. In the root folder of the project, run this command to create the required Azure resources:

Console

```
azd provision
```

The root folder contains the `azure.yaml` definition file required by `azd`.

If you aren't already signed-in, you're asked to authenticate with your Azure account.

2. When prompted, provide these required deployment parameters:

Parameter	Description
<i>Azure subscription</i>	Subscription in which your resources are created.
<i>Azure location</i>	Azure region in which to create the resource group that contains the new Azure resources. Only regions that currently support the Flex Consumption plan are shown.

The `azd provision` command uses your response to these prompts with the Bicep configuration files to create and configure these required Azure resources:

- Flex Consumption plan and function app
- Azure Storage (required) and Application Insights (recommended)
- Access policies and roles for your account
- Service-to-service connections using managed identities (instead of stored connection strings)
- Virtual network to securely run both the function app and the other Azure resources

After the command completes successfully, you can deploy your project code to this new function app in Azure.

Deploy to Azure

You can use Core Tools to package your code and deploy it to Azure from the `target` output folder.

1. Navigate to the app folder equivalent in the `target` output folder:

```
Console
cd http/target/azure-functions/contoso-functions
```

This folder should have a `host.json` file, which indicates that it's the root of your compiled Java function app.

2. Run these commands to deploy your compiled Java code project to the new function app resource in Azure using Core Tools:

```
bash
```

Bash

```
APP_NAME=$(azd env get-value AZURE_FUNCTION_NAME)
func azure functionapp publish $APP_NAME
```

The `azd env get-value` command gets your function app name from the local environment, which is required for deployment using `func azure functionapp publish`. After publishing completes successfully, you see links to the HTTP trigger endpoints in Azure.

Deploy to Azure

This project is configured to use the `azd up` command to deploy this project to a new function app in a Flex Consumption plan in Azure.

Tip

This project includes a set of Bicep files that `azd` uses to create a secure deployment to a Flex consumption plan that follows best practices.

1. Run this command to have `azd` create the required Azure resources in Azure and deploy your code project to the new function app:

Console

```
azd up
```

The root folder contains the `azure.yaml` definition file required by `azd`.

If you aren't already signed-in, you're asked to authenticate with your Azure account.

2. When prompted, provide these required deployment parameters:

[\[+\] Expand table](#)

Parameter	Description
<code>Azure subscription</code>	Subscription in which your resources are created.

Parameter	Description
<i>Azure location</i>	Azure region in which to create the resource group that contains the new Azure resources. Only regions that currently support the Flex Consumption plan are shown.

The `azd up` command uses your response to these prompts with the Bicep configuration files to complete these deployment tasks:

- Create and configure these required Azure resources (equivalent to `azd provision`):
 - Flex Consumption plan and function app
 - Azure Storage (required) and Application Insights (recommended)
 - Access policies and roles for your account
 - Service-to-service connections using managed identities (instead of stored connection strings)
 - Virtual network to securely run both the function app and the other Azure resources
- Package and deploy your code to the deployment container (equivalent to `azd deploy`). The app is then started and runs in the deployed package.

After the command completes successfully, you see links to the resources you created.

Invoke the function on Azure

You can now invoke your function endpoints in Azure by making HTTP requests to their URLs using your HTTP test tool or from the browser (for GET requests). When your functions run in Azure, access key authorization is enforced, and you must provide a function access key with your request.

You can use the Core Tools to obtain the URL endpoints of your functions running in Azure.

1. In your local terminal or command prompt, run these commands to get the URL endpoint values:

```
bash
```

Bash

```
SET APP_NAME=(azd env get-value AZURE_FUNCTION_NAME)
func azure functionapp list-functions $APP_NAME --show-keys
```

PowerShell

```
$APP_NAME = azd env get-value AZURE_FUNCTION_NAME
func azure functionapp list-functions $APP_NAME --show-keys
```

The `azd env get-value` command gets your function app name from the local environment. Using the `--show-keys` option with `func azure functionapp list-functions` means that the returned **Invoke URL:** value for each endpoint includes a function-level access key.

2. As before, use your HTTP test tool to validate these URLs in your function app running in Azure.

Redeploy your code

You can run the `azd up` command as many times as you need to both provision your Azure resources and deploy code updates to your function app.

 **Note**

Deployed code files are always overwritten by the latest deployment package.

Your initial responses to `azd` prompts and any environment variables generated by `azd` are stored locally in your named environment. Use the `azd env get-values` command to review all of the variables in your environment that were used when creating Azure resources.

Clean up resources

When you're done working with your function app and related resources, you can use this command to delete the function app and its related resources from Azure and avoid incurring any further costs:

Console

```
azd down --no-prompt
```

Note

The `--no-prompt` option instructs `azd` to delete your resource group without a confirmation from you.

This command doesn't affect your local code project.

Quickstart: Create a Go or Rust function in Azure using Visual Studio Code

Article • 07/18/2024

In this article, you use Visual Studio Code to create a [custom handler](#) function that responds to HTTP requests. After testing the code locally, you deploy it to the serverless environment of Azure Functions.

Custom handlers can be used to create functions in any language or runtime by running an HTTP server process. This article supports both [Go](#) and [Rust](#).

Completing this quickstart incurs a small cost of a few USD cents or less in your Azure account.

Configure your environment

Before you get started, make sure you have the following requirements in place:

Go

- An Azure account with an active subscription. [Create an account for free ↗](#).
- [Visual Studio Code ↗](#) on one of the [supported platforms ↗](#).
- The [Azure Functions extension ↗](#) for Visual Studio Code.
- [Go ↗](#), latest version recommended. Use the `go version` command to check your version.

Install or update Core Tools

The Azure Functions extension for Visual Studio Code integrates with Azure Functions Core Tools so that you can run and debug your functions locally in Visual Studio Code using the Azure Functions runtime. Before getting started, it's a good idea to install Core Tools locally or update an existing installation to use the latest version.

In Visual Studio Code, select F1 to open the command palette, and then search for and run the command **Azure Functions: Install or Update Core Tools**.

This command tries to either start a package-based installation of the latest version of Core Tools or update an existing package-based installation. If you don't have npm or Homebrew installed on your local computer, you must instead [manually install or update Core Tools](#).

Create your local project

In this section, you use Visual Studio Code to create a local Azure Functions custom handlers project. Later in this article, you'll publish your function code to Azure.

1. In Visual Studio Code, press `F1` to open the command palette and search for and run the command `Azure Functions: Create New Project...`.
2. Choose the directory location for your project workspace and choose **Select**. You should either create a new folder or choose an empty folder for the project workspace. Don't choose a project folder that is already part of a workspace.
3. Provide the following information at the prompts:

[+] Expand table

Prompt	Selection
Select a language for your function project	Choose <code>Custom Handler</code> .
Select a template for your project's first function	Choose <code>HTTP trigger</code> .
Provide a function name	Type <code>HttpExample</code> .
Authorization level	Choose <code>Anonymous</code> , which enables anyone to call your function endpoint. For more information, see Authorization level .
Select how you would like to open your project	Choose <code>Open in current window</code> .

Using this information, Visual Studio Code generates an Azure Functions project with an HTTP trigger. You can view the local project files in the Explorer.

Create and build your function

The `function.json` file in the `HttpExample` folder declares an HTTP trigger function. You complete the function by adding a handler and compiling it into an executable.

Go

1. Press **Ctrl + N** (**Cmd + N** on macOS) to create a new file. Save it as *handler.go* in the function app root (in the same folder as *host.json*).
2. In *handler.go*, add the following code and save the file. This is your Go custom handler.

Go

```
package main

import (
    "fmt"
    "log"
    "net/http"
    "os"
)

func helloHandler(w http.ResponseWriter, r *http.Request) {
    message := "This HTTP triggered function executed successfully.
    Pass a name in the query string for a personalized response.\n"
    name := r.URL.Query().Get("name")
    if name != "" {
        message = fmt.Sprintf("Hello, %s. This HTTP triggered
        function executed successfully.\n", name)
    }
    fmt.Fprint(w, message)
}

func main() {
    listenAddr := ":8080"
    if val, ok := os.LookupEnv("FUNCTIONS_CUSTOMHANDLER_PORT"); ok
    {
        listenAddr = ":" + val
    }
    http.HandleFunc("/api/HttpExample", helloHandler)
    log.Printf("About to listen on %s. Go to https://127.0.0.1%s/",
    listenAddr, listenAddr)
    log.Fatal(http.ListenAndServe(listenAddr, nil))
}
```

3. Press **Ctrl + Shift + `** or select *New Terminal* from the *Terminal* menu to open a new integrated terminal in VS Code.
4. Compile your custom handler using the following command. An executable file named `handler` (`handler.exe` on Windows) is output in the function app root folder.

The screenshot shows a VS Code interface with the following details:

- Explorer View:** Shows a folder named "20201122-TEST-GO" containing ".vscode", "HttpExample", "handler.go", "host.json", "local.settings.json", and "proxies.json".
- Editor View:** Displays the file "handler.go" with the following code:

```

1 package main
2
3 import (
4     "fmt"
5     "log"
6     "net/http"
7     "os"
8 )
9
10 func helloHandler(w http.ResponseWriter, r *http.Request) {
11     name := r.URL.Query().Get("name")
12     if name == "" {
13         w.Write([]byte("This HTTP triggered function executed successfully. Pass a query parameter named 'name'"))
14     } else {
15         w.Write([]byte("Hello, " + name + ". This HTTP triggered function executed"))
16     }

```
- Terminal View:** Shows the command "go build handler.go" being run in the terminal, with the output "antchu-macbook:20201122-test-go antchu\$ go build handler.go" and "antchu-macbook:20201122-test-go antchu\$".

Configure your function app

The function host needs to be configured to run your custom handler binary when it starts.

1. Open `host.json`.
2. In the `customHandler.description` section, set the value of `defaultExecutablePath` to `handler` (on Windows, set it to `handler.exe`).
3. In the `customHandler` section, add a property named `enableForwardingHttpRequest` and set its value to `true`. For functions consisting of only an HTTP trigger, this setting simplifies programming by allow you to work with a typical HTTP request instead of the custom handler `request payload`.
4. Confirm the `customHandler` section looks like this example. Save the file.

```

"customHandler": {
    "description": {
        "defaultExecutablePath": "handler",
        "workingDirectory": "",
        "arguments": []
    },
}

```

```
        "enableForwardingHttpRequest": true  
    }
```

The function app is configured to start your custom handler executable.

Run the function locally

You can run this project on your local development computer before you publish to Azure.

1. In the integrated terminal, start the function app using Azure Functions Core Tools.

```
Bash
```

```
func start
```

2. With Core Tools running, navigate to the following URL to execute a GET request, which includes `?name=Functions` query string.

```
http://localhost:7071/api/HttpExample?name=Functions
```

3. A response is returned, which looks like the following in a browser:

4. Information about the request is shown in **Terminal** panel.

```
[1/30/2020 7:26:15 PM] Executing HTTP request: {
[1/30/2020 7:26:15 PM]   "requestId": "6660fd29-2b0d-41fc-9a17-a4f700415a84",
[1/30/2020 7:26:15 PM]   "method": "GET",
[1/30/2020 7:26:15 PM]   "uri": "/api/HttpExample"
[1/30/2020 7:26:15 PM] }
[1/30/2020 7:26:15 PM] Executing 'Functions.HttpExample' (Reason='This function was programmatically called via
a the host APIs.', Id=65d05c7f-5192-4ff2-a1c6-d8b3a78385d3)
[1/30/2020 7:26:15 PM] JavaScript HTTP trigger function processed a request.
[1/30/2020 7:26:15 PM] Executed 'Functions.HttpExample' (Succeeded, Id=65d05c7f-5192-4ff2-a1c6-d8b3a78385d3)
[1/30/2020 7:26:15 PM] Executed HTTP request: {
[1/30/2020 7:26:15 PM]   "requestId": "6660fd29-2b0d-41fc-9a17-a4f700415a84",
[1/30/2020 7:26:15 PM]   "method": "GET",
[1/30/2020 7:26:15 PM]   "uri": "/api/HttpExample",
[1/30/2020 7:26:15 PM]   "identities": [
[1/30/2020 7:26:15 PM]     {
[1/30/2020 7:26:15 PM]       "type": "WebJobsAuthLevel",
[1/30/2020 7:26:15 PM]       "level": "Admin"
[1/30/2020 7:26:15 PM]     }
[1/30/2020 7:26:15 PM]   ],
[1/30/2020 7:26:15 PM]   "status": 200,
[1/30/2020 7:26:15 PM]   "duration": 39
[1/30/2020 7:26:15 PM] }
```

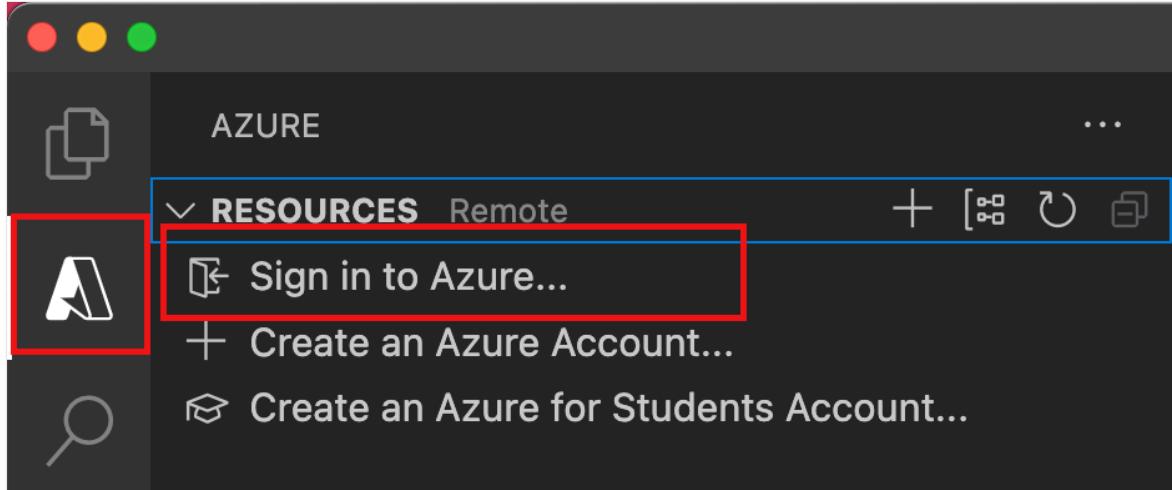

5. Press `ctrl + c` to stop Core Tools.

After you've verified that the function runs correctly on your local computer, it's time to use Visual Studio Code to publish the project directly to Azure.

Sign in to Azure

Before you can create Azure resources or publish your app, you must sign in to Azure.

1. If you aren't already signed in, in the **Activity bar**, select the Azure icon. Then under **Resources**, select **Sign in to Azure**.

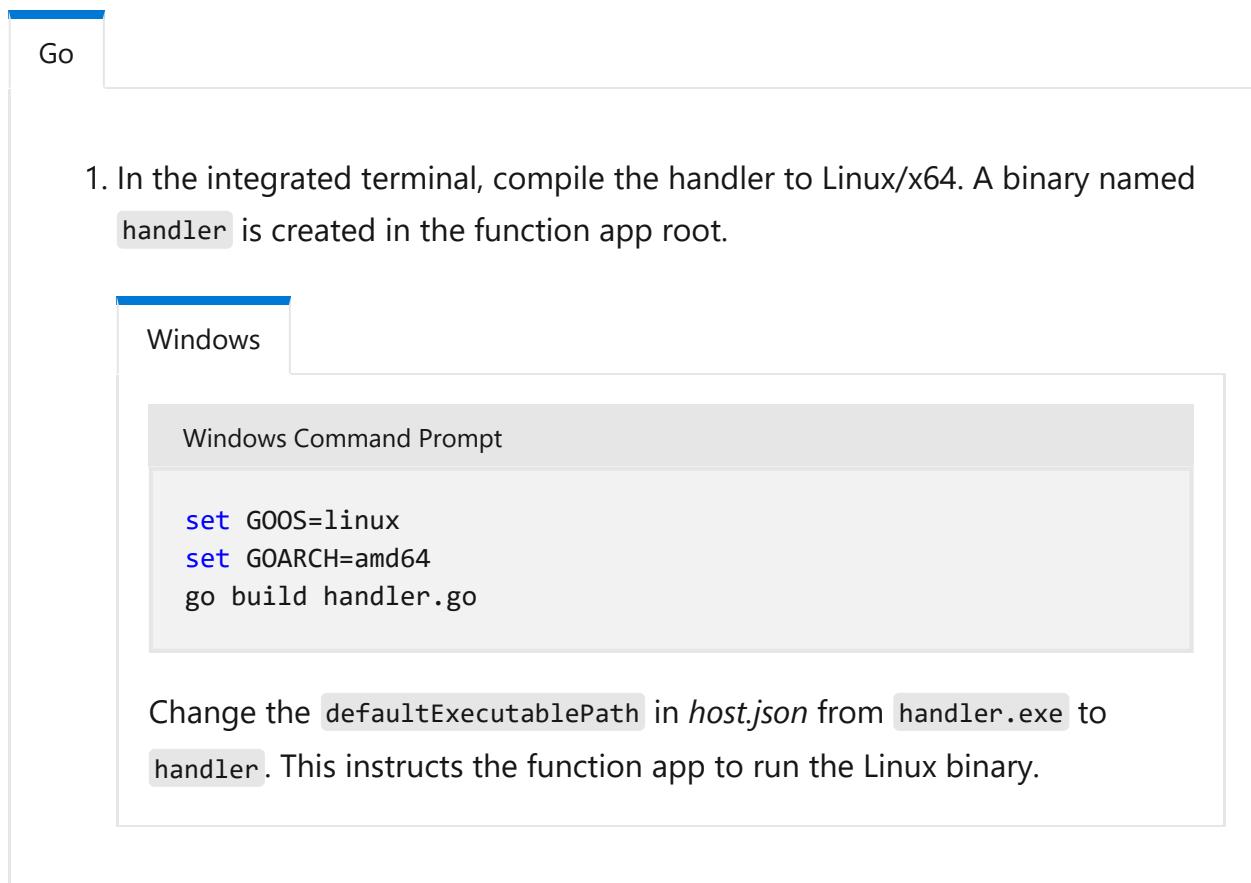

If you're already signed in and can see your existing subscriptions, go to the next section. If you don't yet have an Azure account, select **Create an Azure Account**. Students can select **Create an Azure for Students Account**.

- When you are prompted in the browser, select your Azure account and sign in by using your Azure account credentials. If you create a new account, you can sign in after your account is created.

3. After you successfully sign in, you can close the new browser window. The subscriptions that belong to your Azure account are displayed in the side bar.

Compile the custom handler for Azure

In this section, you publish your project to Azure in a function app running Linux. In most cases, you must recompile your binary and adjust your configuration to match the target platform before publishing it to Azure.

The screenshot shows the Azure Functions developer tools interface. At the top, there's a navigation bar with a blue bar on the left and a 'Go' button on the right. Below this is a main area with a 'Windows' tab selected. A 'Windows Command Prompt' window is open, showing the following command sequence:

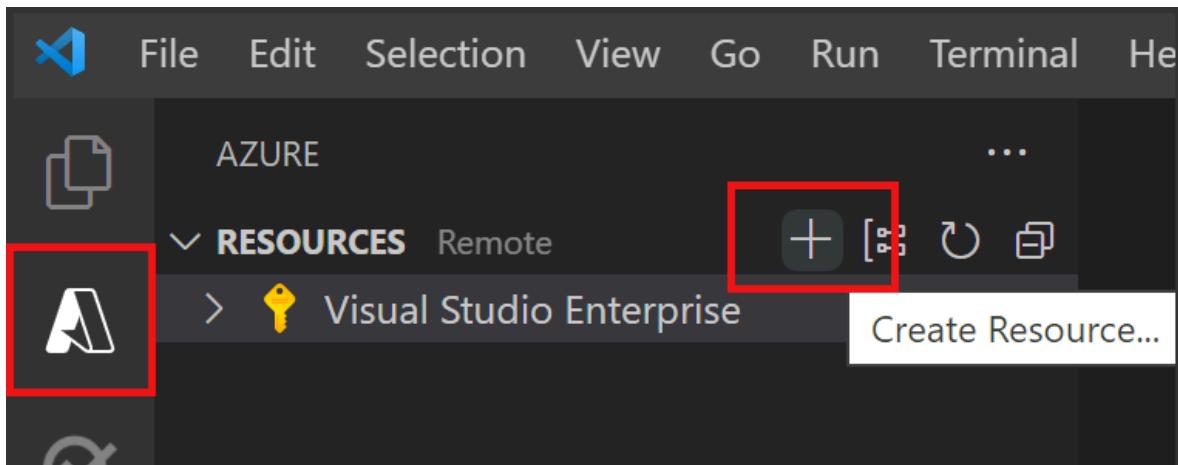

```
set GOOS=linux
set GOARCH=amd64
go build handler.go
```

Below the terminal window, there's a note: "Change the `defaultExecutablePath` in `host.json` from `handler.exe` to `handler`. This instructs the function app to run the Linux binary."

Create the function app in Azure

In this section, you create a function app and related resources in your Azure subscription.

1. Choose the Azure icon in the Activity bar. Then in the **Resources** area, select the + icon and choose the **Create Function App in Azure** option.

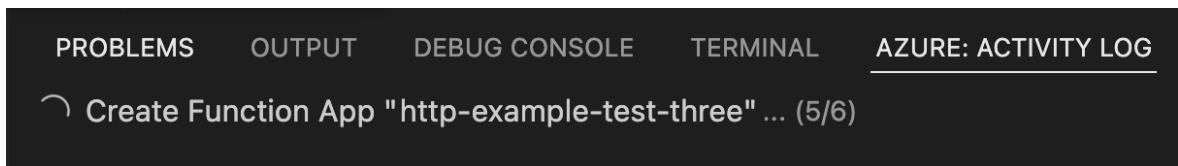

2. Provide the following information at the prompts:

[+] Expand table

Prompt	Selection
Select subscription	Choose the subscription to use. You won't see this when you have only one subscription visible under Resources.
Enter a globally unique name for the function app	Type a name that is valid in a URL path. The name you type is validated to make sure that it's unique in Azure Functions.
Select a runtime stack	Choose Custom Handler.
Select a location for new resources	For better performance, choose a region near you.

The extension shows the status of individual resources as they are being created in Azure in the **Azure: Activity Log** panel.

3. When the creation is complete, the following Azure resources are created in your subscription. The resources are named based on your function app name:

- A [resource group](#), which is a logical container for related resources.
- A standard [Azure Storage account](#), which maintains state and other information about your projects.
- A function app, which provides the environment for executing your function code. A function app lets you group functions as a logical unit for easier

management, deployment, and sharing of resources within the same hosting plan.

- An Azure App Service plan, which defines the underlying host for your function app.
- An Application Insights instance that's connected to the function app, and which tracks the use of your functions in the app.

A notification is displayed after your function app is created and the deployment package is applied.

 **Tip**

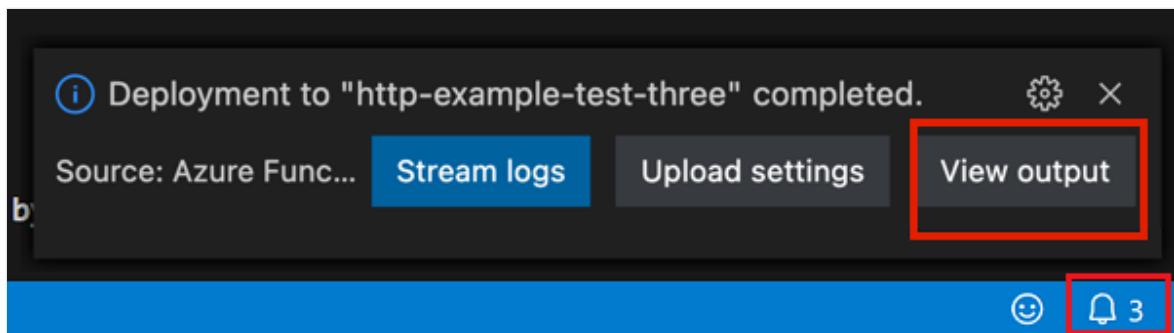

By default, the Azure resources required by your function app are created based on the name you enter for your function app. By default, the resources are created with the function app in the same, new resource group. If you want to customize the names of the associated resources or reuse existing resources, [publish the project with advanced create options](#).

Deploy the project to Azure

 **Important**

Deploying to an existing function app always overwrites the contents of that app in Azure.

1. In the command palette, enter and then select **Azure Functions: Deploy to Function App**.
2. Select the function app you just created. When prompted about overwriting previous deployments, select **Deploy** to deploy your function code to the new function app resource.
3. When deployment is completed, select **View Output** to view the creation and deployment results, including the Azure resources that you created. If you miss the notification, select the bell icon in the lower-right corner to see it again.

Run the function in Azure

1. Press `F1` to display the command palette, then search for and run the command `Azure Functions:Execute Function Now....`. If prompted, select your subscription.
2. Select your new function app resource and `HttpExample` as your function.
3. In `Enter request body` type `{ "name": "Azure" }`, then press Enter to send this request message to your function.
4. When the function executes in Azure, the response is displayed in the notification area. Expand the notification to review the full response.

Clean up resources

When you continue to the [next step](#) and add an Azure Storage queue binding to your function, you'll need to keep all your resources in place to build on what you've already done.

Otherwise, you can use the following steps to delete the function app and its related resources to avoid incurring any further costs.

1. In Visual Studio Code, press `F1` to open the command palette. In the command palette, search for and select `Azure: Open in portal`.
2. Choose your function app and press `Enter`. The function app page opens in the Azure portal.
3. In the **Overview** tab, select the named link next to **Resource group**.

Quickstart: Create and deploy Azure Functions resources using Bicep

Article • 04/05/2023

In this article, you use Azure Functions with Bicep to create a function app and related resources in Azure. The function app provides an execution context for your function code executions.

Completing this quickstart incurs a small cost of a few USD cents or less in your Azure account.

Bicep is a domain-specific language (DSL) that uses declarative syntax to deploy Azure resources. It provides concise syntax, reliable type safety, and support for code reuse. Bicep offers the best authoring experience for your infrastructure-as-code solutions in Azure.

After you create the function app, you can deploy Azure Functions project code to that app.

Prerequisites

Azure account

Before you begin, you must have an Azure account with an active subscription. [Create an account for free](#).

Review the Bicep file

The Bicep file used in this quickstart is from [Azure Quickstart Templates](#).

Bicep

```
@description('The name of the function app that you wish to create.')
param appName string = 'fnapp${uniqueString(resourceGroup().id)}'

@description('Storage Account type')
@allowed([
    'Standard_LRS'
    'Standard_GRS'
    'Standard_RAGRS'
])
param storageAccountType string = 'Standard_LRS'
```

```

@description('Location for all resources.')
param location string = resourceGroup().location

@description('Location for Application Insights')
param appInsightsLocation string

@description('The language worker runtime to load in the function app.')
@allowed([
    'node'
    'dotnet'
    'java'
])
param runtime string = 'node'

var functionAppName = appName
var hostingPlanName = appName
var applicationInsightsName = appName
var storageAccountName = '${uniqueString(resourceGroup().id)}azfunctions'
var functionWorkerRuntime = runtime

resource storageAccount 'Microsoft.Storage/storageAccounts@2022-05-01' = {
    name: storageAccountName
    location: location
    sku: {
        name: storageAccountType
    }
    kind: 'Storage'
    properties: {
        supportsHttpsTrafficOnly: true
        defaultToOAuthAuthentication: true
    }
}

resource hostingPlan 'Microsoft.Web/serverfarms@2021-03-01' = {
    name: hostingPlanName
    location: location
    sku: {
        name: 'Y1'
        tier: 'Dynamic'
    }
    properties: {}
}

resource functionApp 'Microsoft.Web/sites@2021-03-01' = {
    name: functionAppName
    location: location
    kind: 'functionapp'
    identity: {
        type: 'SystemAssigned'
    }
    properties: {
        serverFarmId: hostingPlan.id
        siteConfig: {
            appSettings: [

```

```

    {
        name: 'AzureWebJobsStorage'
        value:
'DefaultEndpointsProtocol=https;AccountName=${storageAccountName};EndpointS
ffix=${environment().suffixes.storage};AccountKey=${storageAccount.listKeys(
).keys[0].value}'
    }
    {
        name: 'WEBSITE_CONTENTAZUREFILECONNECTIONSTRING'
        value:
'DefaultEndpointsProtocol=https;AccountName=${storageAccountName};EndpointS
ffix=${environment().suffixes.storage};AccountKey=${storageAccount.listKeys(
).keys[0].value}'
    }
    {
        name: 'WEBSITE_CONTENTSHARE'
        value: toLower(functionAppName)
    }
    {
        name: 'FUNCTIONS_EXTENSION_VERSION'
        value: '~4'
    }
    {
        name: 'WEBSITE_NODE_DEFAULT_VERSION'
        value: '~14'
    }
    {
        name: 'APPINSIGHTS_INSTRUMENTATIONKEY'
        value: applicationInsights.properties.InstrumentationKey
    }
    {
        name: 'FUNCTIONS_WORKER_RUNTIME'
        value: functionWorkerRuntime
    }
]
ftpsState: 'FtpsOnly'
minTlsVersion: '1.2'
}
httpsOnly: true
}

resource applicationInsights 'Microsoft.Insights/components@2020-02-02' = {
    name: applicationInsightsName
    location: appInsightsLocation
    kind: 'web'
    properties: {
        Application_Type: 'web'
        Request_Source: 'rest'
    }
}

```

The following four Azure resources are created by this Bicep file:

- **Microsoft.Storage/storageAccounts**: create an Azure Storage account, which is required by Functions.
- **Microsoft.Web/serverfarms**: create a serverless Consumption hosting plan for the function app.
- **Microsoft.Web/sites**: create a function app.
- **microsoft.insights/components**: create an Application Insights instance for monitoring.

ⓘ Important

The storage account is used to store important app data, sometimes including the application code itself. You should limit access from other apps and users to the storage account.

Deploy the Bicep file

1. Save the Bicep file as **main.bicep** to your local computer.
2. Deploy the Bicep file using either Azure CLI or Azure PowerShell.

CLI

Azure CLI

```
az group create --name exampleRG --location eastus
az deployment group create --resource-group exampleRG --template-file main.bicep --parameters appInsightsLocation=<app-location>
```

ⓘ Note

Replace **<app-location>** with the region for Application Insights, which is usually the same as the resource group.

When the deployment finishes, you should see a message indicating the deployment succeeded.

Validate the deployment

Use Azure CLI or Azure PowerShell to validate the deployment.

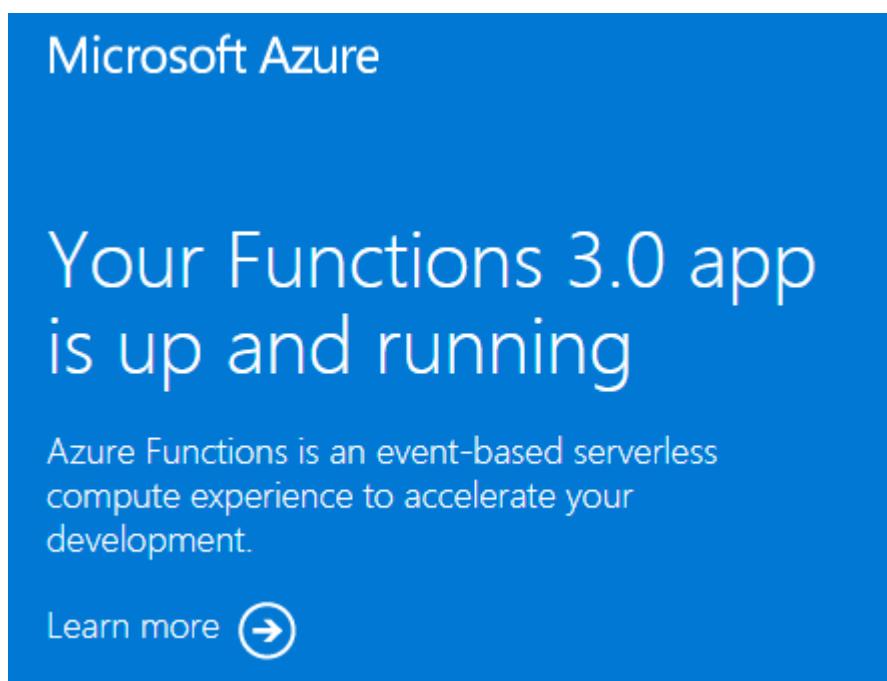

Azure CLI

```
az resource list --resource-group exampleRG
```

Visit function app welcome page

1. Use the output from the previous validation step to retrieve the unique name created for your function app.
2. Open a browser and enter the following URL:
`<https://<appName.azurewebsites.net>`. Make sure to replace `<\appName>` with the unique name created for your function app.

When you visit the URL, you should see a page like this:

Clean up resources

If you continue to the next step and add an Azure Storage queue output binding, keep all your resources in place as you'll build on what you've already done.

Otherwise, if you no longer need the resources, use Azure CLI, PowerShell, or Azure portal to delete the resource group and its resources.

Azure CLI

```
az group delete --name exampleRG
```

Next steps

Now that you've created your function app resources in Azure, you can deploy your code to the existing app by using one of the following tools:

- [Visual Studio Code](#)
- [Visual Studio](#)
- [Azure Functions Core Tools](#)

Quickstart: Create and deploy Azure Functions resources from an ARM template

Article • 04/05/2023

In this article, you use Azure Functions with an Azure Resource Manager template (ARM template) to create a function app and related resources in Azure. The function app provides an execution context for your function code executions.

Completing this quickstart incurs a small cost of a few USD cents or less in your Azure account.

A [resource manager template](#) is a JavaScript Object Notation (JSON) file that defines the infrastructure and configuration for your project. The template uses declarative syntax. In declarative syntax, you describe your intended deployment without writing the sequence of programming commands to create the deployment.

If your environment meets the prerequisites and you're familiar with using ARM templates, select the **Deploy to Azure** button. The template will open in the Azure portal.

After you create the function app, you can deploy Azure Functions project code to that app.

Prerequisites

Azure account

Before you begin, you must have an Azure account with an active subscription. [Create an account for free](#).

Review the template

The template used in this quickstart is from [Azure Quickstart Templates](#).

JSON

```
{
    "$schema": "https://schema.management.azure.com/schemas/2019-04-01/deploymentTemplate.json#",

            }
        },
        "runtime": {
            "type": "string",
            "defaultValue": "node",
            "allowedValues": [
                "node",
                "dotnet",
                "java"
            ],
            "metadata": {
                "description": "Runtime for the function app"
            }
        }
    }
}
```

```
    "metadata": {
        "description": "The language worker runtime to load in the function
app."
    }
},
{
    "variables": {
        "functionAppName": "[parameters('appName')]",
        "hostingPlanName": "[parameters('appName')]",
        "applicationInsightsName": "[parameters('appName')]",
        "storageAccountName": "[format('{0}azfunctions',
uniqueString(resourceGroup().id))]",
        "functionWorkerRuntime": "[parameters('runtime')]"
    },
    "resources": [
        {
            "type": "Microsoft.Storage/storageAccounts",
            "apiVersion": "2022-05-01",
            "name": "[variables('storageAccountName')]",
            "location": "[parameters('location')]",
            "sku": {
                "name": "[parameters('storageAccountType')]"
            },
            "kind": "Storage",
            "properties": {
                "supportsHttpsTrafficOnly": true,
                "defaultToOAuthAuthentication": true
            }
        },
        {
            "type": "Microsoft.Web/serverfarms",
            "apiVersion": "2021-03-01",
            "name": "[variables('hostingPlanName')]",
            "location": "[parameters('location')]",
            "sku": {
                "name": "Y1",
                "tier": "Dynamic"
            },
            "properties": {}
        },
        {
            "type": "Microsoft.Web/sites",
            "apiVersion": "2021-03-01",
            "name": "[variables('functionAppName')]",
            "location": "[parameters('location')]",
            "kind": "functionapp",
            "identity": {
                "type": "SystemAssigned"
            },
            "properties": {
                "serverFarmId": "[resourceId('Microsoft.Web/serverfarms',
variables('hostingPlanName'))]",
                "siteConfig": {
                    "appSettings": [
                        {
                            "name": "FUNCTIONS_EXTENSION_VERSION",
                            "value": "3.x"
                        }
                    ],
                    "bindings": [
                        {
                            "type": "httpTrigger",
                            "name": "req",
                            "method": "get",
                            "route": "hello-world"
                        }
                    ]
                }
            }
        }
    ]
}
```

```

        "name": "AzureWebJobsStorage",
        "value": "[format('DefaultEndpointsProtocol=https;AccountName={0};EndpointSuffix={1};AccountKey={2}', variables('storageAccountName'), environment().suffixes.storage, listKeys(resourceId('Microsoft.Storage/storageAccounts', variables('storageAccountName')), '2022-05-01').keys[0].value)]"
    },
    {
        "name": "WEBSITE_CONTENTAZUREFILECONNECTIONSTRING",

            "value": "[variables('functionWorkerRuntime')]"
        }
    ],
    "ftpsState": "FtpsOnly",
    "minTlsVersion": "1.2"
},
{
    "httpsOnly": true
},
"dependsOn": [
    "[resourceId('Microsoft.Insights/components', variables('applicationInsightsName'))]",
    "[resourceId('Microsoft.Web/serverfarms', variables('hostingPlanName'))]",
    "[resourceId('Microsoft.Storage/storageAccounts', variables('storageAccountName'))]"
]
},
{
    "type": "Microsoft.Insights/components",
    "apiVersion": "2020-02-02",
    "properties": {
        "name": "MyAppInsights"
    }
}

```

```
        "name": "[variables('applicationInsightsName')]",
        "location": "[parameters('appInsightsLocation')]",
        "kind": "web",
        "properties": {
            "Application_Type": "web",
            "Request_Source": "rest"
        }
    }
]
```

The following four Azure resources are created by this template:

- **Microsoft.Storage/storageAccounts**: create an Azure Storage account, which is required by Functions.
- **Microsoft.Web/serverfarms**: create a serverless Consumption hosting plan for the function app.
- **Microsoft.Web/sites**: create a function app.
- **microsoft.insights/components**: create an Application Insights instance for monitoring.

ⓘ Important

The storage account is used to store important app data, sometimes including the application code itself. You should limit access from other apps and users to the storage account.

Deploy the template

The following scripts are designed for and tested in [Azure Cloud Shell](#). Choose Try It to open a Cloud Shell instance right in your browser.

Azure CLI

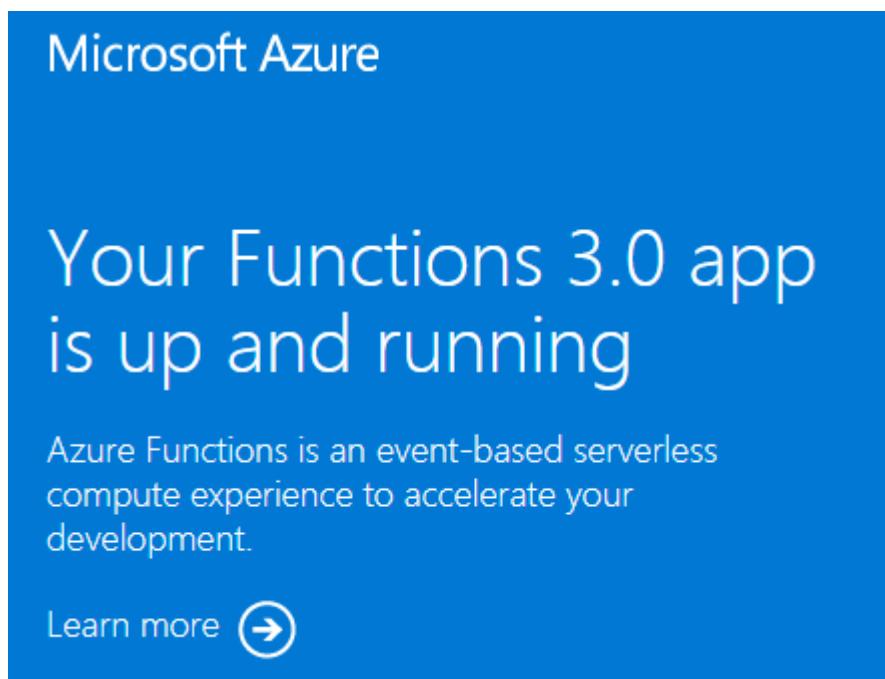

```
read -p "Enter a resource group name that is used for generating
resource names:" resourceGroupName &&
read -p "Enter the location (like 'eastus' or 'northeurope'):" location
&&
templateUri="https://raw.githubusercontent.com/Azure/azure-quickstart-
templates/master/quickstarts/microsoft.web/function-app-create-
dynamic/azuredeploy.json" &&
az group create --name $resourceGroupName --location "$location" &&
az deployment group create --resource-group $resourceGroupName --
```

```
template-uri $templateUri &&
echo "Press [ENTER] to continue ..." &&
read
```

Visit function app welcome page

1. Use the output from the previous validation step to retrieve the unique name created for your function app.
2. Open a browser and enter the following URL:
`<https://<appName.azurewebsites.net>`. Make sure to replace `<\appName>` with the unique name created for your function app.

When you visit the URL, you should see a page like this:

Clean up resources

If you continue to the next step and add an Azure Storage queue output binding, keep all your resources in place as you'll build on what you've already done.

Otherwise, use the following command to delete the resource group and all its contained resources to avoid incurring further costs.

Azure CLI

```
az group delete -n myResourceGroup --yes
```

```
az group delete --name <RESOURCE_GROUP_NAME>
```

Replace `<RESOURCE_GROUP_NAME>` with the name of your resource group.

Next steps

Now that you've created your function app resources in Azure, you can deploy your code to the existing app by using one of the following tools:

- [Visual Studio Code](#)
- [Visual Studio](#)
- [Azure Functions Core Tools](#)

Create your first function on Azure Arc (preview)

Article • 08/24/2023

In this quickstart, you create an Azure Functions project and deploy it to a function app running on an [Azure Arc-enabled Kubernetes cluster](#). To learn more, see [App Service, Functions, and Logic Apps on Azure Arc](#). This scenario only supports function apps running on Linux.

ⓘ Note

Support for running functions on an Azure Arc-enabled Kubernetes cluster is currently in preview.

Publishing PowerShell function projects to Azure Arc-enabled Kubernetes clusters isn't currently supported. If you need to deploy PowerShell functions to Azure Arc-enabled Kubernetes clusters, [create your function app in a container](#).

If you need to customize the container in which your function app runs, instead see [Create your first containerized functions on Azure Arc \(preview\)](#).

Prerequisites

On your local computer:

C#

- [.NET 6.0 SDK](#)
- [Azure CLI](#) version 2.4 or later

Install the Azure Functions Core Tools

The recommended way to install Core Tools depends on the operating system of your local development computer.

Windows

The following steps use a Windows installer (MSI) to install Core Tools v4.x. For more information about other package-based installers, see the [Core Tools readme](#).

Download and run the Core Tools installer, based on your version of Windows:

- [v4.x - Windows 64-bit](#) (Recommended. Visual Studio Code debugging requires 64-bit.)
- [v4.x - Windows 32-bit](#)

If you previously used Windows installer (MSI) to install Core Tools on Windows, you should uninstall the old version from Add Remove Programs before installing the latest version.

Create an App Service Kubernetes environment

Before you begin, you must [create an App Service Kubernetes environment](#) for an Azure Arc-enabled Kubernetes cluster.

Note

When you create the environment, make sure to make note of both the custom location name and the name of the resource group that contains the custom location. You can use these to find the custom location ID, which you'll need when creating your function app in the environment.

If you didn't create the environment, check with your cluster administrator.

Add Azure CLI extensions

Launch the Bash environment in [Azure Cloud Shell](#).

[Launch Cloud Shell](#)

Because these CLI commands are not yet part of the core CLI set, add them with the following commands:

Azure CLI

```
az extension add --upgrade --yes --name customlocation  
az extension remove --name appservice-kube
```

```
az extension add --upgrade --yes --name appservice-kube
```

Create the local function project

In Azure Functions, a function project is the unit of deployment and execution for one or more individual functions that each responds to a specific trigger. All functions in a project share the same local and hosting configurations. In this section, you create a function project that contains a single function.

1. Run the `func init` command, as follows, to create a functions project in a folder named *LocalFunctionProj* with the specified runtime:

The screenshot shows a terminal window with a blue header bar containing the text "C#". Below the header, there are two tabs: "Console" and "Output". The "Console" tab is active and displays the command "func init LocalFunctionProj --dotnet" in white text on a dark background. The "Output" tab is visible below it but is currently empty.

2. Navigate into the project folder:

The screenshot shows a terminal window with a blue header bar containing the text "Console". Below the header, there is one tab labeled "Console". The console area displays the command "cd LocalFunctionProj" in white text on a dark background.

This folder contains various files for the project, including configurations files named `local.settings.json` and `host.json`. By default, the `local.settings.json` file is excluded from source control in the `.gitignore` file. This exclusion is because the file can contain secrets that are downloaded from Azure.

3. Add a function to your project by using the following command, where the `--name` argument is the unique name of your function (HttpExample) and the `--template` argument specifies the function's trigger (HTTP).

The screenshot shows a terminal window with a blue header bar containing the text "Console". Below the header, there is one tab labeled "Console". The console area displays the command "func new --name HttpExample --template \"HTTP trigger\" --authlevel \"anonymous\"" in white text on a dark background.

Run the function locally

1. Run your function by starting the local Azure Functions runtime host from the *LocalFunctionProj* folder.

```
Console
```

```
func start
```

Toward the end of the output, the following lines must appear:

```
Azure Functions Core Tools
Core Tools Version:        4.0.5049 Commit hash: N/A  (64-bit)
Function Runtime Version: 4.15.2.20177

[2023-03-17T03:27:12.372Z] Worker process started and initialized.

Functions:

    HttpExample: [GET,POST] http://localhost:7071/api/HttpExample
```

 **Note**

If `HttpExample` doesn't appear as shown above, you likely started the host from outside the root folder of the project. In that case, use **Ctrl+C** to stop the host, go to the project's root folder, and run the previous command again.

2. Copy the URL of your HTTP function from this output to a browser and append the query string `?name=<YOUR_NAME>`, making the full URL like

`http://localhost:7071/api/HttpExample?name=Functions`. The browser should display a response message that echoes back your query string value. The terminal in which you started your project also shows log output as you make requests.

3. When you're done, press `Ctrl + C` and type `y` to stop the functions host.

Get the custom location

To be able to create a function app in a custom location, you'll need to get information about the environment.

Get the following information about the custom location from your cluster administrator (see [Create a custom location](#)).

```
Azure CLI
```

```
customLocationGroup="<resource-group-containing-custom-location>"
```

```
customLocationName="<name-of-custom-location>"
```

Get the custom location ID for the next step.

Azure CLI

```
customLocationId=$(az customlocation show \  
    --resource-group $customLocationGroup \  
    --name $customLocationName \  
    --query id \  
    --output tsv)
```

Create Azure resources

Before you can deploy your function code to your new App Service Kubernetes environment, you need to create two more resources:

- A [Storage account](#). While this article creates a storage account, in some cases a storage account may not be required. For more information, see [Azure Arc-enabled clusters](#) in the storage considerations article.
- A function app, which provides the context for executing your function code. The function app runs in the App Service Kubernetes environment and maps to your local function project. A function app lets you group functions as a logical unit for easier management, deployment, and sharing of resources.

 **Note**

Function apps run in an App Service Kubernetes environment on a Dedicated (App Service) plan. When you create your function app without an existing plan, the correct plan is created for you.

Create Storage account

Use the [az storage account create](#) command to create a general-purpose storage account in your resource group and region:

Azure CLI

```
az storage account create --name <STORAGE_NAME> --location westeurope --  
resource-group myResourceGroup --sku Standard_LRS
```

ⓘ Note

In some cases, a storage account may not be required. For more information, see [Azure Arc-enabled clusters in the storage considerations article](#).

In the previous example, replace `<STORAGE_NAME>` with a name that is appropriate to you and unique in Azure Storage. Names must contain three to 24 characters numbers and lowercase letters only. `Standard_LRS` specifies a general-purpose account, which is [supported by Functions](#). The `--location` value is a standard Azure region.

Create the function app

Run the `az functionapp create` command to create a new function app in the environment.

C#

Azure CLI

```
az functionapp create --resource-group MyResourceGroup --name <APP_NAME>
--custom-location <CUSTOM_LOCATION_ID> --storage-account <STORAGE_NAME>
--functions-version 4 --runtime dotnet
```

In this example, replace `<CUSTOM_LOCATION_ID>` with the ID of the custom location you determined for the App Service Kubernetes environment. Also, replace `<STORAGE_NAME>` with the name of the account you used in the previous step, and replace `<APP_NAME>` with a globally unique name appropriate to you.

Deploy the function project to Azure

After you've successfully created your function app in Azure, you're now ready to deploy your local functions project by using the `func azure functionapp publish` command.

In the following example, replace `<APP_NAME>` with the name of your app.

Console

```
func azure functionapp publish <APP_NAME>
```

The publish command shows results similar to the following output (truncated for simplicity):

```
...
Getting site publishing info...
Creating archive for current directory...
Performing remote build for functions project.

...
Deployment successful.
Remote build succeeded!
Syncing triggers...
Functions in msdocs-azurefunctions-qs:
  HttpExample - [httpTrigger]
    Invoke url: https://msdocs-azurefunctions-
qs.azurewebsites.net/api/httpexample
```

Because it can take some time for a full deployment to complete on an Azure Arc-enabled Kubernetes cluster, you may want to rerun the following command to verify your published functions:

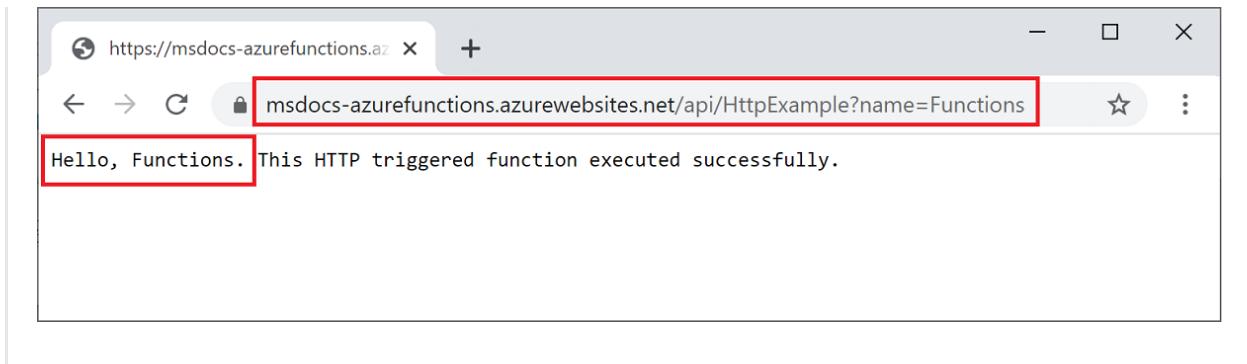

```
command
func azure functionapp list-functions
```

Invoke the function on Azure

Because your function uses an HTTP trigger, you invoke it by making an HTTP request to its URL in the browser or with a tool like curl.

Browser

Copy the complete **Invoke URL** shown in the output of the publish command into a browser address bar, appending the query parameter `?name=Functions`. The browser should display similar output as when you ran the function locally.

Next steps

Now that you have your function app running in a container in an Azure Arc-enabled App Service Kubernetes environment, you can connect it to Azure Storage by adding a Queue Storage output binding.

C#

[Connect to an Azure Storage queue](#)

Create your first containerized Azure Functions on Azure Arc (preview)

Article • 06/05/2023

In this article, you create a function app running in a Linux container and deploy it to an [Azure Arc-enabled Kubernetes cluster](#) from a container registry. When you create your own container, you can customize the execution environment for your function app. To learn more, see [App Service, Functions, and Logic Apps on Azure Arc](#).

ⓘ Note

Support for deploying a custom container to an Azure Arc-enabled Kubernetes cluster is currently in preview.

You can also publish your functions to an Azure Arc-enabled Kubernetes cluster without first creating a container. To learn more, see [Create your first function on Azure Arc \(preview\)](#)

Choose your development language

First, you use Azure Functions tools to create your project code as a function app in a Docker container using a language-specific Linux base image. Make sure to select your language of choice at the top of the article.

Core Tools automatically generates a Dockerfile for your project that uses the most up-to-date version of the correct base image for your functions language. You should regularly update your container from the latest base image and redeploy from the updated version of your container. For more information, see [Creating containerized function apps](#).

Prerequisites

Before you begin, you must have the following requirements in place:

- Install the [.NET 6 SDK](#).
- Install [Azure Functions Core Tools](#) version 4.0.5198, or a later version.
- [Azure CLI](#) version 2.4 or a later version.

If you don't have an [Azure subscription](#), create an [Azure free account](#) before you begin.

To publish the containerized function app image you create to a container registry, you need a Docker ID and [Docker](#) running on your local computer. If you don't have a Docker ID, you can [create a Docker account](#).

Azure Container Registry

You also need to complete the [Create a container registry](#) section of the Container Registry quickstart to create a registry instance. Make a note of your fully qualified login server name.

Create and test the local functions project

In a terminal or command prompt, run the following command for your chosen language to create a function app project in the current folder:

Console

```
func init --worker-runtime dotnet-isolated --docker
```

The `--docker` option generates a *Dockerfile* for the project, which defines a suitable container for use with Azure Functions and the selected runtime.

Use the following command to add a function to your project, where the `--name` argument is the unique name of your function and the `--template` argument specifies the function's trigger. `func new` creates a C# code file in your project.

Console

```
func new --name HttpExample --template "HTTP trigger" --authlevel anonymous
```

To test the function locally, start the local Azure Functions runtime host in the root of the project folder.

Console

```
func start
```

After you see the `HttpExample` endpoint written to the output, navigate to that endpoint. You should see a welcome message in the response output.

Press **Ctrl+C** (**Command+C** on macOS) to stop the host.

Build the container image and verify locally

(Optional) Examine the *Dockerfile* in the root of the project folder. The *Dockerfile* describes the required environment to run the function app on Linux. The complete list of supported base images for Azure Functions can be found in the [Azure Functions base image page](#).

In the root project folder, run the [docker build](#) command, provide a name as `azurefunctionsimage`, and tag as `v1.0.0`. Replace `<DOCKER_ID>` with your Docker Hub account ID. This command builds the Docker image for the container.

Console

```
docker build --tag <DOCKER_ID>/azurefunctionsimage:v1.0.0 .
```

When the command completes, you can run the new container locally.

To verify the build, run the image in a local container using the [docker run](#) command, replace `<DOCKER_ID>` again with your Docker Hub account ID, and add the ports argument as `-p 8080:80`:

Console

```
docker run -p 8080:80 -it <DOCKER_ID>/azurefunctionsimage:v1.0.0
```

After the image starts in the local container, browse to `http://localhost:8080/api/HttpExample`, which must display the same greeting message as before. Because the HTTP triggered function you created uses anonymous authorization, you can call the function running in the container without having to obtain an access key. For more information, see [authorization keys](#).

After verifying the function app in the container, press **Ctrl+C** (**Command+C** on macOS) to stop execution.

Publish the container image to a registry

To make your container image available for deployment to a hosting environment, you must push it to a container registry.

Azure Container Registry

Azure Container Apps is a private registry service for building, storing, and managing container images and related artifacts. You should use a private registry service for publishing your containers to Azure services.

1. Use the following command to sign in to your registry instance:

Azure CLI

```
az acr login --name <REGISTRY_NAME>
```

In the previous command, replace `<REGISTRY_NAME>` with the name of your Container Registry instance.

2. Use the following command to tag your image with the fully qualified name of your registry login server:

docker

```
docker tag <DOCKER_ID>/azurefunctionsimage:v1.0.0  
<LOGIN_SERVER>/azurefunctionsimage:v1.0.0
```

Replace `<LOGIN_SERVER>` with the fully qualified name of your registry login server and `<DOCKER_ID>` with your Docker ID.

3. Use the following command to push the container to your registry instance:

docker

```
docker push <LOGIN_SERVER>/azurefunctionsimage:v1.0.0
```

4. Use the following command to enable the built-in admin account so that Functions can connect to the registry with a username and password:

Azure CLI

```
az acr update -n <REGISTRY_NAME> --admin-enabled true
```

 **Important**

The admin account is designed for a single user to access the registry, mainly for testing purposes and for specific Azure services. In a production scenario, you should instead [add a user-assigned managed identity](#) to which you can grant access to the registry.

5. Use the following command to retrieve the admin username and password, which Functions needs to connect to the registry:

Azure CLI

```
az acr credential show -n <REGISTRY_NAME> --query "[username, passwords[0].value]" -o tsv
```

 **Important**

The admin account username and password are important credentials. Make sure to store them securely and never in an accessible location like a public repository.

Create an App Service Kubernetes environment

Before you begin, you must [create an App Service Kubernetes environment](#) for an Azure Arc-enabled Kubernetes cluster.

 **Note**

When you create the environment, make sure to make note of both the custom location name and the name of the resource group that contains the custom location. You can use these to find the custom location ID, which you'll need when creating your function app in the environment.

If you didn't create the environment, check with your cluster administrator.

Add Azure CLI extensions

Launch the Bash environment in [Azure Cloud Shell](#).

 [Launch Cloud Shell](#) 

Because these CLI commands are not yet part of the core CLI set, add them with the following commands:

Azure CLI

```
az extension add --upgrade --yes --name customlocation  
az extension remove --name appservice-kube  
az extension add --upgrade --yes --name appservice-kube
```

Create Azure resources

Before you can deploy your container to your new App Service Kubernetes environment, you need to create two more resources:

- A [Storage account](#). While this article creates a storage account, in some cases a storage account may not be required. For more information, see [Azure Arc-enabled clusters](#) in the storage considerations article.
- A function app, which provides the context for running your container. The function app runs in the App Service Kubernetes environment and maps to your local function project. A function app lets you group functions as a logical unit for easier management, deployment, and sharing of resources.

ⓘ Note

Function apps run in an App Service Kubernetes environment on a Dedicated (App Service) plan. When you create your function app without an existing plan, a plan is created for you.

Create Storage account

Use the [az storage account create](#) command to create a general-purpose storage account in your resource group and region:

Azure CLI

```
az storage account create --name <STORAGE_NAME> --location westeurope --  
resource-group myResourceGroup --sku Standard_LRS
```

ⓘ Note

In some cases, a storage account may not be required. For more information, see [Azure Arc-enabled clusters](#) in the storage considerations article.

In the previous example, replace `<STORAGE_NAME>` with a name that is appropriate to you and unique in Azure Storage. Names must contain three to 24 characters numbers and lowercase letters only. `Standard_LRS` specifies a general-purpose account, which is [supported by Functions](#). The `--location` value is a standard Azure region.

Create the function app

Run the `az functionapp create` command to create a new function app in the environment.

```
Azure Container Registry

Azure CLI

az functionapp create --name <APP_NAME> --custom-location
<CUSTOM_LOCATION_ID> --storage-account <STORAGE_NAME> --resource-group
AzureFunctionsContainers-rg --image
<LOGIN_SERVER>/azurefunctionsimage:v1.0.0 --registry-username <USERNAME>
--registry-password <SECURE_PASSWORD>
```

In this example, replace `<CUSTOM_LOCATION_ID>` with the ID of the custom location you determined for the App Service Kubernetes environment. Also, replace `<STORAGE_NAME>` with the name of the account you used in the previous step, `<APP_NAME>` with a globally unique name, and `<DOCKER_ID>` or `<LOGIN_SERVER>` with your Docker Hub account ID or Container Registry server, respectively. When you're deploying from a custom container registry, the image name indicates the URL of the registry.

When you first create the function app, it pulls the initial image from your Docker Hub.

Set required app settings

Run the following commands to create an app setting for the storage account connection string:

```
Azure CLI

storageConnectionString=$(az storage account show-connection-string --
resource-group AzureFunctionsContainers-rg --name <STORAGE_NAME> --query
connectionString --output tsv)
```

```
az functionapp config appsettings set --name <app_name> --resource-group  
AzureFunctionsContainers-rg --settings  
AzureWebJobsStorage=$storageConnectionString
```

This code must be run either in Cloud Shell or in Bash on your local computer. Replace `<STORAGE_NAME>` with the name of the storage account and `<APP_NAME>` with the function app name.

Invoke the function on Azure

Because your function uses an HTTP trigger, you invoke it by making an HTTP request to its URL in the browser or with a tool like curl.

Browser

Copy the complete **Invoke URL** shown in the output of the publish command into a browser address bar, appending the query parameter `?name=Functions`. The browser should display similar output as when you ran the function locally.

Clean up resources

If you want to continue working with Azure Function using the resources you created in this article, you can leave all those resources in place.

When you are done working with this function app deployment, delete the `AzureFunctionsContainers-rg` resource group to clean up all the resources in that group:

Azure CLI

```
az group delete --name AzureFunctionsContainers-rg
```

This only removes the resources created in this article. The underlying Azure Arc environment remains in place.

Next steps

[Working with custom containers and Azure Functions](#)

Create your first containerized functions on Azure Container Apps

Article • 07/20/2024

In this article, you create a function app running in a Linux container and deploy it to an Azure Container Apps environment from a container registry. By deploying to Container Apps, you're able to integrate your function apps into cloud-native microservices. For more information, see [Azure Container Apps hosting of Azure Functions](#).

This article shows you how to create functions running in a Linux container and deploy the container to a Container Apps environment.

Completing this quickstart incurs a small cost of a few USD cents or less in your Azure account, which you can minimize by [cleaning-up resources](#) when you're done.

Choose your development language

First, you use Azure Functions tools to create your project code as a function app in a Docker container using a language-specific Linux base image. Make sure to select your language of choice at the top of the article.

Core Tools automatically generates a Dockerfile for your project that uses the most up-to-date version of the correct base image for your functions language. You should regularly update your container from the latest base image and redeploy from the updated version of your container. For more information, see [Creating containerized function apps](#).

Prerequisites

Before you begin, you must have the following requirements in place:

- Install the [.NET 8.0 SDK](#).
- Install [Azure Functions Core Tools](#) version 4.0.5198, or a later version.
- [Azure CLI](#) version 2.4 or a later version.

If you don't have an [Azure subscription](#), create an [Azure free account](#) before you begin.

To publish the containerized function app image you create to a container registry, you need a Docker ID and [Docker](#) running on your local computer. If you don't have a Docker ID, you can [create a Docker account](#).

Azure Container Registry

You also need to complete the [Create a container registry](#) section of the Container Registry quickstart to create a registry instance. Make a note of your fully qualified login server name.

Create and test the local functions project

In a terminal or command prompt, run the following command for your chosen language to create a function app project in the current folder:

Console

```
func init --worker-runtime dotnet-isolated --docker
```

The `--docker` option generates a *Dockerfile* for the project, which defines a suitable container for use with Azure Functions and the selected runtime.

Use the following command to add a function to your project, where the `--name` argument is the unique name of your function and the `--template` argument specifies the function's trigger. `func new` creates a C# code file in your project.

Console

```
func new --name HttpExample --template "HTTP trigger"
```

To test the function locally, start the local Azure Functions runtime host in the root of the project folder.

Console

```
func start
```

After you see the `HttpExample` endpoint written to the output, navigate to that endpoint. You should see a welcome message in the response output.

Press **Ctrl+C** (**Command+C** on macOS) to stop the host.

Build the container image and verify locally

(Optional) Examine the *Dockerfile* in the root of the project folder. The *Dockerfile* describes the required environment to run the function app on Linux. The complete list of supported base images for Azure Functions can be found in the [Azure Functions base image page](#).

In the root project folder, run the [docker build](#) command, provide a name as `azurefunctionsimage`, and tag as `v1.0.0`. Replace `<DOCKER_ID>` with your Docker Hub account ID. This command builds the Docker image for the container.

Console

```
docker build --tag <DOCKER_ID>/azurefunctionsimage:v1.0.0 .
```

When the command completes, you can run the new container locally.

To verify the build, run the image in a local container using the [docker run](#) command, replace `<DOCKER_ID>` again with your Docker Hub account ID, and add the ports argument as `-p 8080:80`:

Console

```
docker run -p 8080:80 -it <DOCKER_ID>/azurefunctionsimage:v1.0.0
```

After the image starts in the local container, browse to

`http://localhost:8080/api/HttpExample`, which must display the same greeting message as before. Because the HTTP triggered function you created uses anonymous authorization, you can call the function running in the container without having to obtain an access key. For more information, see [authorization keys](#).

After verifying the function app in the container, press **Ctrl+C** (**Command+C** on macOS) to stop execution.

Publish the container image to a registry

To make your container image available for deployment to a hosting environment, you must push it to a container registry.

Azure Container Registry

Azure Container Registry is a private registry service for building, storing, and managing container images and related artifacts. You should use a private registry service for publishing your containers to Azure services.

1. Use this command to sign in to your registry instance using your current Azure credentials:

```
Azure CLI
```

```
az acr login --name <REGISTRY_NAME>
```

In the previous command, replace `<REGISTRY_NAME>` with the name of your Container Registry instance.

2. Use this command to tag your image with the fully qualified name of your registry login server:

```
docker
```

```
docker tag <DOCKER_ID>/azurefunctionsimage:v1.0.0  
<LOGIN_SERVER>/azurefunctionsimage:v1.0.0
```

Replace `<LOGIN_SERVER>` with the fully qualified name of your registry login server and `<DOCKER_ID>` with your Docker ID.

3. Use this command to push the container to your registry instance:

```
docker
```

```
docker push <LOGIN_SERVER>/azurefunctionsimage:v1.0.0
```

Create supporting Azure resources for your function

Before you can deploy your container to Azure, you need to create three resources:

- A [resource group](#), which is a logical container for related resources.
- A [Storage account](#), which is used to maintain state and other information about your functions.
- An Azure Container Apps environment with a Log Analytics workspace.

Use the following commands to create these items.

1. If you haven't done so already, sign in to Azure.

The `az login` command signs you into your Azure account. Use `az account set` when you have more than one subscription associated with your account.

2. Run the following command to update the Azure CLI to the latest version:

```
Azure CLI
```

```
az upgrade
```

If your version of Azure CLI isn't the latest version, an installation begins. The manner of upgrade depends on your operating system. You can proceed after the upgrade is complete.

3. Run the following commands that upgrade the Azure Container Apps extension and register namespaces required by Container Apps:

```
Azure CLI
```

```
az extension add --name containerapp --upgrade -y  
az provider register --namespace Microsoft.Web  
az provider register --namespace Microsoft.App  
az provider register --namespace Microsoft.OperationalInsights
```

4. Create a resource group named `AzureFunctionsContainers-rg`.

```
Azure CLI
```

```
az group create --name AzureFunctionsContainers-rg --location eastus
```

This `az group create` command creates a resource group in the East US region. If you instead want to use a region near you, using an available region code returned from the `az account list-locations` command. You must modify subsequent commands to use your custom region instead of `eastus`.

5. Create Azure Container App environment with workload profiles enabled.

```
Azure CLI
```

```
az containerapp env create --name MyContainerappEnvironment --enable-workload-profiles --resource-group AzureFunctionsContainers-rg --location eastus
```

This command can take a few minutes to complete.

6. Create a general-purpose storage account in your resource group and region.

Azure CLI

```
az storage account create --name <STORAGE_NAME> --location eastus --resource-group AzureFunctionsContainers-rg --sku Standard_LRS
```

The [az storage account create](#) command creates the storage account.

In the previous example, replace `<STORAGE_NAME>` with a name that is appropriate to you and unique in Azure Storage. Storage names must contain 3 to 24 characters numbers and lowercase letters only. `Standard_LRS` specifies a general-purpose account [supported by Functions](#).

Create and configure a function app on Azure with the image

A function app on Azure manages the execution of your functions in your Azure Container Apps environment. In this section, you use the Azure resources from the previous section to create a function app from an image in a container registry in a Container Apps environment. You also configure the new environment with a connection string to the required Azure Storage account.

Use the [az functionapp create](#) command to create a function app in the new managed environment backed by Azure Container Apps:

Azure Container Registry

Azure CLI

```
az functionapp create --name <APP_NAME> --storage-account <STORAGE_NAME> --environment MyContainerappEnvironment --workload-profile-name "Consumption" --resource-group AzureFunctionsContainers-rg --functions-version 4 --runtime dotnet-isolated --image <LOGIN_SERVER>/azurefunctionsimage:v1.0.0 --assign-identity
```

In the [az functionapp create](#) command, the `--environment` parameter specifies the Container Apps environment and the `--image` parameter specifies the image to use for the function app. In this example, replace `<STORAGE_NAME>` with the name you used in the previous section for the storage account. Also, replace `<APP_NAME>` with

a globally unique name appropriate to you and <LOGIN_SERVER> with your fully qualified Container Registry server.

To use a system-assigned managed identity to access the container registry, you need to enable managed identities in your app and grant the system-assigned managed identity access to the container registry. This example uses `az functionapp identity assign` and `az role assignment create` command to enable managed identities in the app and assign the system-assigned identity to the `ACRPull` role in the container registry:

Azure CLI

```
FUNCTION_APP_ID=$(az functionapp identity assign --name <APP_NAME> --resource-group AzureFunctionsContainers-rg --query principalId --output tsv)
ACR_ID=$(az acr show --name <REGISTRY_NAME> --query id --output tsv)
az role assignment create --assignee $FUNCTION_APP_ID --role AcrPull --scope $ACR_ID
```

In this example, replace `<APP_NAME>` and `<REGISTRY_NAME>` with the name of your function app and container registry, respectively.

Specifying `--workload-profile-name "Consumption"` creates your app in an environment using the default `Consumption` workload profile, which costs the same as running in a Container Apps Consumption plan. When you first create the function app, it pulls the initial image from your registry.

At this point, your functions are running in a Container Apps environment, with the required application settings already added. When needed, you can add other settings in your functions app in the standard way for Functions. For more information, see [Use application settings](#).

Tip

When you make subsequent changes to your function code, you need to rebuild the container, republish the image to the registry, and update the function app with the new image version. For more information, see [Update an image in the registry](#)

Verify your functions on Azure

With the image deployed to your function app in Azure, you can now invoke the function through HTTP requests.

1. Run the following `az functionapp function show` command to get the URL of your new function:

```
Azure CLI
```

```
az functionapp function show --resource-group AzureFunctionsContainers-rg --name <APP_NAME> --function-name HttpExample --query invokeUrlTemplate
```

Replace `<APP_NAME>` with the name of your function app.

2. Use the URL you just obtained to call the `HttpExample` function endpoint.

When you navigate to this URL, the browser must display similar output as when you ran the function locally.

The request URL should look something like this:

```
https://myfunctionapp.kindtree-  
796af82b.eastus.azurecontainerapps.io/api/httpexample
```

Clean up resources

If you want to continue working with Azure Function using the resources you created in this article, you can leave all those resources in place.

When you're done working with this function app deployment, delete the `AzureFunctionsContainers-rg` resource group to clean up all the resources in that group:

```
Azure CLI
```

```
az group delete --name AzureFunctionsContainers-rg
```

Connect functions to Azure Storage using Visual Studio

Article • 03/31/2024

Azure Functions lets you connect Azure services and other resources to functions without having to write your own integration code. These *bindings*, which represent both input and output, are declared within the function definition. Data from bindings is provided to the function as parameters. A *trigger* is a special type of input binding. Although a function has only one trigger, it can have multiple input and output bindings. To learn more, see [Azure Functions triggers and bindings concepts](#).

This article shows you how to use Visual Studio to connect the function you created in the [previous quickstart article](#) to Azure Storage. The output binding that you add to this function writes data from the HTTP request to a message in an Azure Queue storage queue.

Most bindings require a stored connection string that Functions uses to access the bound service. To make it easier, you use the Storage account that you created with your function app. The connection to this account is already stored in an app setting named `AzureWebJobsStorage`.

Prerequisites

Before you start this article, you must:

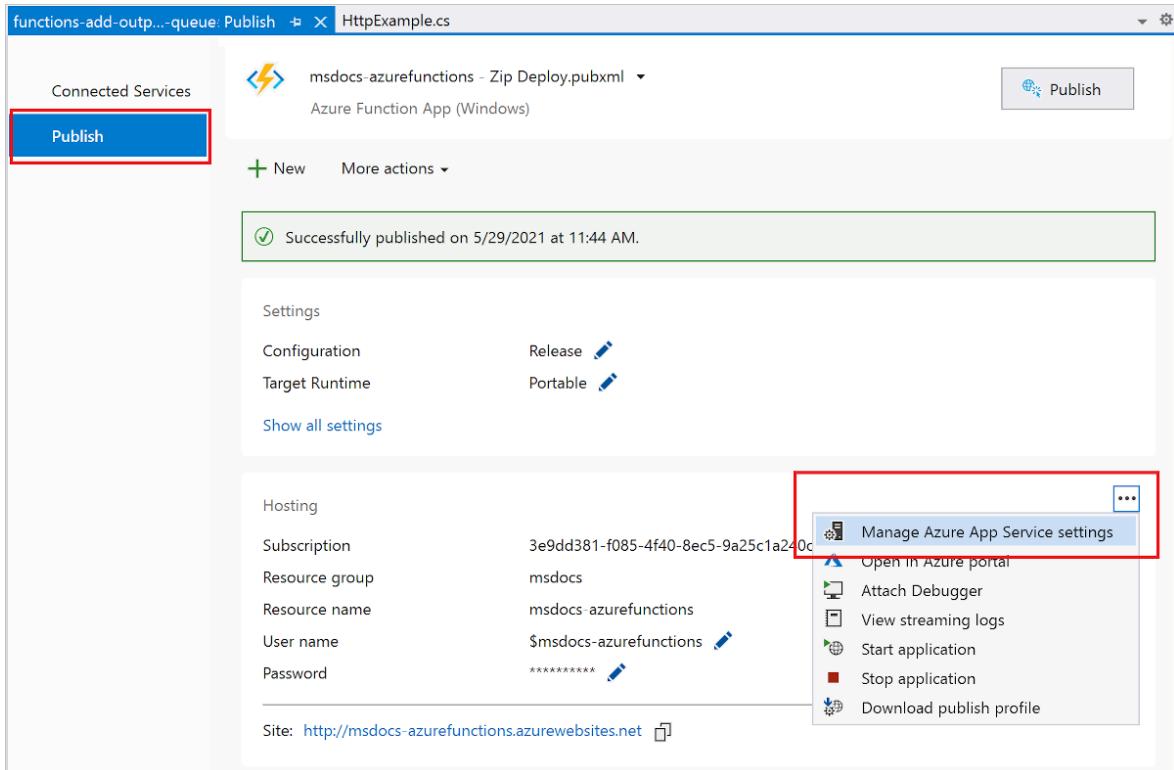

- Complete [part 1 of the Visual Studio quickstart](#).
- Install [Azure Storage Explorer](#). Storage Explorer is a tool that you'll use to examine queue messages generated by your output binding. Storage Explorer is supported on macOS, Windows, and Linux-based operating systems.
- Sign in to your Azure subscription from Visual Studio.

Download the function app settings

In the [previous quickstart article](#), you created a function app in Azure along with the required Storage account. The connection string for this account is stored securely in app settings in Azure. In this article, you write messages to a Storage queue in the same account. To connect to your Storage account when running the function locally, you must download app settings to the `local.settings.json` file.

1. In **Solution Explorer**, right-click the project and select **Publish**.

2. In the Publish tab under **Hosting**, expand the three dots (...) and select **Manage Azure App Service settings**.

3. Under **AzureWebJobsStorage**, copy the **Remote** string value to **Local**, and then select **OK**.

The storage binding, which uses the `AzureWebJobsStorage` setting for the connection, can now connect to your Queue storage when running locally.

Register binding extensions

Because you're using a Queue storage output binding, you need the Storage bindings extension installed before you run the project. Except for HTTP and timer triggers, bindings are implemented as extension packages.

1. From the **Tools** menu, select **NuGet Package Manager > Package Manager Console**.
2. In the console, run the following `Install-Package` command to install the Storage extensions:

Isolated worker model

Bash

```
Install-Package  
Microsoft.Azure.Functions.Worker.Extensions.Storage.Queues
```

Now, you can add the storage output binding to your project.

Add an output binding

In a C# project, the bindings are defined as binding attributes on the function method. Specific definitions depend on whether your app runs in-process (C# class library) or in an isolated worker process.

Isolated worker model

Open the *HttpExample.cs* project file and add the following `MultiResponse` class:

C#

```
public class MultiResponse  
{  
    [QueueOutput("outqueue", Connection = "AzureWebJobsStorage")]  
    public string[] Messages { get; set; }  
    public HttpResponseMessage HttpResponseMessage { get; set; }  
}
```

The `MultiResponse` class allows you to write to a storage queue named `outqueue` and an HTTP success message. Multiple messages could be sent to the queue because the `QueueOutput` attribute is applied to a string array.

The `Connection` property sets the connection string for the storage account. In this case, you could omit `Connection` because you're already using the default storage account.

Add code that uses the output binding

After the binding is defined, you can use the `name` of the binding to access it as an attribute in the function signature. By using an output binding, you don't have to use the Azure Storage SDK code for authentication, getting a queue reference, or writing data. The Functions runtime and queue output binding do those tasks for you.

Replace the existing `HttpExample` class with the following code:

C#

```
[Function("HttpExample")]
public static MultiResponse
Run([HttpTrigger(AuthorizationLevel.Function, "get", "post")]
HttpRequestData req,
    FunctionContext executionContext)
{
    var logger = executionContext.GetLogger("HttpExample");
    logger.LogInformation("C# HTTP trigger function processed a
request.");

    var message = "Welcome to Azure Functions!";

    var response = req.CreateResponse(HttpStatusCode.OK);
    response.Headers.Add("Content-Type", "text/plain; charset=utf-
8");
    response.WriteString(message);

    // Return a response to both HTTP trigger and storage output
binding.
    return new MultiResponse()
    {
        // Write a single message.
        Messages = new string[] { message },
        HttpResponseMessage = response
    };
}
```

Run the function locally

1. To run your function, press `F5` in Visual Studio. You might need to enable a firewall exception so that the tools can handle HTTP requests. Authorization levels are never enforced when you run a function locally.
2. Copy the URL of your function from the Azure Functions runtime output.

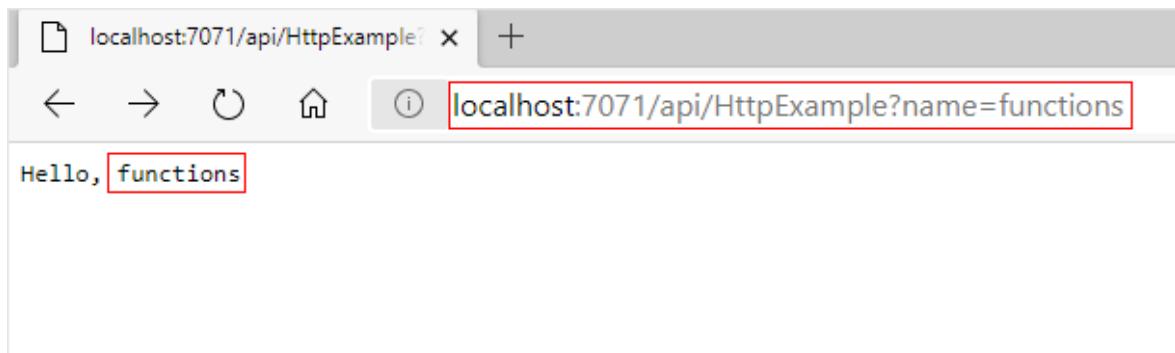

```
C:\Users\AppData\Local\AzureFunctionsTools\Releases\2.49.0\cli_x64\func.exe
[5/27/2020 7:53:39 AM] Loading functions metadata
[5/27/2020 7:53:39 AM] 1 functions loaded
[5/27/2020 7:53:39 AM] Generating 1 job function(s)
[5/27/2020 7:53:40 AM] Found the following functions:
[5/27/2020 7:53:40 AM] FunctionApp2.HttpExample.Run
[5/27/2020 7:53:40 AM]
[5/27/2020 7:53:40 AM] Initializing function HTTP routes
[5/27/2020 7:53:40 AM] Mapped function route 'api/HttpExample' [get,post] to 'HttpExample'
[5/27/2020 7:53:40 AM]
[5/27/2020 7:53:40 AM] Host initialized (691ms)
[5/27/2020 7:53:40 AM] Host started (712ms)
[5/27/2020 7:53:40 AM] Job host started
Hosting environment: Development
Content root path: C:\source\repos\FunctionApp\FunctionApp\bin\Debug\netcoreapp2.1
Now listening on: http://0.0.0.0:7071
Application started. Press Ctrl+C to shut down.

Http Functions:

    HttpExample: [GET,POST] http://localhost:7071/api/HttpExample

[5/27/2020 7:53:47 AM] Host lock lease acquired by instance ID '00000000000000000000000000000000FB2CECE'.
```

- Paste the URL for the HTTP request into your browser's address bar and run the request. The following image shows the response in the browser to the local GET request returned by the function:

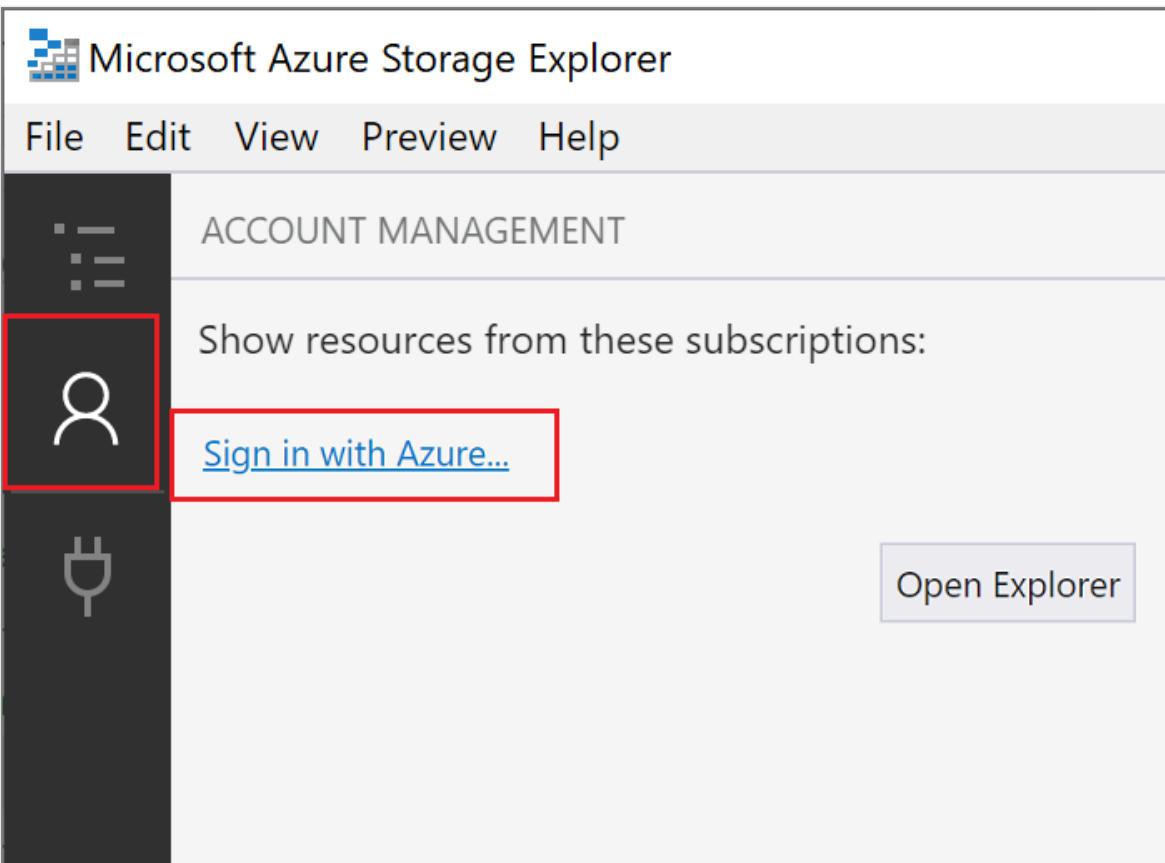

- To stop debugging, press **Shift + F5** in Visual Studio.

A new queue named `outqueue` is created in your storage account by the Functions runtime when the output binding is first used. You'll use Storage Explorer to verify that the queue was created along with the new message.

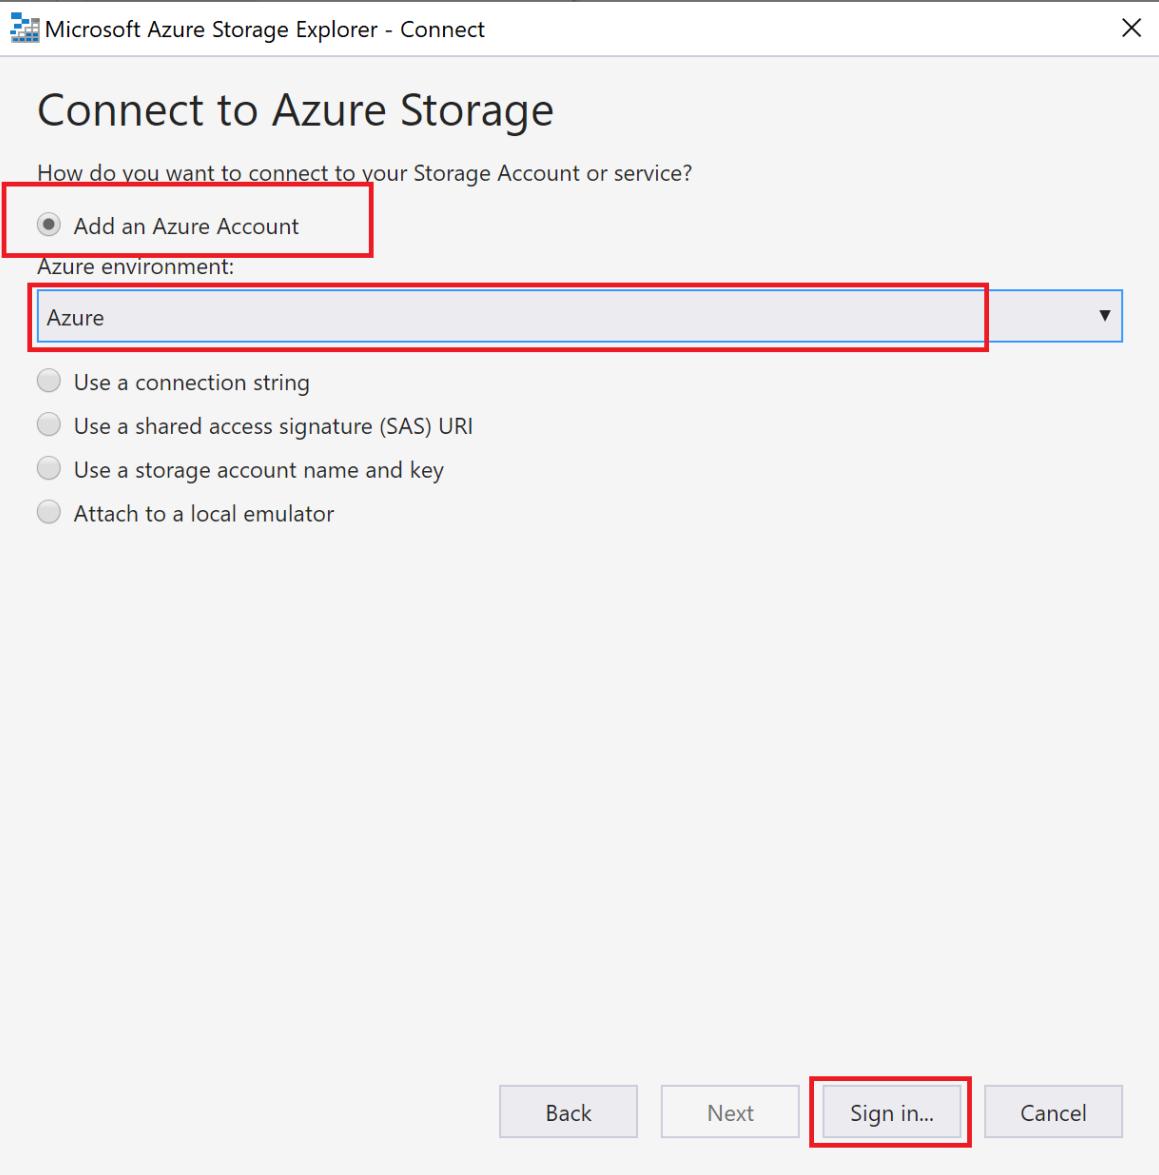

Connect Storage Explorer to your account

Skip this section if you've already installed Azure Storage Explorer and connected it to your Azure account.

- Run the [Azure Storage Explorer](#) tool, select the connect icon on the left, and select **Add an account**.

2. In the **Connect** dialog, choose **Add an Azure account**, choose your **Azure environment**, and then select **Sign in....**

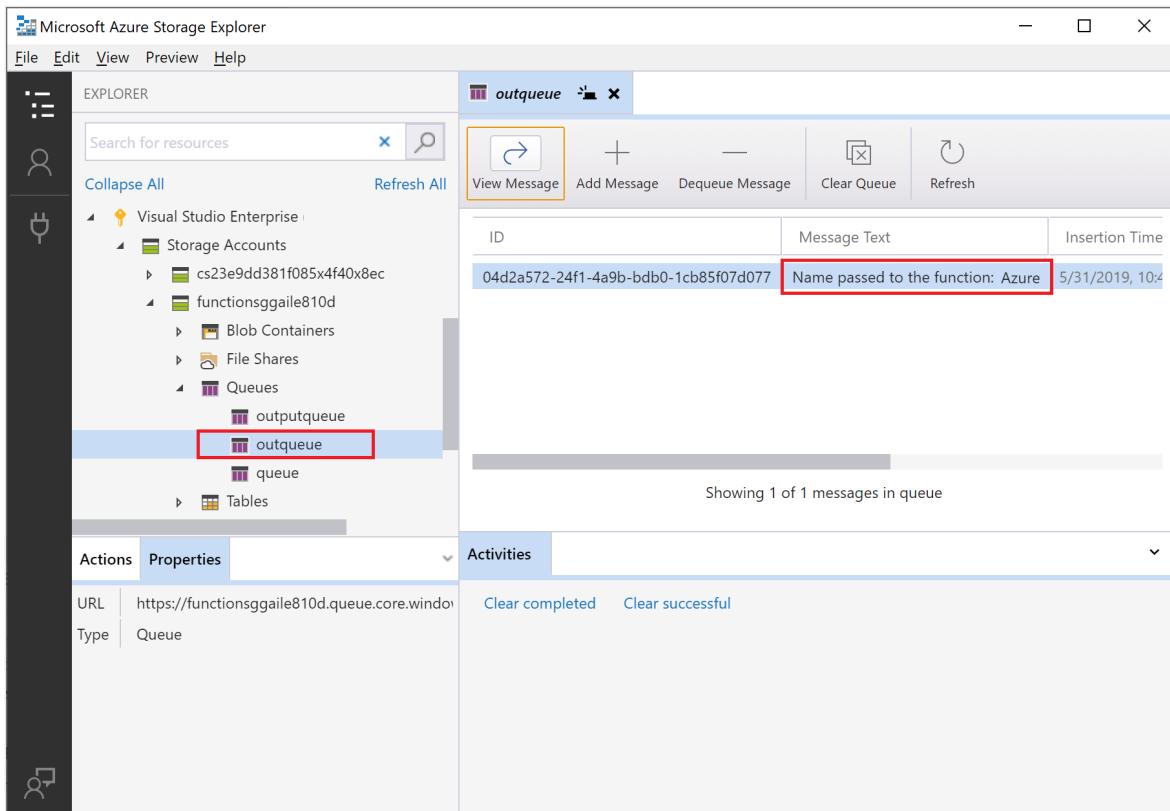

After you successfully sign in to your account, you see all of the Azure subscriptions associated with your account. Choose your subscription and select **Open Explorer**.

Examine the output queue

1. In Storage Explorer, expand the **Queues** node, and then select the queue named **outqueue**.

The queue contains the message that the queue output binding created when you ran the HTTP-triggered function. If you invoked the function with the default `name` value of *Azure*, the queue message is *Name passed to the function: Azure*.

- Run the function again, send another request, and you see a new message in the queue.

Now, it's time to republish the updated function app to Azure.

Redeploy and verify the updated app

- In **Solution Explorer**, right-click the project and select **Publish**, then choose **Publish** to republish the project to Azure.
- After deployment completes, you can again use the browser to test the redeployed function. As before, append the query string `&name=<yourname>` to the URL.
- Again **view the message in the storage queue** to verify that the output binding again generates a new message in the queue.

Clean up resources

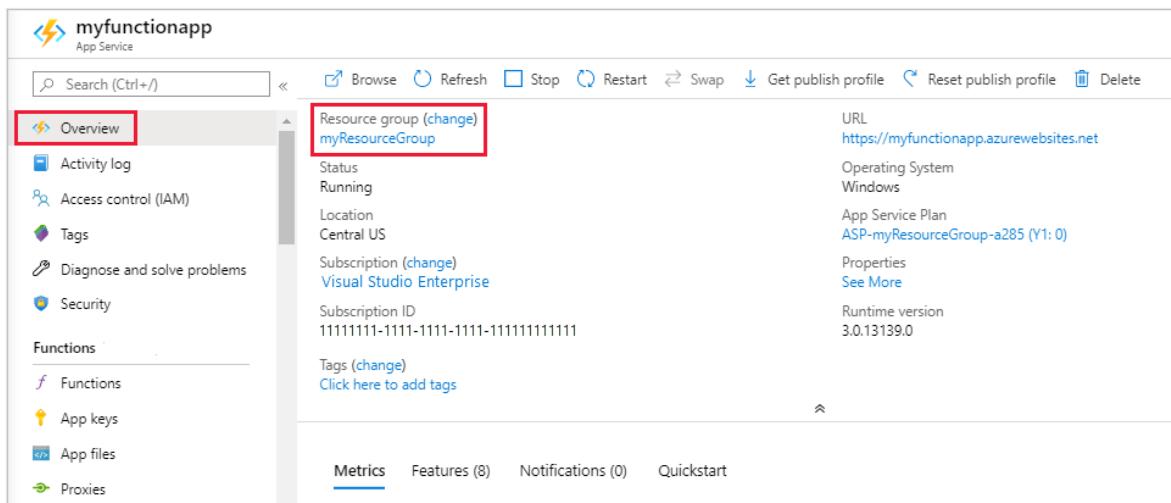

Other quickstarts in this collection build upon this quickstart. If you plan to work with subsequent quickstarts, tutorials, or with any of the services you've created in this quickstart, don't clean up the resources.

Resources in Azure refer to function apps, functions, storage accounts, and so forth. They're grouped into *resource groups*, and you can delete everything in a group by deleting the group.

You've created resources to complete these quickstarts. You might be billed for these resources, depending on your [account status](#) and [service pricing](#). If you don't need the resources anymore, here's how to delete them:

1. In the Azure portal, go to the **Resource group** page.

To get to that page from the function app page, select the **Overview** tab, and then select the link under **Resource group**.

The screenshot shows the Azure portal interface for a function app named "myfunctionapp". The left sidebar has a "Functions" section with "myfunctionapp" selected. The main content area is the "Overview" tab, which displays the following details:

Setting	Value
URL	https://myfunctionapp.azurewebsites.net
Operating System	Windows
App Service Plan	ASP-myResourceGroup-a285 (Y1: 0)
Properties	See More
Runtime version	3.0.13139.0

Under "Resource group (change)", it shows "myResourceGroup" with the following details:

- Status: Running
- Location: Central US
- Subscription (change): Visual Studio Enterprise
- Subscription ID: 1111111-1111-1111-1111-111111111111
- Tags (change): Click here to add tags

To get to that page from the dashboard, select **Resource groups**, and then select the resource group that you used for this article.

2. In the **Resource group** page, review the list of included resources, and verify that they're the ones you want to delete.
3. Select **Delete resource group** and follow the instructions.

Deletion might take a couple of minutes. When it's done, a notification appears for a few seconds. You can also select the bell icon at the top of the page to view the notification.

Next steps

You've updated your HTTP triggered function to write data to a Storage queue. To learn more about developing Functions, see [Develop Azure Functions using Visual Studio](#).

Next, you should enable Application Insights monitoring for your function app:

[Enable Application Insights integration](#)

Connect Azure Functions to Azure Storage using Visual Studio Code

Article • 04/26/2024

Azure Functions lets you connect Azure services and other resources to functions without having to write your own integration code. These *bindings*, which represent both input and output, are declared within the function definition. Data from bindings is provided to the function as parameters. A *trigger* is a special type of input binding. Although a function has only one trigger, it can have multiple input and output bindings. To learn more, see [Azure Functions triggers and bindings concepts](#).

In this article, you learn how to use Visual Studio Code to connect Azure Storage to the function you created in the previous quickstart article. The output binding that you add to this function writes data from the HTTP request to a message in an Azure Queue storage queue.

Most bindings require a stored connection string that Functions uses to access the bound service. To make it easier, you use the storage account that you created with your function app. The connection to this account is already stored in an app setting named `AzureWebJobsStorage`.

Configure your local environment

Before you begin, you must meet the following requirements:

- Install the [Azure Storage extension for Visual Studio Code](#).
- Install [Azure Storage Explorer](#). Storage Explorer is a tool that you'll use to examine queue messages generated by your output binding. Storage Explorer is supported on macOS, Windows, and Linux-based operating systems.
- Install [.NET Core CLI tools](#).
- Complete the steps in [part 1 of the Visual Studio Code quickstart](#).

This article assumes that you're already signed in to your Azure subscription from Visual Studio Code. You can sign in by running `Azure: Sign In` from the command palette.

Download the function app settings

In the [previous quickstart article](#), you created a function app in Azure along with the required storage account. The connection string for this account is stored securely in the app settings in Azure. In this article, you write messages to a Storage queue in the same account. To connect to your storage account when running the function locally, you must download app settings to the `local.settings.json` file.

1. Press `F1` to open the command palette, then search for and run the command `Azure Functions: Download Remote Settings...`
2. Choose the function app you created in the previous article. Select **Yes to all** to overwrite the existing local settings.

 **Important**

Because the `local.settings.json` file contains secrets, it never gets published, and is excluded from the source control.

3. Copy the value `AzureWebJobsStorage`, which is the key for the storage account connection string value. You use this connection to verify that the output binding works as expected.

Register binding extensions

Because you're using a Queue storage output binding, you must have the Storage bindings extension installed before you run the project.

Except for HTTP and timer triggers, bindings are implemented as extension packages. Run the following [dotnet add package](#) command in the Terminal window to add the Storage extension package to your project.

```
Isolated process

Bash

dotnet add package
Microsoft.Azure.Functions.Worker.Extensions.Storage.Queues --prerelease
```

Now, you can add the storage output binding to your project.

Add an output binding

In a C# project, the bindings are defined as binding attributes on the function method. Specific definitions depend on whether your app runs in-process (C# class library) or in an isolated worker process.

Isolated worker model

Open the `HttpExample.cs` project file and add the following `MultiResponse` class:

C#

```
public class MultiResponse
{
    [QueueOutput("outqueue", Connection = "AzureWebJobsStorage")]
    public string[] Messages { get; set; }
    public HttpResponseMessage HttpResponseMessage { get; set; }
}
```

The `MultiResponse` class allows you to write to a storage queue named `outqueue` and an HTTP success message. Multiple messages could be sent to the queue because the `QueueOutput` attribute is applied to a string array.

The `Connection` property sets the connection string for the storage account. In this case, you could omit `Connection` because you're already using the default storage account.

Add code that uses the output binding

After the binding is defined, you can use the `name` of the binding to access it as an attribute in the function signature. By using an output binding, you don't have to use the Azure Storage SDK code for authentication, getting a queue reference, or writing data. The Functions runtime and queue output binding do those tasks for you.

Isolated worker model

Replace the existing `HttpExample` class with the following code:

C#

```
[Function("HttpExample")]
public static MultiResponse
Run([HttpTrigger(AuthorizationLevel.Function, "get", "post")]
HttpRequestData req,
    FunctionContext executionContext)
```

```

    {
        var logger = ExecutionContext.GetLogger("HttpExample");
        logger.LogInformation("C# HTTP trigger function processed a
request.");
    }

        var message = "Welcome to Azure Functions!";

        var response = req.CreateResponse(HttpStatusCode.OK);
        response.Headers.Add("Content-Type", "text/plain; charset=utf-
8");
        response.WriteString(message);

        // Return a response to both HTTP trigger and storage output
binding.
        return new MultiResponse()
    {
        // Write a single message.
        Messages = new string[] { message },
        HttpResponseMessage = response
    };
}
}

```

Run the function locally

Visual Studio Code integrates with [Azure Functions Core tools](#) to let you run this project on your local development computer before you publish to Azure. If you don't already have Core Tools installed locally, you are prompted to install it the first time you run your project.

1. To call your function, press **F5** to start the function app project. The **Terminal** panel displays the output from Core Tools. Your app starts in the **Terminal** panel. You can see the URL endpoint of your HTTP-triggered function running locally.

```

PROBLEMS OUTPUT DEBUG CONSOLE TERMINAL AZURE: ACTIVITY LOG
✖ host start - Task ✓ + × ☰ 🗑 ⌂ ⌂ ×

Functions:

HttpExample: [GET,POST] http://localhost:7071/api/HttpExample

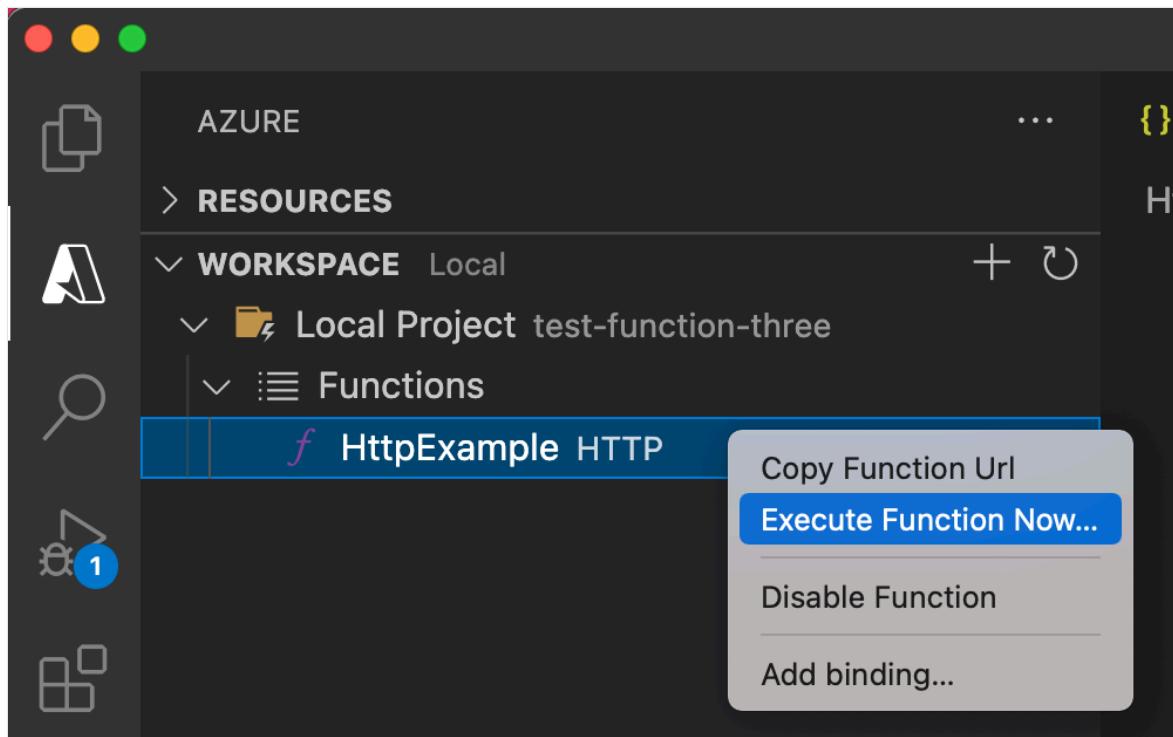

For detailed output, run func with --verbose flag.
[2022-05-25T18:45:53.470Z] Worker process started and initialized.
[2022-05-25T18:45:54.960Z] Host lock lease acquired by instance ID '000000000000000000000000E24CCCAC'.

```

If you don't already have Core Tools installed, select **Install** to install Core Tools when prompted to do so.

If you have trouble running on Windows, make sure that the default terminal for Visual Studio Code isn't set to **WSL Bash**.

- With the Core Tools running, go to the Azure: Functions area. Under Functions, expand Local Project > Functions. Right-click (Windows) or `ctrl -` click (macOS) the `HttpExample` function and choose Execute Function Now....

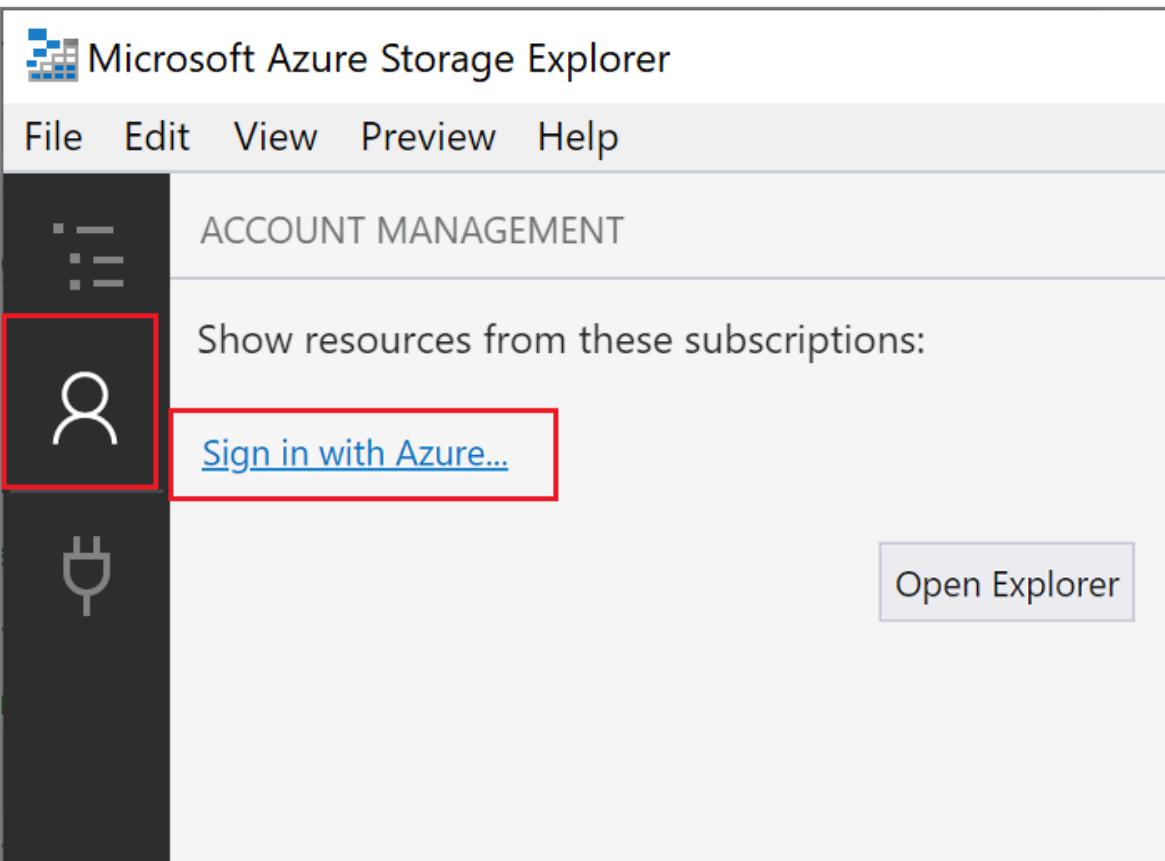

- In the Enter request body, press `Enter` to send a request message to your function.
- When the function executes locally and returns a response, a notification is raised in Visual Studio Code. Information about the function execution is shown in the Terminal panel.
- Press `Ctrl + C` to stop Core Tools and disconnect the debugger.

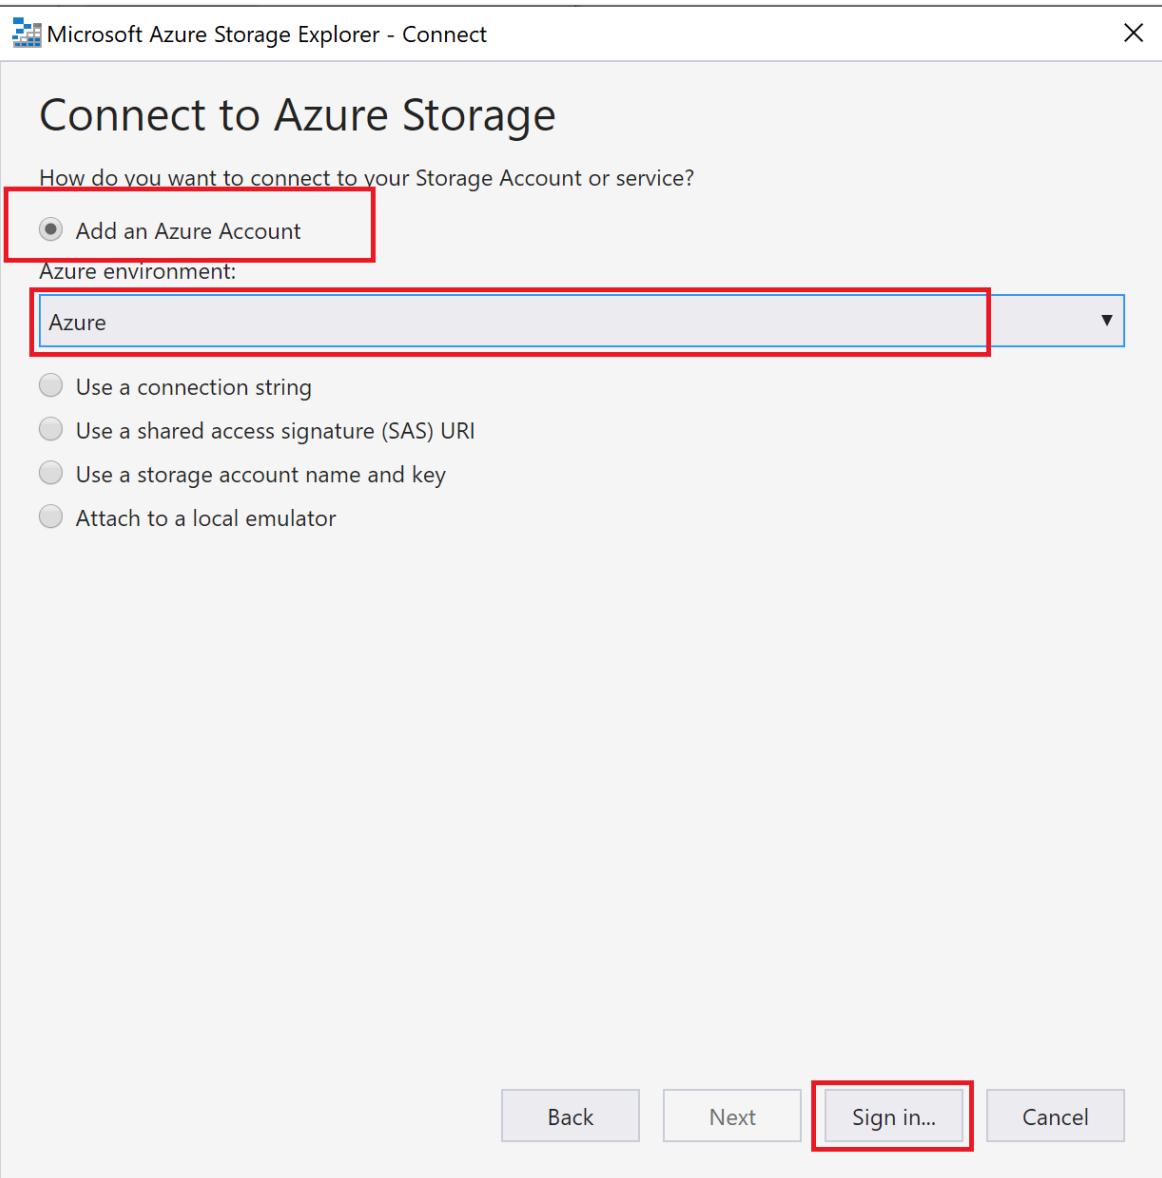

Connect Storage Explorer to your account

Skip this section if you've already installed Azure Storage Explorer and connected it to your Azure account.

- Run the [Azure Storage Explorer](#) tool, select the connect icon on the left, and select Add an account.

2. In the **Connect** dialog, choose **Add an Azure account**, choose your **Azure environment**, and then select **Sign in....**

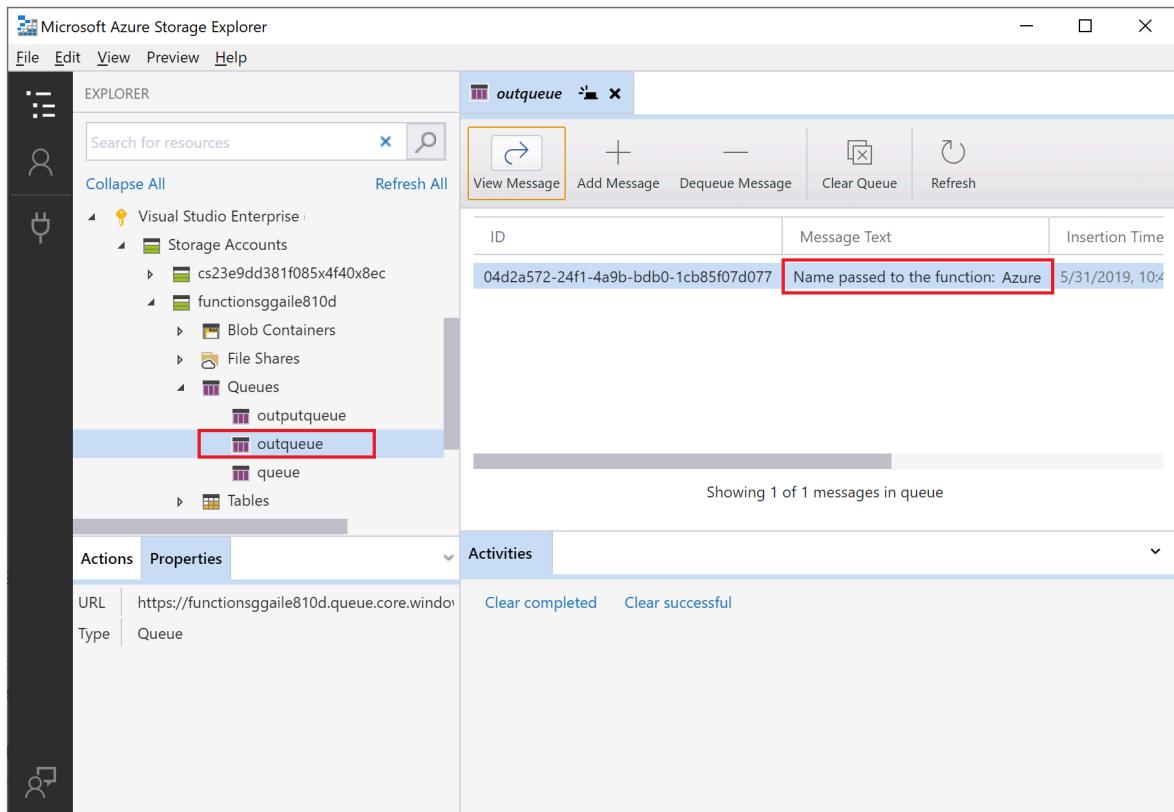

After you successfully sign in to your account, you see all of the Azure subscriptions associated with your account. Choose your subscription and select **Open Explorer**.

Examine the output queue

1. In Visual Studio Code, press **F1** to open the command palette, then search for and run the command **Azure Storage: Open in Storage Explorer** and choose your storage account name. Your storage account opens in the Azure Storage Explorer.
2. Expand the **Queues** node, and then select the queue named **outqueue**.

The queue contains the message that the queue output binding created when you ran the HTTP-triggered function. If you invoked the function with the default **name** value of *Azure*, the queue message is *Name passed to the function: Azure*.

3. Run the function again, send another request, and you see a new message in the queue.

Now, it's time to republish the updated function app to Azure.

Redeploy and verify the updated app

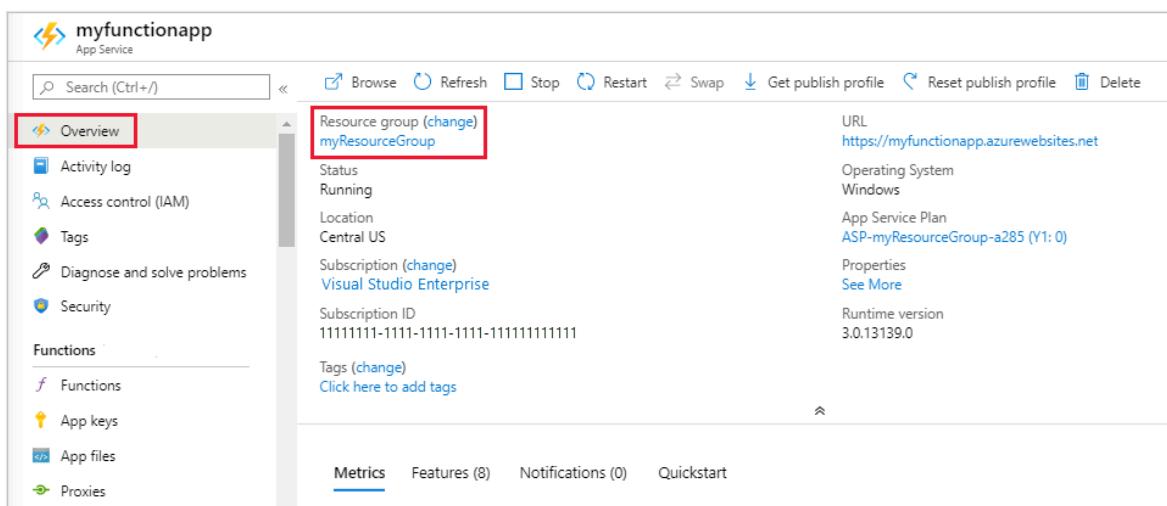

1. In Visual Studio Code, press **F1** to open the command palette. In the command palette, search for and select **Azure Functions: Deploy to function app....**
2. Choose the function app that you created in the first article. Because you're redeploying your project to the same app, select **Deploy** to dismiss the warning about overwriting files.
3. After the deployment completes, you can again use the **Execute Function Now...** feature to trigger the function in Azure.
4. Again [view the message in the storage queue](#) to verify that the output binding generates a new message in the queue.

Clean up resources

In Azure, *resources* refer to function apps, functions, storage accounts, and so forth. They're grouped into *resource groups*, and you can delete everything in a group by deleting the group.

You've created resources to complete these quickstarts. You may be billed for these resources, depending on your [account status](#) and [service pricing](#). If you don't need the resources anymore, here's how to delete them:

1. In Visual Studio Code, press `F1` to open the command palette. In the command palette, search for and select `Azure: Open in portal`.
2. Choose your function app and press `Enter`. The function app page opens in the Azure portal.
3. In the **Overview** tab, select the named link next to **Resource group**.

The screenshot shows the Azure portal interface for a function app named "myfunctionapp". The left sidebar has links for Overview, Activity log, Access control (IAM), Tags, Diagnose and solve problems, Security, Functions (with sub-links for Functions, App keys, App files, and Proxies), Metrics, Features (8), Notifications (0), and Quickstart. The main content area is the "Overview" tab, which displays details about the app: Status (Running), Location (Central US), Subscription (Visual Studio Enterprise), Subscription ID (11111111-1111-1111-1111-111111111111), and Tags (with a link to add tags). A red box highlights the "Resource group (change)" link, which points to "myResourceGroup". To the right of the main content, there are sections for URL (<https://myfunctionapp.azurewebsites.net>), Operating System (Windows), App Service Plan (ASP-myResourceGroup-a285 (Y1: 0)), Properties (with a "See More" link), and Runtime version (3.0.13139.0).

4. On the **Resource group** page, review the list of included resources, and verify that they're the ones you want to delete.
5. Select **Delete resource group**, and follow the instructions.

Deletion may take a couple of minutes. When it's done, a notification appears for a few seconds. You can also select the bell icon at the top of the page to view the notification.

Next steps

You've updated your HTTP triggered function to write data to a Storage queue. Now you can learn more about developing Functions using Visual Studio Code:

- [Develop Azure Functions using Visual Studio Code](#)
- [Azure Functions triggers and bindings](#).
- [Examples of complete Function projects in C#.](#)
- [Azure Functions C# developer reference](#)

Connect Azure Functions to Azure Storage using command line tools

Article • 04/25/2024

In this article, you integrate an Azure Storage queue with the function and storage account you created in the previous quickstart article. You achieve this integration by using an *output binding* that writes data from an HTTP request to a message in the queue. Completing this article incurs no additional costs beyond the few USD cents of the previous quickstart. To learn more about bindings, see [Azure Functions triggers and bindings concepts](#).

Configure your local environment

Before you begin, you must complete the article, [Quickstart: Create an Azure Functions project from the command line](#). If you already cleaned up resources at the end of that article, go through the steps again to recreate the function app and related resources in Azure.

Retrieve the Azure Storage connection string

Earlier, you created an Azure Storage account for function app's use. The connection string for this account is stored securely in app settings in Azure. By downloading the setting into the `local.settings.json` file, you can use the connection to write to a Storage queue in the same account when running the function locally.

1. From the root of the project, run the following command, replace `<APP_NAME>` with the name of your function app from the previous step. This command overwrites any existing values in the file.

```
func azure functionapp fetch-app-settings <APP_NAME>
```

2. Open `local.settings.json` file and locate the value named `AzureWebJobsStorage`, which is the Storage account connection string. You use the name `AzureWebJobsStorage` and the connection string in other sections of this article.

 **Important**

Because the `local.settings.json` file contains secrets downloaded from Azure, always exclude this file from source control. The `.gitignore` file created with a local functions project excludes the file by default.

Register binding extensions

Except for HTTP and timer triggers, bindings are implemented as extension packages. Run the following `dotnet add package` command in the Terminal window to add the Storage extension package to your project.

```
Isolated process

Bash

dotnet add package
Microsoft.Azure.Functions.Worker.Extensions.Storage.Queues --prerelease
```

Now, you can add the storage output binding to your project.

Add an output binding definition to the function

Although a function can have only one trigger, it can have multiple input and output bindings, which lets you connect to other Azure services and resources without writing custom integration code.

In a C# project, the bindings are defined as binding attributes on the function method. Specific definitions depend on whether your app runs in-process (C# class library) or in an isolated worker process.

```
Isolated worker model

C#

public class MultiResponse
{
    [QueueOutput("outqueue", Connection = "AzureWebJobsStorage")]
    public string[] Messages { get; set; }
```

```
    public HttpResponseMessage HttpResponse { get; set; }  
}
```

The `MultiResponse` class allows you to write to a storage queue named `outqueue` and an HTTP success message. Multiple messages could be sent to the queue because the `QueueOutput` attribute is applied to a string array.

The `Connection` property sets the connection string for the storage account. In this case, you could omit `Connection` because you're already using the default storage account.

For more information on the details of bindings, see [Azure Functions triggers and bindings concepts](#) and [queue output configuration](#).

Add code to use the output binding

With the queue binding defined, you can now update your function to receive the `msg` output parameter and write messages to the queue.

Isolated worker model

Replace the existing `HttpExample` class with the following code:

C#

```
[Function("HttpExample")]
public static MultiResponse
Run([HttpTrigger(AuthorizationLevel.Function, "get", "post")]
HttpRequestData req,
    FunctionContext executionContext)
{
    var logger = executionContext.GetLogger("HttpExample");
    logger.LogInformation("C# HTTP trigger function processed a
request.");

    var message = "Welcome to Azure Functions!";

    var response = req.CreateResponse(HttpStatusCode.OK);
    response.Headers.Add("Content-Type", "text/plain; charset=utf-
8");
    response.WriteString(message);

    // Return a response to both HTTP trigger and storage output
binding.
    return new MultiResponse()
{
```

```
// Write a single message.  
Messages = new string[] { message },  
HttpServletResponse = response  
};  
}  
}
```

Observe that you *don't* need to write any code for authentication, getting a queue reference, or writing data. All these integration tasks are conveniently handled in the Azure Functions runtime and queue output binding.

Run the function locally

1. Run your function by starting the local Azure Functions runtime host from the *LocalFunctionProj* folder.

```
Console  
  
func start
```

Toward the end of the output, the following lines must appear:

```
Azure Functions Core Tools  
Core Tools Version: 4.0.5049 Commit hash: N/A (64-bit)  
Function Runtime Version: 4.15.2.20177  
  
[2023-03-17T03:27:12.372Z] Worker process started and initialized.  
  
Functions:  
  
    HttpExample: [GET,POST] http://localhost:7071/api/HttpExample
```

ⓘ Note

If `HttpExample` doesn't appear as shown above, you likely started the host from outside the root folder of the project. In that case, use `Ctrl+C` to stop the host, go to the project's root folder, and run the previous command again.

2. Copy the URL of your HTTP function from this output to a browser and append the query string `?name=<YOUR_NAME>`, making the full URL like `http://localhost:7071/api/HttpExample?name=Functions`. The browser should display a response message that echoes back your query string value. The terminal in which you started your project also shows log output as you make requests.

3. When you're done, press `ctrl + c` and type `y` to stop the functions host.

View the message in the Azure Storage queue

You can view the queue in the [Azure portal](#) or in the [Microsoft Azure Storage Explorer](#). You can also view the queue in the Azure CLI, as described in the following steps:

1. Open the function project's `local.setting.json` file and copy the connection string value. In a terminal or command window, run the following command to create an environment variable named `AZURE_STORAGE_CONNECTION_STRING`, and paste your specific connection string in place of `<MY_CONNECTION_STRING>`. (This environment variable means you don't need to supply the connection string to each subsequent command using the `--connection-string` argument.)

```
bash
Bash
export AZURE_STORAGE_CONNECTION_STRING=""
```

2. (Optional) Use the `az storage queue list` command to view the Storage queues in your account. The output from this command must include a queue named `outqueue`, which was created when the function wrote its first message to that queue.

```
Azure CLI
az storage queue list --output tsv
```

3. Use the `az storage message get` command to read the message from this queue, which should be the value you supplied when testing the function earlier. The command reads and removes the first message from the queue.

```
bash
Azure CLI
echo `echo $(az storage message get --queue-name outqueue -o tsv --
query '[].{Message:content}') | base64 --decode`
```

Because the message body is stored [base64 encoded](#), the message must be decoded before it's displayed. After you execute `az storage message get`, the message is removed from the queue. If there was only one message in `outqueue`, you won't retrieve a message when you run this command a second time and instead get an error.

Redeploy the project to Azure

Now that you've verified locally that the function wrote a message to the Azure Storage queue, you can redeploy your project to update the endpoint running on Azure.

In the `LocalFunctionsProj` folder, use the [func azure functionapp publish](#) command to redeploy the project, replacing `<APP_NAME>` with the name of your app.

```
func azure functionapp publish <APP_NAME>
```

Verify in Azure

1. As in the previous quickstart, use a browser or CURL to test the redeployed function.

Browser

Copy the complete **Invoke URL** shown in the output of the publish command into a browser address bar, appending the query parameter `&name=Functions`. The browser should display the same output as when you ran the function locally.

2. Examine the Storage queue again, as described in the previous section, to verify that it contains the new message written to the queue.

Clean up resources

After you've finished, use the following command to delete the resource group and all its contained resources to avoid incurring further costs.

```
Azure CLI
```

```
az group delete --name AzureFunctionsQuickstart-rg
```

Next steps

You've updated your HTTP triggered function to write data to a Storage queue. Now you can learn more about developing Functions from the command line using Core Tools and Azure CLI:

- [Work with Azure Functions Core Tools](#)
- [Azure Functions triggers and bindings](#)

Connect Azure Functions to Azure Storage using Visual Studio Code

Article • 04/26/2024

Azure Functions lets you connect Azure services and other resources to functions without having to write your own integration code. These *bindings*, which represent both input and output, are declared within the function definition. Data from bindings is provided to the function as parameters. A *trigger* is a special type of input binding. Although a function has only one trigger, it can have multiple input and output bindings. To learn more, see [Azure Functions triggers and bindings concepts](#).

In this article, you learn how to use Visual Studio Code to connect Azure Storage to the function you created in the previous quickstart article. The output binding that you add to this function writes data from the HTTP request to a message in an Azure Queue storage queue.

Most bindings require a stored connection string that Functions uses to access the bound service. To make it easier, you use the storage account that you created with your function app. The connection to this account is already stored in an app setting named `AzureWebJobsStorage`.

Configure your local environment

Before you begin, you must meet the following requirements:

- Install the [Azure Storage extension for Visual Studio Code](#).
- Install [Azure Storage Explorer](#). Storage Explorer is a tool that you'll use to examine queue messages generated by your output binding. Storage Explorer is supported on macOS, Windows, and Linux-based operating systems.
- Complete the steps in [part 1 of the Visual Studio Code quickstart](#).

This article assumes that you're already signed in to your Azure subscription from Visual Studio Code. You can sign in by running `Azure: Sign In` from the command palette.

Download the function app settings

In the [previous quickstart article](#), you created a function app in Azure along with the required storage account. The connection string for this account is stored securely in the

app settings in Azure. In this article, you write messages to a Storage queue in the same account. To connect to your storage account when running the function locally, you must download app settings to the `local.settings.json` file.

1. Press `F1` to open the command palette, then search for and run the command `Azure Functions: Download Remote Settings....`
2. Choose the function app you created in the previous article. Select **Yes to all** to overwrite the existing local settings.

 **Important**

Because the `local.settings.json` file contains secrets, it never gets published, and is excluded from the source control.

3. Copy the value `AzureWebJobsStorage`, which is the key for the storage account connection string value. You use this connection to verify that the output binding works as expected.

Register binding extensions

Because you're using a Queue storage output binding, you must have the Storage bindings extension installed before you run the project.

Your project has been configured to use [extension bundles](#), which automatically installs a predefined set of extension packages.

Extension bundles is already enabled in the `host.json` file at the root of the project, which should look like the following example:

```
JSON

{
  "version": "2.0",
  "extensionBundle": {
    "id": "Microsoft.Azure.Functions.ExtensionBundle",
    "version": "[3.*, 4.0.0)"
  }
}
```

Now, you can add the storage output binding to your project.

Add an output binding

In a Java project, the bindings are defined as binding annotations on the function method. The *function.json* file is then autogenerated based on these annotations.

Browse to the location of your function code under *src/main/java*, open the *Function.java* project file, and add the following parameter to the `run` method definition:

Java

```
@QueueOutput(name = "msg", queueName = "outqueue",
connection = "AzureWebJobsStorage") OutputBinding<String> msg,
```

The `msg` parameter is an `OutputBinding<T>` type, which represents a collection of strings that are written as messages to an output binding when the function completes. In this case, the output is a storage queue named `outqueue`. The connection string for the Storage account is set by the `connection` method. Rather than the connection string itself, you pass the application setting that contains the Storage account connection string.

The `run` method definition should now look like the following example:

Java

```
@FunctionName("HttpExample")
public HttpResponseMessage run(
    @HttpTrigger(name = "req", methods = {HttpMethod.GET,
HttpMethod.POST}, authLevel = AuthorizationLevel.ANONYMOUS)
    HttpRequestMessage<Optional<String>> request,
    @QueueOutput(name = "msg", queueName = "outqueue",
connection = "AzureWebJobsStorage") OutputBinding<String> msg,
    final ExecutionContext context) {
```

Add code that uses the output binding

After the binding is defined, you can use the `name` of the binding to access it as an attribute in the function signature. By using an output binding, you don't have to use the Azure Storage SDK code for authentication, getting a queue reference, or writing data. The Functions runtime and queue output binding do those tasks for you.

Now, you can use the new `msg` parameter to write to the output binding from your function code. Add the following line of code before the success response to add the value of `name` to the `msg` output binding.

Java

```
msg.setValue(name);
```

When you use an output binding, you don't have to use the Azure Storage SDK code for authentication, getting a queue reference, or writing data. The Functions runtime and queue output binding do those tasks for you.

Your `run` method should now look like the following example:

Java

```
@FunctionName("HttpExample")
public HttpResponseMessage run(
    @HttpTrigger(name = "req", methods = {HttpMethod.GET,
HttpMethod.POST}, authLevel = AuthorizationLevel.ANONYMOUS)
    HttpRequestMessage<Optional<String>> request,
    @QueueOutput(name = "msg", queueName = "outqueue",
        connection = "AzureWebJobsStorage") OutputBinding<String> msg,
    final ExecutionContext context) {
    context.getLogger().info("Java HTTP trigger processed a request.");

    // Parse query parameter
    String query = request.getQueryParameters().get("name");
    String name = request.getBody().orElse(query);

    if (name == null) {
        return request.createResponseBuilder(HttpStatus.BAD_REQUEST)
            .body("Please pass a name on the query string or in the request
body").build();
    } else {
        // Write the name to the message queue.
        msg.setValue(name);

        return request.createResponseBuilder(HttpStatus.OK).body("Hello, " +
name).build();
    }
}
```

Update the tests

Because the archetype also creates a set of tests, you need to update these tests to handle the new `msg` parameter in the `run` method signature.

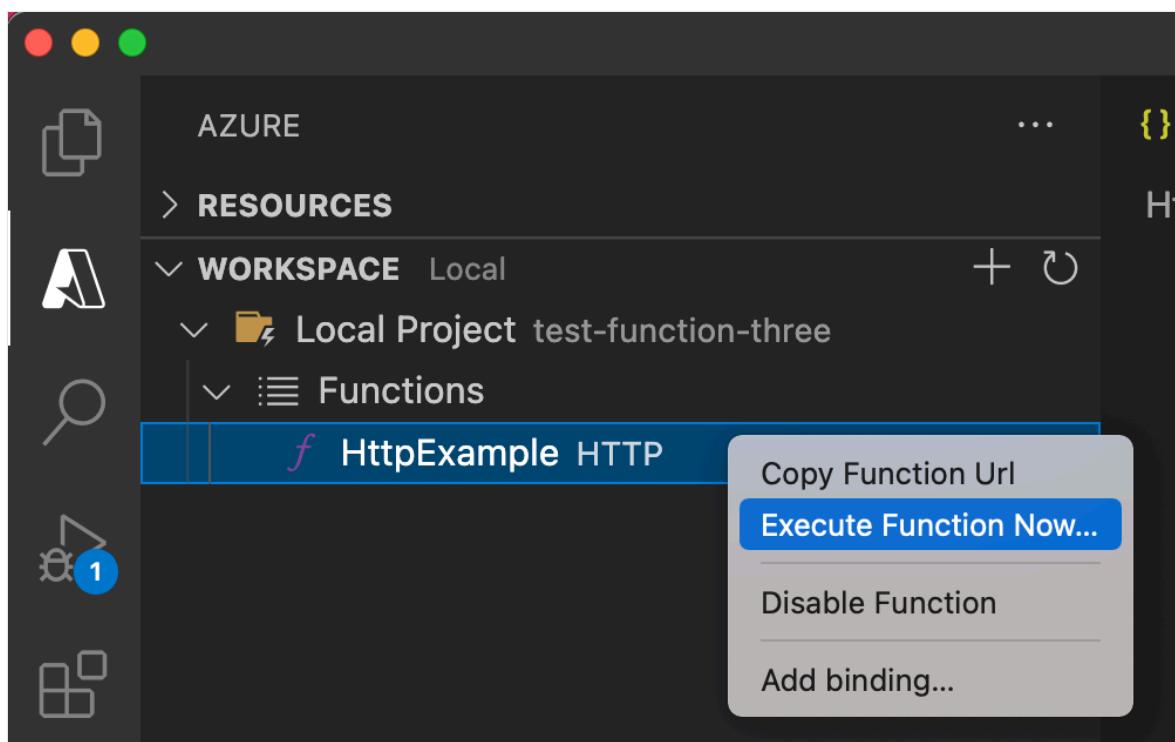

Browse to the location of your test code under `src/test/java`, open the `Function.java` project file, and replace the line of code under `//Invoke` with the following code.

Java

```
@SuppressWarnings("unchecked")
final OutputBinding<String> msg =
(OutputBinding<String>)mock(OutputBinding.class);
final HttpResponseMessage ret = new Function().run(req, msg, context);
```

Run the function locally

1. As in the previous article, press `F5` to start the function app project and Core Tools.
2. With the Core Tools running, go to the **Azure: Functions** area. Under **Functions**, expand **Local Project > Functions**. Right-click (Ctrl-click on Mac) the `HttpExample` function and select **Execute Function Now....**

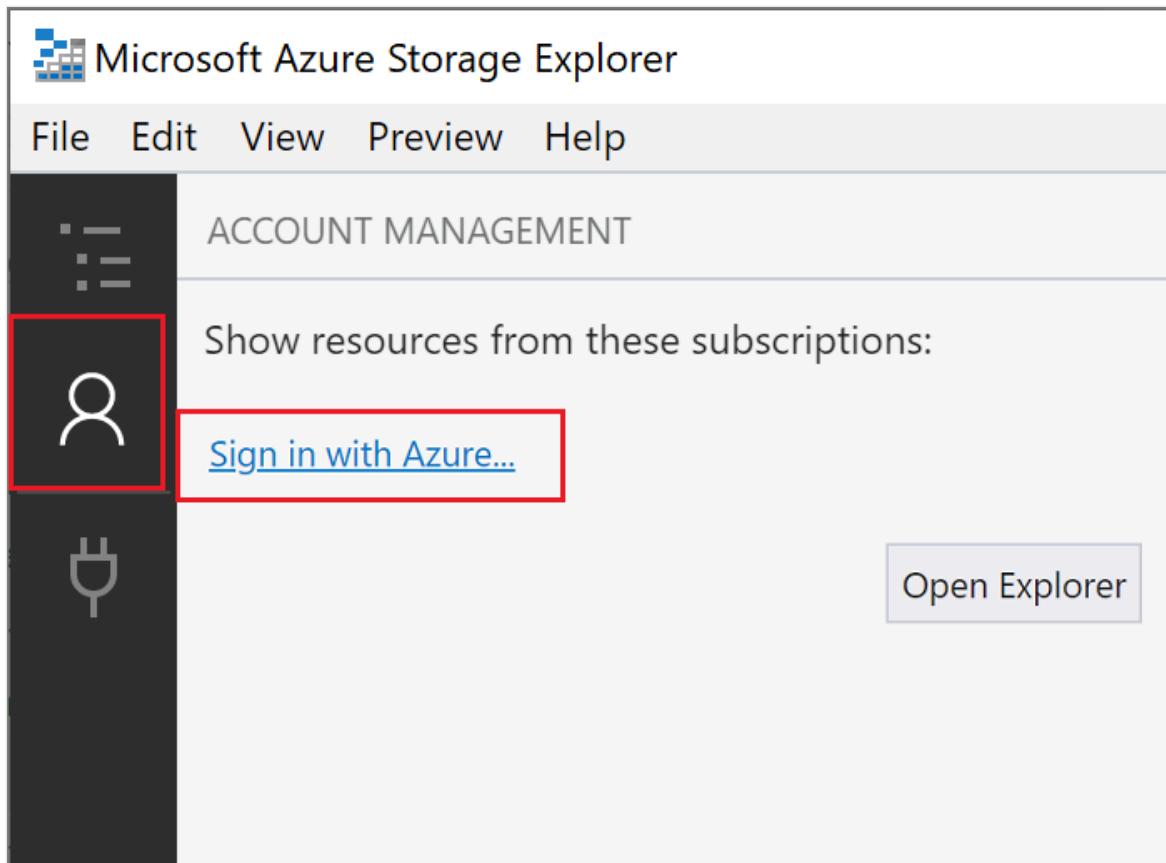

3. In the **Enter request body**, you see the request message body value of `{ "name": "Azure" }`. Press `Enter` to send this request message to your function.
4. After a response is returned, press `Ctrl + C` to stop Core Tools.

Because you're using the storage connection string, your function connects to the Azure storage account when running locally. A new queue named `outqueue` is created in your storage account by the Functions runtime when the output binding is first used. You'll use Storage Explorer to verify that the queue was created along with the new message.

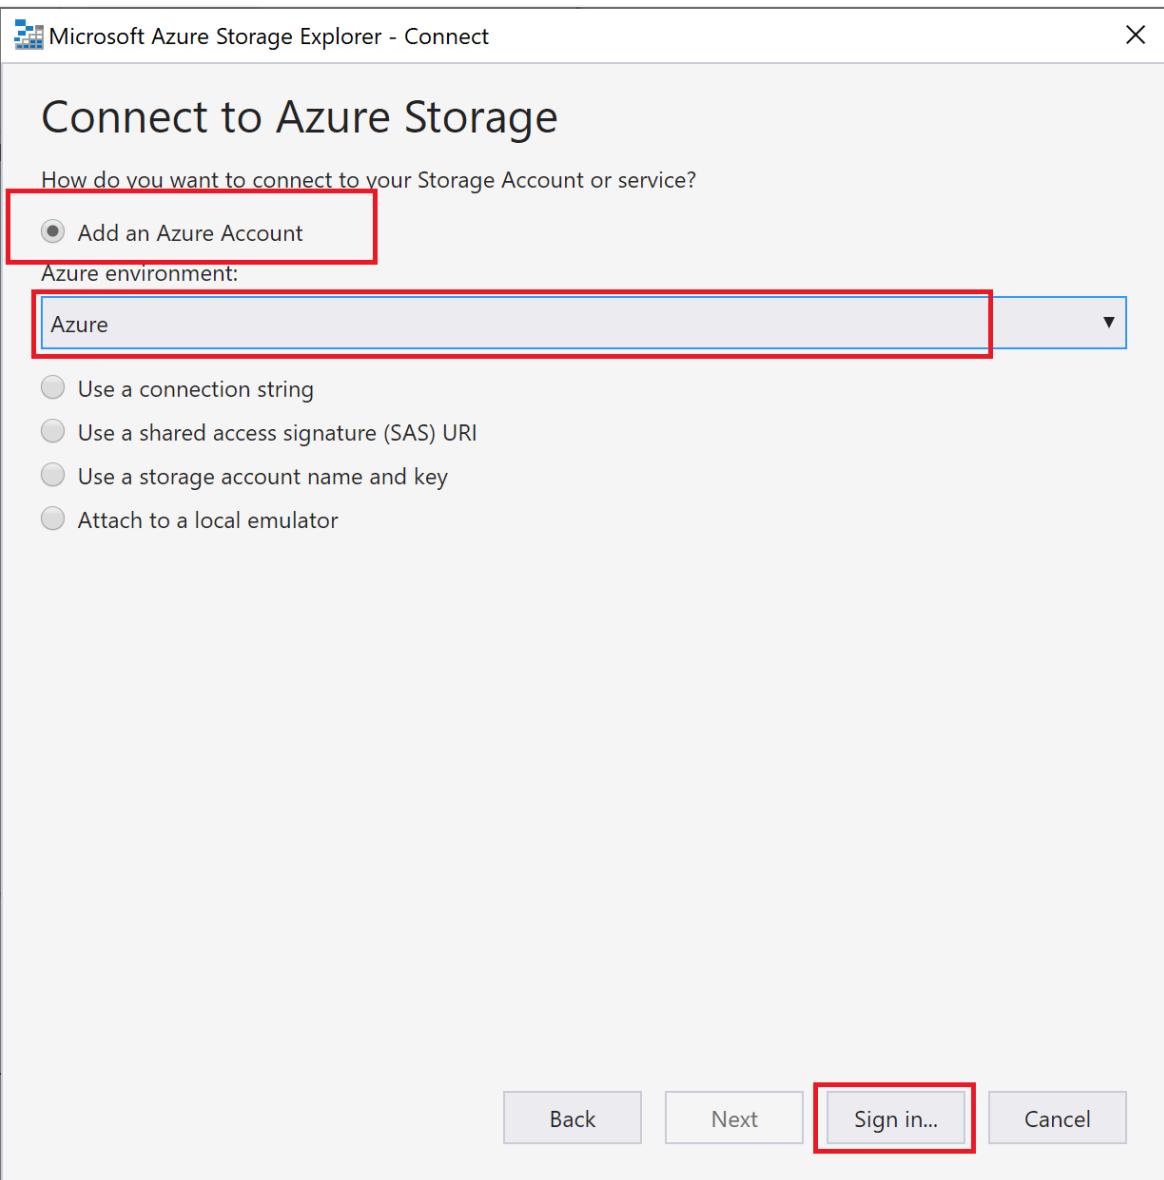

Connect Storage Explorer to your account

Skip this section if you've already installed Azure Storage Explorer and connected it to your Azure account.

1. Run the [Azure Storage Explorer](#) tool, select the connect icon on the left, and select Add an account.

2. In the Connect dialog, choose Add an Azure account, choose your Azure environment, and then select Sign in....

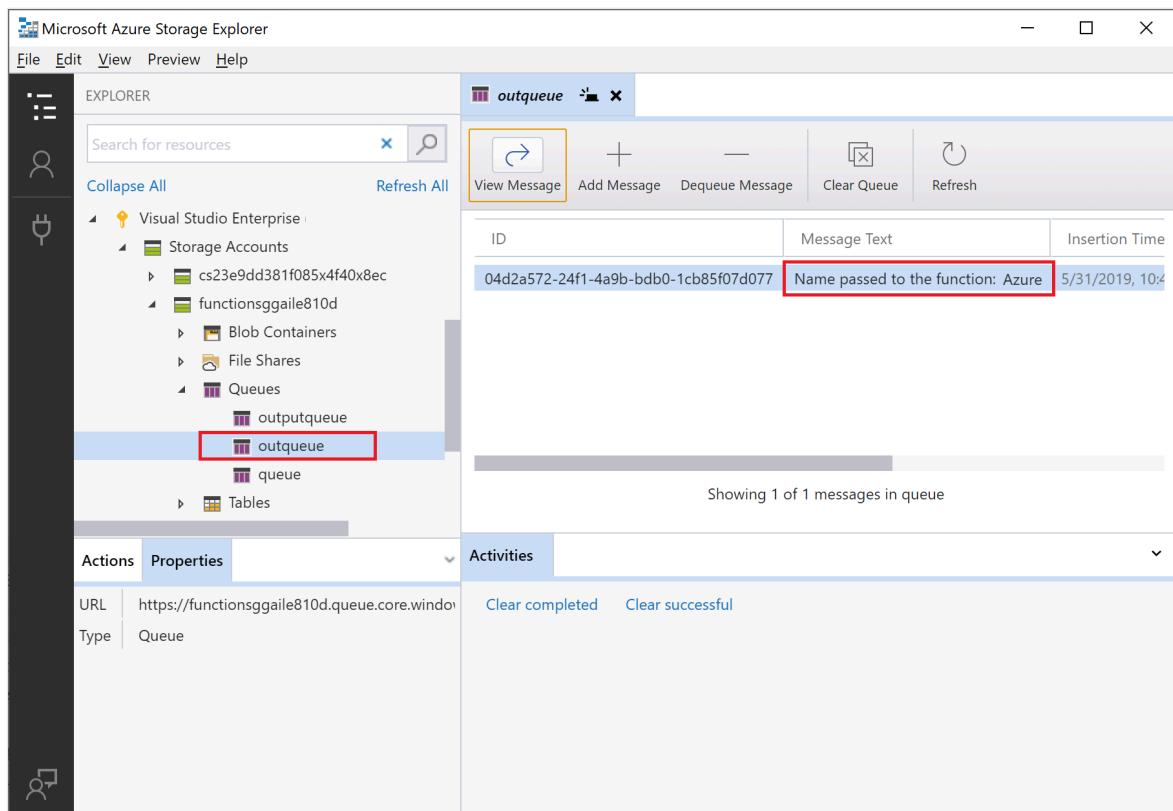

After you successfully sign in to your account, you see all of the Azure subscriptions associated with your account. Choose your subscription and select **Open Explorer**.

Examine the output queue

1. In Visual Studio Code, press **F1** to open the command palette, then search for and run the command **Azure Storage: Open in Storage Explorer** and choose your storage account name. Your storage account opens in the Azure Storage Explorer.
2. Expand the **Queues** node, and then select the queue named **outqueue**.

The queue contains the message that the queue output binding created when you ran the HTTP-triggered function. If you invoked the function with the default **name** value of *Azure*, the queue message is *Name passed to the function: Azure*.

- Run the function again, send another request, and you see a new message in the queue.

Now, it's time to republish the updated function app to Azure.

Redeploy and verify the updated app

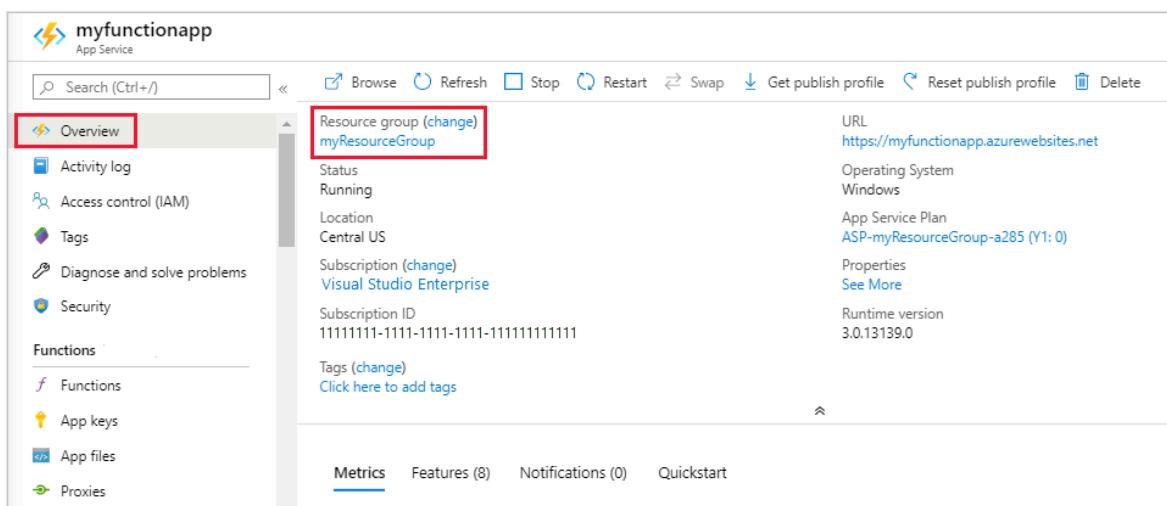

- In Visual Studio Code, press **F1** to open the command palette. In the command palette, search for and select **Azure Functions: Deploy to function app....**
- Choose the function app that you created in the first article. Because you're redeploying your project to the same app, select **Deploy** to dismiss the warning about overwriting files.
- After the deployment completes, you can again use the **Execute Function Now...** feature to trigger the function in Azure.
- Again [view the message in the storage queue](#) to verify that the output binding generates a new message in the queue.

Clean up resources

In Azure, *resources* refer to function apps, functions, storage accounts, and so forth. They're grouped into *resource groups*, and you can delete everything in a group by deleting the group.

You've created resources to complete these quickstarts. You may be billed for these resources, depending on your [account status](#) and [service pricing](#). If you don't need the resources anymore, here's how to delete them:

1. In Visual Studio Code, press `F1` to open the command palette. In the command palette, search for and select `Azure: Open in portal`.
2. Choose your function app and press `Enter`. The function app page opens in the Azure portal.
3. In the **Overview** tab, select the named link next to **Resource group**.

The screenshot shows the Azure portal interface for a function app named "myfunctionapp". The left sidebar has links for Activity log, Access control (IAM), Tags, Diagnose and solve problems, Security, Functions (with sub-links for Functions, App keys, App files, and Proxies), Metrics, Features (8), Notifications (0), and Quickstart. The main content area is the "Overview" tab, which displays details about the app: Status (Running), Location (Central US), Subscription (Visual Studio Enterprise), Subscription ID (11111111-1111-1111-1111-111111111111), and Tags (with a link to add tags). A red box highlights the "Resource group (change)" link, which points to "myResourceGroup". To the right of the main content, there are sections for URL (<https://myfunctionapp.azurewebsites.net>), Operating System (Windows), App Service Plan (ASP-myResourceGroup-a285 (Y1: 0)), Properties (with a "See More" link), and Runtime version (3.0.13139.0).

4. On the **Resource group** page, review the list of included resources, and verify that they're the ones you want to delete.
5. Select **Delete resource group**, and follow the instructions.

Deletion may take a couple of minutes. When it's done, a notification appears for a few seconds. You can also select the bell icon at the top of the page to view the notification.

Next steps

You've updated your HTTP triggered function to write data to a Storage queue. Now you can learn more about developing Functions using Visual Studio Code:

- [Azure Functions Java developer guide](#)

Connect Azure Functions to Azure Storage using command line tools

Article • 04/25/2024

In this article, you integrate an Azure Storage queue with the function and storage account you created in the previous quickstart article. You achieve this integration by using an *output binding* that writes data from an HTTP request to a message in the queue. Completing this article incurs no additional costs beyond the few USD cents of the previous quickstart. To learn more about bindings, see [Azure Functions triggers and bindings concepts](#).

Configure your local environment

Before you begin, you must complete the article, [Quickstart: Create an Azure Functions project from the command line](#). If you already cleaned up resources at the end of that article, go through the steps again to recreate the function app and related resources in Azure.

Retrieve the Azure Storage connection string

Earlier, you created an Azure Storage account for function app's use. The connection string for this account is stored securely in app settings in Azure. By downloading the setting into the `local.settings.json` file, you can use the connection to write to a Storage queue in the same account when running the function locally.

1. From the root of the project, run the following command, replace `<APP_NAME>` with the name of your function app from the previous step. This command overwrites any existing values in the file.

```
func azure functionapp fetch-app-settings <APP_NAME>
```

2. Open `local.settings.json` file and locate the value named `AzureWebJobsStorage`, which is the Storage account connection string. You use the name `AzureWebJobsStorage` and the connection string in other sections of this article.

 **Important**

Because the `local.settings.json` file contains secrets downloaded from Azure, always exclude this file from source control. The `.gitignore` file created with a local functions project excludes the file by default.

Add an output binding definition to the function

Although a function can have only one trigger, it can have multiple input and output bindings, which lets you connect to other Azure services and resources without writing custom integration code.

In a Java project, the bindings are defined as binding annotations on the function method. The `function.json` file is then autogenerated based on these annotations.

Browse to the location of your function code under `src/main/java`, open the `Function.java` project file, and add the following parameter to the `run` method definition:

Java

```
@QueueOutput(name = "msg", queueName = "outqueue", connection =
"AzureWebJobsStorage") OutputBinding<String> msg
```

The `msg` parameter is an `OutputBinding<T>` type, which represents a collection of strings. These strings are written as messages to an output binding when the function completes. In this case, the output is a storage queue named `outqueue`. The connection string for the Storage account is set by the `connection` method. You pass the application setting that contains the Storage account connection string, rather than passing the connection string itself.

The `run` method definition must now look like the following example:

Java

```
@FunctionName("HttpTrigger-Java")
public HttpResponseMessage run(
    @HttpTrigger(name = "req", methods = {HttpMethod.GET,
    HttpMethod.POST}, authLevel = AuthorizationLevel.FUNCTION)
    HttpRequestMessage<Optional<String>> request,
    @QueueOutput(name = "msg", queueName = "outqueue", connection =
"AzureWebJobsStorage")
    OutputBinding<String> msg, final ExecutionContext context) {
```

```
}
```

For more information on the details of bindings, see [Azure Functions triggers and bindings concepts](#) and [queue output configuration](#).

Add code to use the output binding

With the queue binding defined, you can now update your function to receive the `msg` output parameter and write messages to the queue.

Now, you can use the new `msg` parameter to write to the output binding from your function code. Add the following line of code before the success response to add the value of `name` to the `msg` output binding.

Java

```
msg.setValue(name);
```

When you use an output binding, you don't have to use the Azure Storage SDK code for authentication, getting a queue reference, or writing data. The Functions runtime and queue output binding do those tasks for you.

Your `run` method must now look like the following example:

Java

```
public HttpResponseMessage run(
    @HttpTrigger(name = "req", methods = {HttpMethod.GET,
    HttpMethod.POST}, authLevel = AuthorizationLevel.ANONYMOUS)
    HttpRequestMessage<Optional<String>> request,
    @QueueOutput(name = "msg", queueName = "outqueue",
    connection = "AzureWebJobsStorage") OutputBinding<String> msg,
    final ExecutionContext context) {
    context.getLogger().info("Java HTTP trigger processed a request.");

    // Parse query parameter
    String query = request.getQueryParameters().get("name");
    String name = request.getBody().orElse(query);

    if (name == null) {
        return request.createResponseBuilder(HttpStatus.BAD_REQUEST)
            .body("Please pass a name on the query string or in the request
body").build();
    } else {
        // Write the name to the message queue.
        msg.setValue(name);
```

```
        return request.createResponseBuilder(HttpStatus.OK).body("Hello, " +  
name).build();  
    }  
}
```

Update the tests

Because the archetype also creates a set of tests, you need to update these tests to handle the new `msg` parameter in the `run` method signature.

Browse to the location of your test code under `src/test/java`, open the `Function.java` project file, and replace the line of code under `//Invoke` with the following code:

Java

```
@SuppressWarnings("unchecked")  
final OutputBinding<String> msg =  
(OutputBinding<String>)mock(OutputBinding.class);  
final HttpResponseMessage ret = new Function().run(req, msg, context);
```

Observe that you *don't* need to write any code for authentication, getting a queue reference, or writing data. All these integration tasks are conveniently handled in the Azure Functions runtime and queue output binding.

Run the function locally

1. Run your function by starting the local Azure Functions runtime host from the `LocalFunctionProj` folder.

Console

```
func start
```

Toward the end of the output, the following lines must appear:

```
Azure Functions Core Tools  
Core Tools Version: 4.0.5049 Commit hash: N/A (64-bit)  
Function Runtime Version: 4.15.2.20177  
  
[2023-03-17T03:27:12.372Z] Worker process started and initialized.  
  
Functions:  
  
    HttpExample: [GET,POST] http://localhost:7071/api/HttpExample
```

(!) Note

If `HttpExample` doesn't appear as shown above, you likely started the host from outside the root folder of the project. In that case, use **Ctrl+C** to stop the host, go to the project's root folder, and run the previous command again.

2. Copy the URL of your HTTP function from this output to a browser and append the query string `?name=<YOUR_NAME>`, making the full URL like `http://localhost:7071/api/HttpExample?name=Functions`. The browser should display a response message that echoes back your query string value. The terminal in which you started your project also shows log output as you make requests.
3. When you're done, press `ctrl + c` and type `y` to stop the functions host.

View the message in the Azure Storage queue

You can view the queue in the [Azure portal](#) or in the [Microsoft Azure Storage Explorer](#). You can also view the queue in the Azure CLI, as described in the following steps:

1. Open the function project's `local.setting.json` file and copy the connection string value. In a terminal or command window, run the following command to create an environment variable named `AZURE_STORAGE_CONNECTION_STRING`, and paste your specific connection string in place of `<MY_CONNECTION_STRING>`. (This environment variable means you don't need to supply the connection string to each subsequent command using the `--connection-string` argument.)

```
bash
Bash
export AZURE_STORAGE_CONNECTION_STRING=""
```

2. (Optional) Use the [az storage queue list](#) command to view the Storage queues in your account. The output from this command must include a queue named `outqueue`, which was created when the function wrote its first message to that queue.

```
Azure CLI
```

```
az storage queue list --output tsv
```

3. Use the `az storage message get` command to read the message from this queue, which should be the value you supplied when testing the function earlier. The command reads and removes the first message from the queue.

bash

Azure CLI

```
echo `echo $(az storage message get --queue-name outqueue -o tsv --query '[].{Message:content}') | base64 --decode`
```

Because the message body is stored `base64 encoded`, the message must be decoded before it's displayed. After you execute `az storage message get`, the message is removed from the queue. If there was only one message in `outqueue`, you won't retrieve a message when you run this command a second time and instead get an error.

Redeploy the project to Azure

Now that you've verified locally that the function wrote a message to the Azure Storage queue, you can redeploy your project to update the endpoint running on Azure.

In the local project folder, use the following Maven command to republish your project:

```
mvn azure-functions:deploy
```

Verify in Azure

1. As in the previous quickstart, use a browser or CURL to test the redeployed function.

Browser

Copy the complete **Invoke URL** shown in the output of the publish command into a browser address bar, appending the query parameter `&name=Functions`.

The browser should display the same output as when you ran the function locally.

2. Examine the Storage queue again, as described in the previous section, to verify that it contains the new message written to the queue.

Clean up resources

After you've finished, use the following command to delete the resource group and all its contained resources to avoid incurring further costs.

Azure CLI

```
az group delete --name AzureFunctionsQuickstart-rg
```

Next steps

You've updated your HTTP triggered function to write data to a Storage queue. Now you can learn more about developing Functions from the command line using Core Tools and Azure CLI:

- [Azure Functions triggers and bindings](#)

Connect Azure Functions to Azure Storage using Visual Studio Code

Article • 04/26/2024

Azure Functions lets you connect Azure services and other resources to functions without having to write your own integration code. These *bindings*, which represent both input and output, are declared within the function definition. Data from bindings is provided to the function as parameters. A *trigger* is a special type of input binding. Although a function has only one trigger, it can have multiple input and output bindings. To learn more, see [Azure Functions triggers and bindings concepts](#).

In this article, you learn how to use Visual Studio Code to connect Azure Storage to the function you created in the previous quickstart article. The output binding that you add to this function writes data from the HTTP request to a message in an Azure Queue storage queue.

Most bindings require a stored connection string that Functions uses to access the bound service. To make it easier, you use the storage account that you created with your function app. The connection to this account is already stored in an app setting named `AzureWebJobsStorage`.

ⓘ Note

This article currently supports [Node.js v4 for Functions](#).

Configure your local environment

Before you begin, you must meet the following requirements:

- Install the [Azure Storage extension for Visual Studio Code](#).
- Install [Azure Storage Explorer](#). Storage Explorer is a tool that you'll use to examine queue messages generated by your output binding. Storage Explorer is supported on macOS, Windows, and Linux-based operating systems.
- Complete the steps in [part 1 of the Visual Studio Code quickstart](#).

This article assumes that you're already signed in to your Azure subscription from Visual Studio Code. You can sign in by running `Azure: Sign In` from the command palette.

Download the function app settings

In the [previous quickstart article](#), you created a function app in Azure along with the required storage account. The connection string for this account is stored securely in the app settings in Azure. In this article, you write messages to a Storage queue in the same account. To connect to your storage account when running the function locally, you must download app settings to the `local.settings.json` file.

1. Press `F1` to open the command palette, then search for and run the command `Azure Functions: Download Remote Settings....`

2. Choose the function app you created in the previous article. Select **Yes to all** to overwrite the existing local settings.

i Important

Because the `local.settings.json` file contains secrets, it never gets published, and is excluded from the source control.

3. Copy the value `AzureWebJobsStorage`, which is the key for the storage account connection string value. You use this connection to verify that the output binding works as expected.

Register binding extensions

Because you're using a Queue storage output binding, you must have the Storage bindings extension installed before you run the project.

Your project has been configured to use [extension bundles](#), which automatically installs a predefined set of extension packages.

Extension bundles is already enabled in the `host.json` file at the root of the project, which should look like the following example:

JSON

```
{  
  "version": "2.0",  
  "logging": {  
    "applicationInsights": {  
      "samplingSettings": {  
        "isEnabled": true,  
        "excludedTypes": "Request"  
      }  
    }  
  }  
}
```

```
        },
    },
    "extensionBundle": {
        "id": "Microsoft.Azure.Functions.ExtensionBundle",
        "version": "[4.*, 5.0.0)"
    }
}
```

Now, you can add the storage output binding to your project.

Add an output binding

To write to an Azure Storage queue:

- Add an `extraOutputs` property to the binding configuration

JavaScript

```
{
    methods: ['GET', 'POST'],
    extraOutputs: [sendToQueue], // add output binding to HTTP trigger
    authLevel: 'anonymous',
    handler: () => {}
}
```

- Add a `output.storageQueue` function above the `app.http` call

JavaScript

```
const sendToQueue = output.storageQueue({
    queueName: 'outqueue',
    connection: 'AzureWebJobsStorage',
});
```

Add code that uses the output binding

After the binding is defined, you can use the `name` of the binding to access it as an attribute in the function signature. By using an output binding, you don't have to use the Azure Storage SDK code for authentication, getting a queue reference, or writing data. The Functions runtime and queue output binding do those tasks for you.

Add code that uses the output binding object on `context.extraOutputs` to create a queue message. Add this code before the return statement.

JavaScript

```
context.extraOutputs.set(sendToQueue, [msg]);
```

At this point, your function could look as follows:

JavaScript

```
const { app, output } = require('@azure/functions');

const sendToQueue = output.storageQueue({
    queueName: 'outqueue',
    connection: 'AzureWebJobsStorage',
});

app.http('HttpExample', {
    methods: ['GET', 'POST'],
    authLevel: 'anonymous',
    extraOutputs: [sendToQueue],
    handler: async (request, context) => {
        try {
            context.log(`Http function processed request for url
"${{request.url}}`);

            const name = request.query.get('name') || (await request.text());
            context.log(`Name: ${name}`);

            if (name) {
                const msg = `Name passed to the function ${name}`;
                context.extraOutputs.set(sendToQueue, [msg]);
                return { body: msg };
            } else {
                context.log('Missing required data');
                return { status: 404, body: 'Missing required data' };
            }
        } catch (error) {
            context.log(`Error: ${error}`);
            return { status: 500, body: 'Internal Server Error' };
        }
    },
});
```

Run the function locally

1. As in the previous article, press **F5** to start the function app project and Core Tools.
2. With the Core Tools running, go to the **Azure: Functions** area. Under **Functions**, expand **Local Project > Functions**. Right-click (Ctrl-click on Mac) the **HttpExample**

function and select **Execute Function Now....**

3. In the **Enter request body**, you see the request message body value of `{ "name": "Azure" }`. Press **Enter** to send this request message to your function.

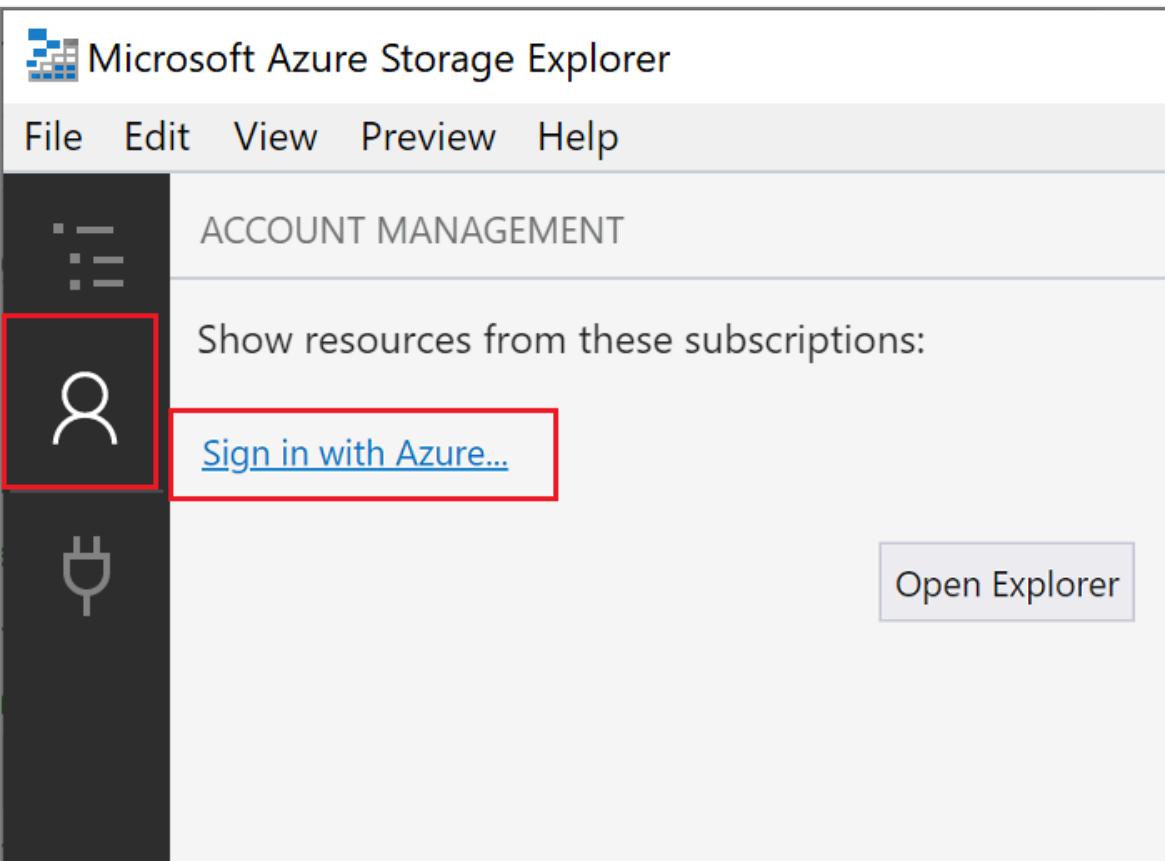

4. After a response is returned, press **Ctrl + c** to stop Core Tools.

Because you're using the storage connection string, your function connects to the Azure storage account when running locally. A new queue named **outqueue** is created in your storage account by the Functions runtime when the output binding is first used. You'll use Storage Explorer to verify that the queue was created along with the new message.

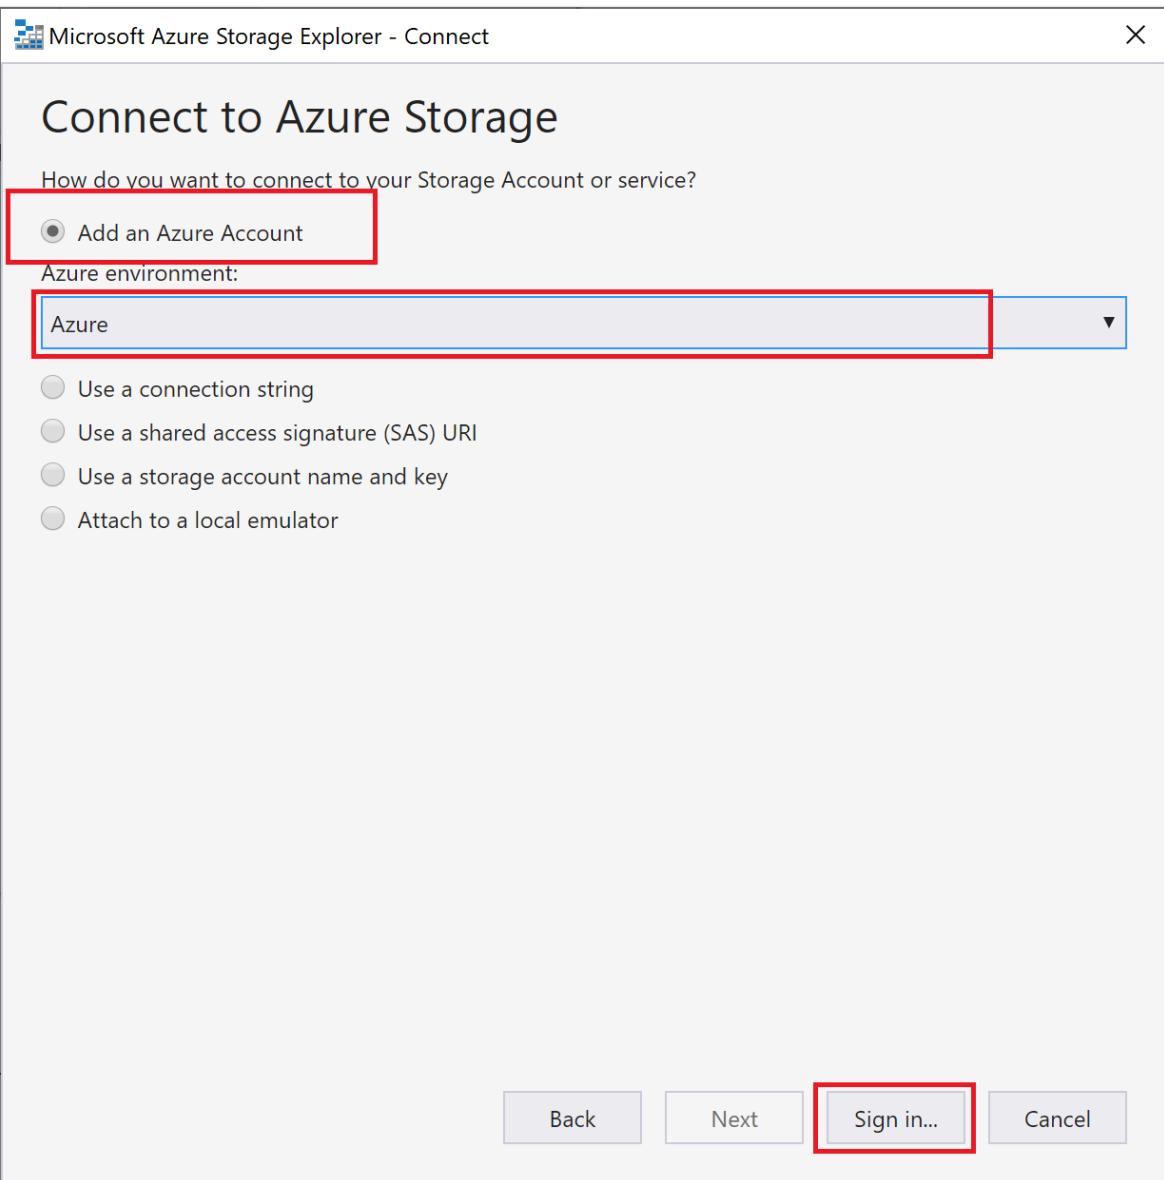

Connect Storage Explorer to your account

Skip this section if you've already installed Azure Storage Explorer and connected it to your Azure account.

1. Run the [Azure Storage Explorer](#) tool, select the connect icon on the left, and select **Add an account**.

2. In the **Connect** dialog, choose **Add an Azure account**, choose your **Azure environment**, and then select **Sign in....**

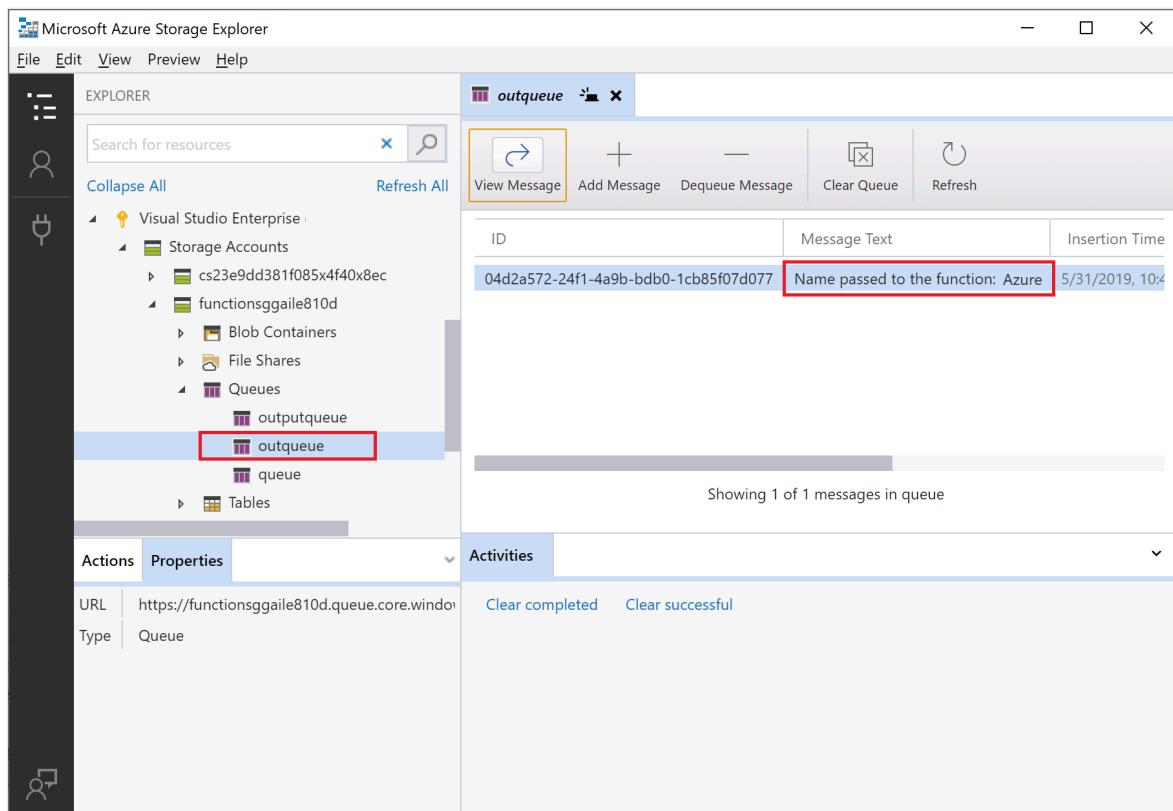

After you successfully sign in to your account, you see all of the Azure subscriptions associated with your account. Choose your subscription and select **Open Explorer**.

Examine the output queue

1. In Visual Studio Code, press **F1** to open the command palette, then search for and run the command **Azure Storage: Open in Storage Explorer** and choose your storage account name. Your storage account opens in the Azure Storage Explorer.
2. Expand the **Queues** node, and then select the queue named **outqueue**.

The queue contains the message that the queue output binding created when you ran the HTTP-triggered function. If you invoked the function with the default **name** value of *Azure*, the queue message is *Name passed to the function: Azure*.

3. Run the function again, send another request, and you see a new message in the queue.

Now, it's time to republish the updated function app to Azure.

Redeploy and verify the updated app

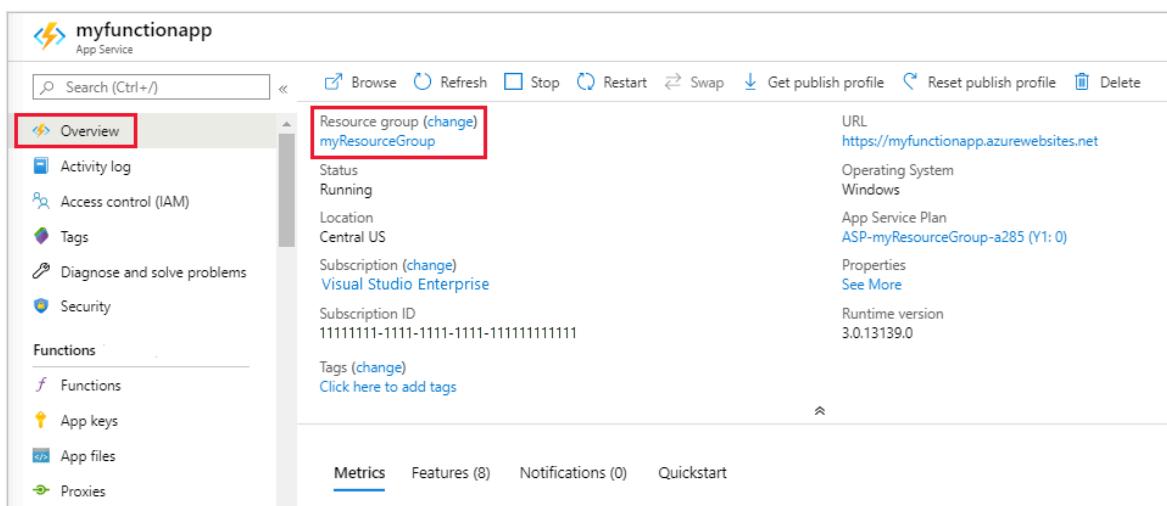

1. In Visual Studio Code, press **F1** to open the command palette. In the command palette, search for and select **Azure Functions: Deploy to function app....**
2. Choose the function app that you created in the first article. Because you're redeploying your project to the same app, select **Deploy** to dismiss the warning about overwriting files.
3. After the deployment completes, you can again use the **Execute Function Now...** feature to trigger the function in Azure.
4. Again [view the message in the storage queue](#) to verify that the output binding generates a new message in the queue.

Clean up resources

In Azure, *resources* refer to function apps, functions, storage accounts, and so forth. They're grouped into *resource groups*, and you can delete everything in a group by deleting the group.

You've created resources to complete these quickstarts. You may be billed for these resources, depending on your [account status](#) and [service pricing](#). If you don't need the resources anymore, here's how to delete them:

1. In Visual Studio Code, press `F1` to open the command palette. In the command palette, search for and select `Azure: Open in portal`.
2. Choose your function app and press `Enter`. The function app page opens in the Azure portal.
3. In the **Overview** tab, select the named link next to **Resource group**.

The screenshot shows the Azure portal interface for a function app named 'myfunctionapp'. The left sidebar has links for Activity log, Access control (IAM), Tags, Diagnose and solve problems, Security, Functions (with sub-links for Functions, App keys, App files, and Proxies), Metrics, Features (8), Notifications (0), and Quickstart. The main content area is the 'Overview' tab, which displays details about the app: Status (Running), Location (Central US), Subscription (Visual Studio Enterprise), Subscription ID (11111111-1111-1111-1111-111111111111), and Tags (with a link to add tags). A red box highlights the 'Resource group (change)' link, which points to 'myResourceGroup'. To the right of the resource group details, there are links for URL (https://myfunctionapp.azurewebsites.net), Operating System (Windows), App Service Plan (ASP-myResourceGroup-a285 (Y1: 0)), Properties, See More, and Runtime version (3.0.13139.0).

4. On the **Resource group** page, review the list of included resources, and verify that they're the ones you want to delete.
5. Select **Delete resource group**, and follow the instructions.

Deletion may take a couple of minutes. When it's done, a notification appears for a few seconds. You can also select the bell icon at the top of the page to view the notification.

Next steps

You've updated your HTTP triggered function to write data to a Storage queue. Now you can learn more about developing Functions using Visual Studio Code:

- [Develop Azure Functions using Visual Studio Code](#)
- [Azure Functions triggers and bindings](#).
- [Examples of complete Function projects in JavaScript](#).
- [Azure Functions JavaScript developer guide](#)

Connect Azure Functions to Azure Storage using command line tools

Article • 04/25/2024

In this article, you integrate an Azure Storage queue with the function and storage account you created in the previous quickstart article. You achieve this integration by using an *output binding* that writes data from an HTTP request to a message in the queue. Completing this article incurs no additional costs beyond the few USD cents of the previous quickstart. To learn more about bindings, see [Azure Functions triggers and bindings concepts](#).

Configure your local environment

Before you begin, you must complete the article, [Quickstart: Create an Azure Functions project from the command line](#). If you already cleaned up resources at the end of that article, go through the steps again to recreate the function app and related resources in Azure.

Retrieve the Azure Storage connection string

Earlier, you created an Azure Storage account for function app's use. The connection string for this account is stored securely in app settings in Azure. By downloading the setting into the `local.settings.json` file, you can use the connection to write to a Storage queue in the same account when running the function locally.

1. From the root of the project, run the following command, replace `<APP_NAME>` with the name of your function app from the previous step. This command overwrites any existing values in the file.

```
func azure functionapp fetch-app-settings <APP_NAME>
```

2. Open `local.settings.json` file and locate the value named `AzureWebJobsStorage`, which is the Storage account connection string. You use the name `AzureWebJobsStorage` and the connection string in other sections of this article.

 **Important**

Because the `local.settings.json` file contains secrets downloaded from Azure, always exclude this file from source control. The `.gitignore` file created with a local functions project excludes the file by default.

Add an output binding definition to the function

Although a function can have only one trigger, it can have multiple input and output bindings, which lets you connect to other Azure services and resources without writing custom integration code.

When using the [Node.js v4 programming model](#), binding attributes are defined directly in the `./src/functions/HttpExample.js` file. From the previous quickstart, your file already contains an HTTP binding defined by the `app.http` method.

JavaScript

```
const { app } = require('@azure/functions');

app.http('httpTrigger', {
    methods: ['GET', 'POST'],
    authLevel: 'anonymous',
    handler: async (request, context) => {
        try {
            context.log(`Http function processed request for url
"${request.url}"`);

            const name = request.query.get('name') || (await request.text());
            context.log(`Name: ${name}`);

            if (!name) {
                return { status: 404, body: 'Not Found' };
            }

            return { body: `Hello, ${name}!` };
        } catch (error) {
            context.log(`Error: ${error}`);
            return { status: 500, body: 'Internal Server Error' };
        }
    },
});
```

To write to an Azure Storage queue:

- Add an `extraOutputs` property to the binding configuration

TypeScript

```
{  
  methods: ['GET', 'POST'],  
  extraOutputs: [sendToQueue], // add output binding to HTTP trigger  
  authLevel: 'anonymous',  
  handler: () => {}  
}
```

- Add a `output.storageQueue` function above the `app.http` call

TypeScript

```
const sendToQueue: StorageQueueOutput = output.storageQueue({  
  queueName: 'outqueue',  
  connection: 'AzureWebJobsStorage',  
});
```

For a `queue` type, you must specify the name of the queue in `queueName` and provide the *name* of the Azure Storage connection (from `local.settings.json` file) in `connection`.

For more information on the details of bindings, see [Azure Functions triggers and bindings concepts](#) and [queue output configuration](#).

Add code to use the output binding

With the queue binding defined, you can now update your function to receive the `msg` output parameter and write messages to the queue.

Add code that uses the output binding object on `context.extraOutputs` to create a queue message. Add this code before the return statement.

JavaScript

```
context.extraOutputs.set(sendToQueue, [msg]);
```

At this point, your function could look as follows:

JavaScript

```
const { app, output } = require('@azure/functions');  
  
const sendToQueue = output.storageQueue({  
  queueName: 'outqueue',  
  connection: 'AzureWebJobsStorage',  
});
```

```

app.http('HttpExample', {
  methods: ['GET', 'POST'],
  authLevel: 'anonymous',
  extraOutputs: [sendToQueue],
  handler: async (request, context) => {
    try {
      context.log(`Http function processed request for url
      "${request.url}"`);

      const name = request.query.get('name') || (await request.text());
      context.log(`Name: ${name}`);

      if (name) {
        const msg = `Name passed to the function ${name}`;
        context.extraOutputs.set(sendToQueue, [msg]);
        return { body: msg };
      } else {
        context.log('Missing required data');
        return { status: 404, body: 'Missing required data' };
      }
    } catch (error) {
      context.log(`Error: ${error}`);
      return { status: 500, body: 'Internal Server Error' };
    }
  },
});

```

Observe that you *don't* need to write any code for authentication, getting a queue reference, or writing data. All these integration tasks are conveniently handled in the Azure Functions runtime and queue output binding.

Run the function locally

1. Run your function by starting the local Azure Functions runtime host from the *LocalFunctionProj* folder.

Console

```
func start
```

Toward the end of the output, the following lines must appear:

```
Azure Functions Core Tools
Core Tools Version:    4.0.5049 Commit hash: N/A  (64-bit)
Function Runtime Version: 4.15.2.20177

[2023-03-17T03:27:12.372Z] Worker process started and initialized.

Functions:

    HttpExample: [GET,POST] http://localhost:7071/api/HttpExample
```

ⓘ Note

If `HttpExample` doesn't appear as shown above, you likely started the host from outside the root folder of the project. In that case, use `Ctrl+C` to stop the host, go to the project's root folder, and run the previous command again.

2. Copy the URL of your HTTP function from this output to a browser and append the query string `?name=<YOUR_NAME>`, making the full URL like `http://localhost:7071/api/HttpExample?name=Functions`. The browser should display a response message that echoes back your query string value. The terminal in which you started your project also shows log output as you make requests.
3. When you're done, press `Ctrl + C` and type `y` to stop the functions host.

💡 Tip

During startup, the host downloads and installs the [Storage binding extension](#) and other Microsoft binding extensions. This installation happens because binding extensions are enabled by default in the `host.json` file with the following properties:

JSON

```
{
  "version": "2.0",
  "extensionBundle": {
    "id": "Microsoft.Azure.Functions.ExtensionBundle",
    "version": "[1.*, 2.0.0)"
  }
}
```

If you encounter any errors related to binding extensions, check that the above properties are present in `host.json`.

View the message in the Azure Storage queue

You can view the queue in the [Azure portal](#) or in the [Microsoft Azure Storage Explorer](#).

You can also view the queue in the Azure CLI, as described in the following steps:

1. Open the function project's `local.setting.json` file and copy the connection string value. In a terminal or command window, run the following command to create an environment variable named `AZURE_STORAGE_CONNECTION_STRING`, and paste your specific connection string in place of `<MY_CONNECTION_STRING>`. (This environment variable means you don't need to supply the connection string to each subsequent command using the `--connection-string` argument.)

```
bash
Bash
export AZURE_STORAGE_CONNECTION_STRING=<MY_CONNECTION_STRING>
```

2. (Optional) Use the `az storage queue list` command to view the Storage queues in your account. The output from this command must include a queue named `outqueue`, which was created when the function wrote its first message to that queue.

```
Azure CLI
az storage queue list --output tsv
```

3. Use the `az storage message get` command to read the message from this queue, which should be the value you supplied when testing the function earlier. The command reads and removes the first message from the queue.

```
bash
Azure CLI
echo `echo $(az storage message get --queue-name outqueue -o tsv --query '[].{Message:content}') | base64 --decode`
```

Because the message body is stored [base64 encoded](#), the message must be decoded before it's displayed. After you execute `az storage message get`, the message is removed from the queue. If there was only one message in `outqueue`,

you won't retrieve a message when you run this command a second time and instead get an error.

Redeploy the project to Azure

Now that you've verified locally that the function wrote a message to the Azure Storage queue, you can redeploy your project to update the endpoint running on Azure.

In the *LocalFunctionsProj* folder, use the `func azure functionapp publish` command to redeploy the project, replacing `<APP_NAME>` with the name of your app.

```
func azure functionapp publish <APP_NAME>
```

Verify in Azure

1. As in the previous quickstart, use a browser or CURL to test the redeployed function.

Browser

Copy the complete **Invoke URL** shown in the output of the publish command into a browser address bar, appending the query parameter `&name=Functions`. The browser should display the same output as when you ran the function locally.

2. Examine the Storage queue again, as described in the previous section, to verify that it contains the new message written to the queue.

Clean up resources

After you've finished, use the following command to delete the resource group and all its contained resources to avoid incurring further costs.

Azure CLI

```
az group delete --name AzureFunctionsQuickstart-rg
```

Next steps

You've updated your HTTP triggered function to write data to a Storage queue. Now you can learn more about developing Functions from the command line using Core Tools and Azure CLI:

- [Work with Azure Functions Core Tools](#)
- [Azure Functions triggers and bindings](#)
- [Examples of complete Function projects in JavaScript.](#)
- [Azure Functions JavaScript developer guide](#)

Connect Azure Functions to Azure Storage using Visual Studio Code

Article • 04/26/2024

Azure Functions lets you connect Azure services and other resources to functions without having to write your own integration code. These *bindings*, which represent both input and output, are declared within the function definition. Data from bindings is provided to the function as parameters. A *trigger* is a special type of input binding. Although a function has only one trigger, it can have multiple input and output bindings. To learn more, see [Azure Functions triggers and bindings concepts](#).

In this article, you learn how to use Visual Studio Code to connect Azure Storage to the function you created in the previous quickstart article. The output binding that you add to this function writes data from the HTTP request to a message in an Azure Queue storage queue.

Most bindings require a stored connection string that Functions uses to access the bound service. To make it easier, you use the storage account that you created with your function app. The connection to this account is already stored in an app setting named `AzureWebJobsStorage`.

Configure your local environment

Before you begin, you must meet the following requirements:

- Install the [Azure Storage extension for Visual Studio Code](#).
- Install [Azure Storage Explorer](#). Storage Explorer is a tool that you'll use to examine queue messages generated by your output binding. Storage Explorer is supported on macOS, Windows, and Linux-based operating systems.
- Complete the steps in [part 1 of the Visual Studio Code quickstart](#).

This article assumes that you're already signed in to your Azure subscription from Visual Studio Code. You can sign in by running `Azure: Sign In` from the command palette.

Download the function app settings

In the [previous quickstart article](#), you created a function app in Azure along with the required storage account. The connection string for this account is stored securely in the

app settings in Azure. In this article, you write messages to a Storage queue in the same account. To connect to your storage account when running the function locally, you must download app settings to the `local.settings.json` file.

1. Press `F1` to open the command palette, then search for and run the command `Azure Functions: Download Remote Settings....`
2. Choose the function app you created in the previous article. Select **Yes to all** to overwrite the existing local settings.

 **Important**

Because the `local.settings.json` file contains secrets, it never gets published, and is excluded from the source control.

3. Copy the value `AzureWebJobsStorage`, which is the key for the storage account connection string value. You use this connection to verify that the output binding works as expected.

Register binding extensions

Because you're using a Queue storage output binding, you must have the Storage bindings extension installed before you run the project.

Your project has been configured to use [extension bundles](#), which automatically installs a predefined set of extension packages.

Extension bundles is already enabled in the `host.json` file at the root of the project, which should look like the following example:

```
JSON

{
  "version": "2.0",
  "extensionBundle": {
    "id": "Microsoft.Azure.Functions.ExtensionBundle",
    "version": "[3.*, 4.0.0)"
  }
}
```

Now, you can add the storage output binding to your project.

Add an output binding

In Functions, each type of binding requires a `direction`, `type`, and unique `name`. The way you define these attributes depends on the language of your function app.

Binding attributes are defined in the `function.json` file for a given function. Depending on the binding type, additional properties may be required. The [queue output configuration](#) describes the fields required for an Azure Storage queue binding. The extension makes it easy to add bindings to the `function.json` file.

To create a binding, right-click (Ctrl+click on macOS) the `function.json` file in your `HttpTrigger` folder and choose **Add binding....** Follow the prompts to define the following binding properties for the new binding:

[\[+\] Expand table](#)

Prompt	Value	Description
Select binding direction	<code>out</code>	The binding is an output binding.
Select binding with direction...	<code>Azure Queue Storage</code>	The binding is an Azure Storage queue binding.
The name used to identify this binding in your code	<code>msg</code>	Name that identifies the binding parameter referenced in your code.
The queue to which the message will be sent	<code>outqueue</code>	The name of the queue that the binding writes to. When the <code>queueName</code> doesn't exist, the binding creates it on first use.
Select setting from "local.setting.json"	<code>AzureWebJobsStorage</code>	The name of an application setting that contains the connection string for the Storage account. The <code>AzureWebJobsStorage</code> setting contains the connection string for the Storage account you created with the function app.

A binding is added to the `bindings` array in your `function.json`, which should look like the following:

```
JSON
{
  "bindings": [
    {
      "name": "msg",
      "queueName": "outqueue",
      "connection": "AzureWebJobsStorage"
    }
  ]
}
```

Add code that uses the output binding

After the binding is defined, you can use the `name` of the binding to access it as an attribute in the function signature. By using an output binding, you don't have to use the Azure Storage SDK code for authentication, getting a queue reference, or writing data. The Functions runtime and queue output binding do those tasks for you.

Add code that uses the `Push-OutputBinding` cmdlet to write text to the queue using the `msg` output binding. Add this code before you set the OK status in the `if` statement.

PowerShell

```
$outputMsg = $name
Push-OutputBinding -name msg -Value $outputMsg
```

At this point, your function must look as follows:

PowerShell

```
using namespace System.Net

# Input bindings are passed in via param block.
param($Request, $TriggerMetadata)

# Write to the Azure Functions log stream.
Write-Host "PowerShell HTTP trigger function processed a request."

# Interact with query parameters or the body of the request.
$name = $Request.Query.Name
if (-not $name) {
    $name = $Request.Body.Name
}

if ($name) {
    # Write the $name value to the queue,
    # which is the name passed to the function.
    $outputMsg = $name
    Push-OutputBinding -name msg -Value $outputMsg

    $status = [HttpStatusCode]::OK
    $body = "Hello $name"
}
else {
    $status = [HttpStatusCode]::BadRequest
    $body = "Please pass a name on the query string or in the request body."
}

# Associate values to output bindings by calling 'Push-OutputBinding'.
Push-OutputBinding -Name Response -Value ([HttpResponseContext]@{
    StatusCode = $status
})
```

```
    Body = $body  
})
```

Run the function locally

1. As in the previous article, press `F5` to start the function app project and Core Tools.
2. With the Core Tools running, go to the **Azure: Functions** area. Under **Functions**, expand **Local Project > Functions**. Right-click (Ctrl-click on Mac) the `HttpExample` function and select **Execute Function Now....**

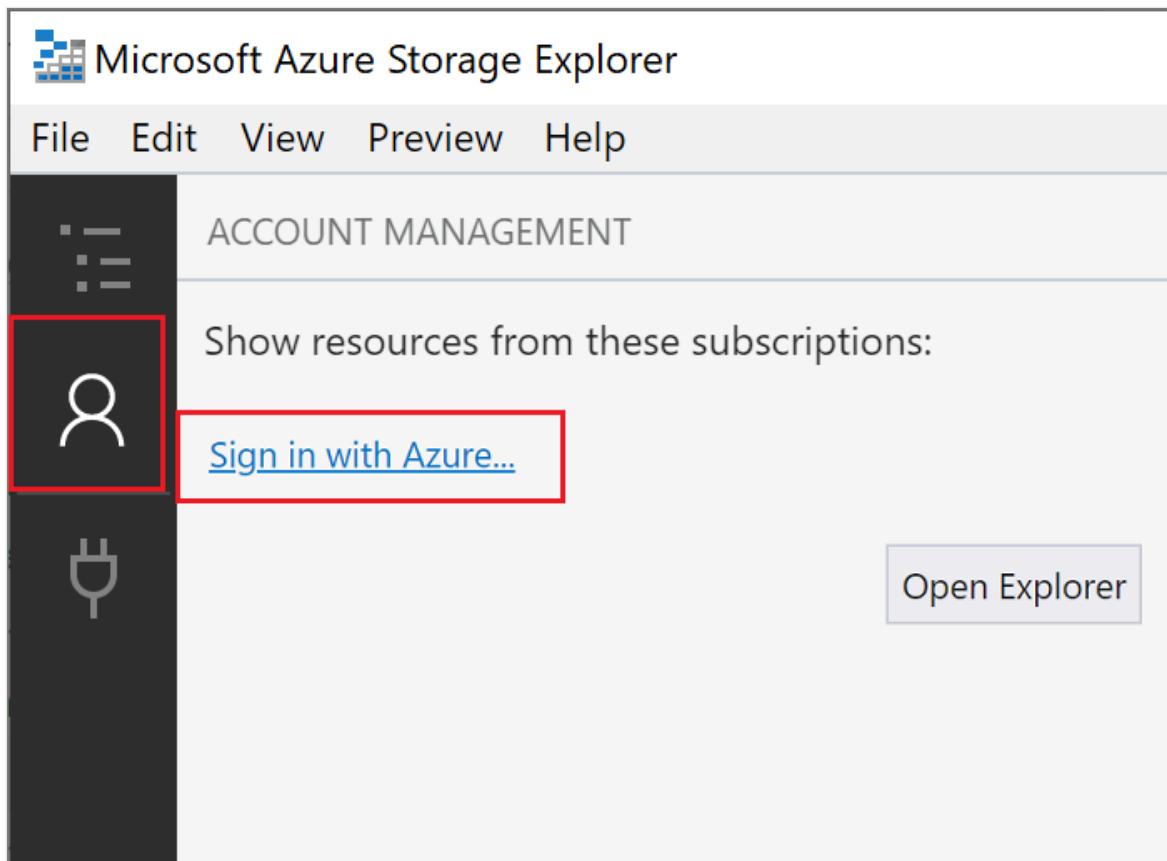

3. In the **Enter request body**, you see the request message body value of `{ "name": "Azure" }`. Press `Enter` to send this request message to your function.
4. After a response is returned, press `Ctrl + C` to stop Core Tools.

Because you're using the storage connection string, your function connects to the Azure storage account when running locally. A new queue named **outqueue** is created in your storage account by the Functions runtime when the output binding is first used. You'll use Storage Explorer to verify that the queue was created along with the new message.

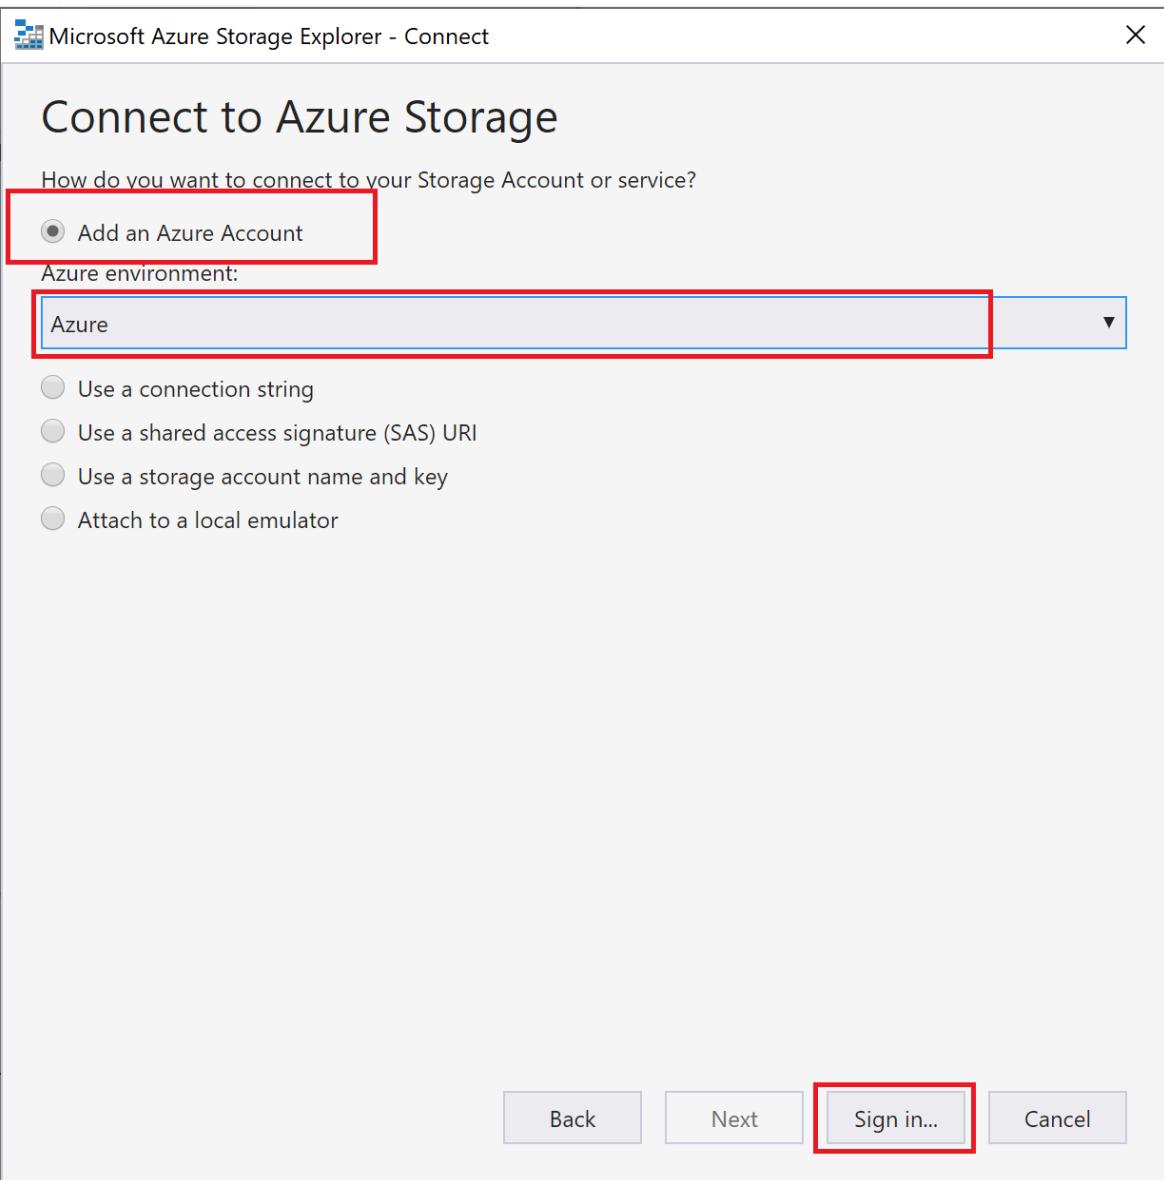

Connect Storage Explorer to your account

Skip this section if you've already installed Azure Storage Explorer and connected it to your Azure account.

1. Run the [Azure Storage Explorer](#) tool, select the connect icon on the left, and select **Add an account**.

2. In the **Connect** dialog, choose **Add an Azure account**, choose your **Azure environment**, and then select **Sign in....**

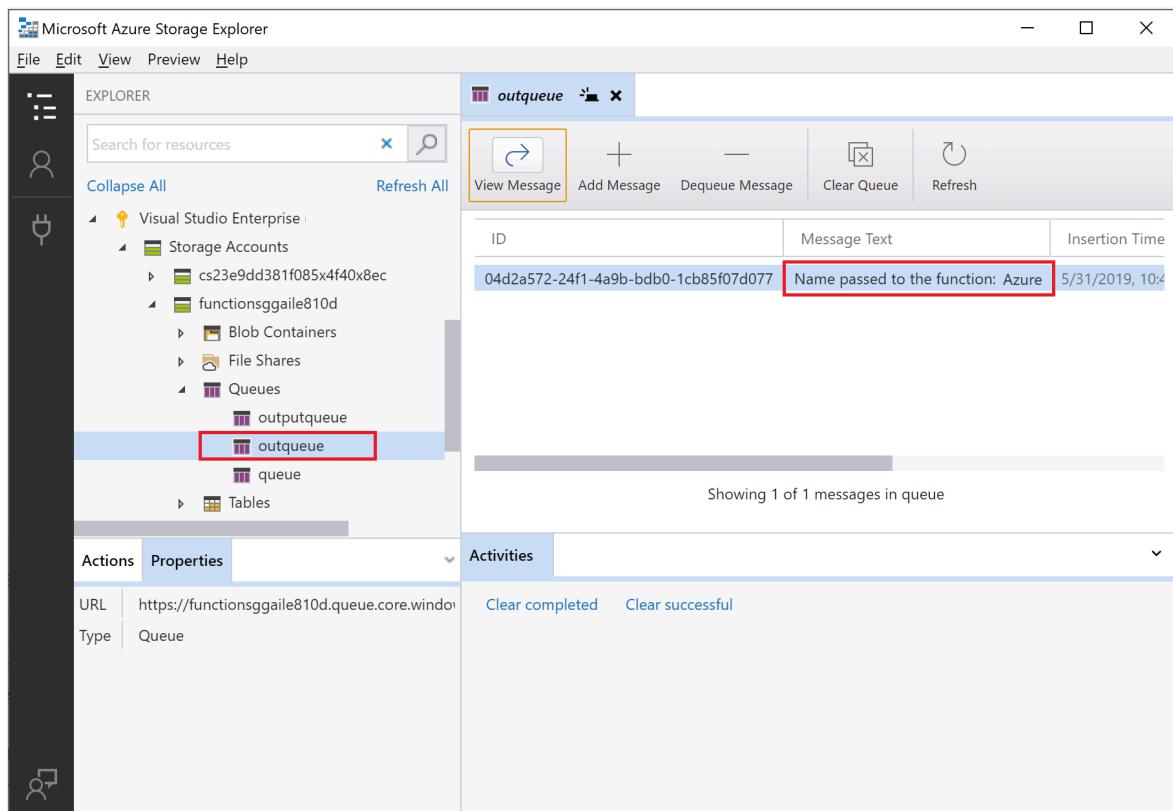

After you successfully sign in to your account, you see all of the Azure subscriptions associated with your account. Choose your subscription and select **Open Explorer**.

Examine the output queue

1. In Visual Studio Code, press **F1** to open the command palette, then search for and run the command **Azure Storage: Open in Storage Explorer** and choose your storage account name. Your storage account opens in the Azure Storage Explorer.
2. Expand the **Queues** node, and then select the queue named **outqueue**.

The queue contains the message that the queue output binding created when you ran the HTTP-triggered function. If you invoked the function with the default **name** value of *Azure*, the queue message is *Name passed to the function: Azure*.

3. Run the function again, send another request, and you see a new message in the queue.

Now, it's time to republish the updated function app to Azure.

Redeploy and verify the updated app

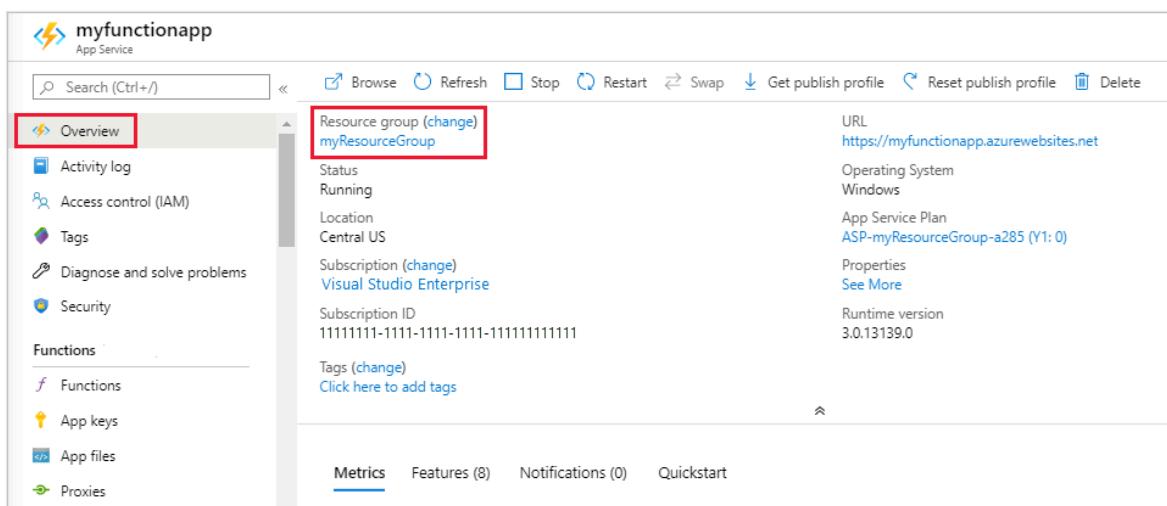

1. In Visual Studio Code, press **F1** to open the command palette. In the command palette, search for and select **Azure Functions: Deploy to function app....**
2. Choose the function app that you created in the first article. Because you're redeploying your project to the same app, select **Deploy** to dismiss the warning about overwriting files.
3. After the deployment completes, you can again use the **Execute Function Now...** feature to trigger the function in Azure.
4. Again [view the message in the storage queue](#) to verify that the output binding generates a new message in the queue.

Clean up resources

In Azure, *resources* refer to function apps, functions, storage accounts, and so forth. They're grouped into *resource groups*, and you can delete everything in a group by deleting the group.

You've created resources to complete these quickstarts. You may be billed for these resources, depending on your [account status](#) and [service pricing](#). If you don't need the resources anymore, here's how to delete them:

1. In Visual Studio Code, press `F1` to open the command palette. In the command palette, search for and select `Azure: Open in portal`.
2. Choose your function app and press `Enter`. The function app page opens in the Azure portal.
3. In the **Overview** tab, select the named link next to **Resource group**.

The screenshot shows the Azure portal interface for a function app named 'myfunctionapp'. The left sidebar has links for Activity log, Access control (IAM), Tags, Diagnose and solve problems, Security, Functions (with sub-links for Functions, App keys, App files, and Proxies), Metrics, Features (8), Notifications (0), and Quickstart. The main content area is the 'Overview' tab, which displays the following details:

- Resource group (change)**: myResourceGroup
- Status: Running
- Location: Central US
- Subscription (change): Visual Studio Enterprise
- Subscription ID: 11111111-1111-1111-1111-111111111111
- Tags (change): Click here to add tags
- URL: https://myfunctionapp.azurewebsites.net
- Operating System: Windows
- App Service Plan: ASP-myResourceGroup-a285 (Y1: 0)
- Properties: See More
- Runtime version: 3.0.13139.0

4. On the **Resource group** page, review the list of included resources, and verify that they're the ones you want to delete.
5. Select **Delete resource group**, and follow the instructions.

Deletion may take a couple of minutes. When it's done, a notification appears for a few seconds. You can also select the bell icon at the top of the page to view the notification.

Next steps

You've updated your HTTP triggered function to write data to a Storage queue. Now you can learn more about developing Functions using Visual Studio Code:

- [Develop Azure Functions using Visual Studio Code](#)
- [Azure Functions triggers and bindings](#).
- [Examples of complete Function projects in PowerShell](#).
- [Azure Functions PowerShell developer guide](#)

Connect Azure Functions to Azure Storage using command line tools

Article • 04/25/2024

In this article, you integrate an Azure Storage queue with the function and storage account you created in the previous quickstart article. You achieve this integration by using an *output binding* that writes data from an HTTP request to a message in the queue. Completing this article incurs no additional costs beyond the few USD cents of the previous quickstart. To learn more about bindings, see [Azure Functions triggers and bindings concepts](#).

Configure your local environment

Before you begin, you must complete the article, [Quickstart: Create an Azure Functions project from the command line](#). If you already cleaned up resources at the end of that article, go through the steps again to recreate the function app and related resources in Azure.

Retrieve the Azure Storage connection string

Earlier, you created an Azure Storage account for function app's use. The connection string for this account is stored securely in app settings in Azure. By downloading the setting into the `local.settings.json` file, you can use the connection to write to a Storage queue in the same account when running the function locally.

1. From the root of the project, run the following command, replace `<APP_NAME>` with the name of your function app from the previous step. This command overwrites any existing values in the file.

```
func azure functionapp fetch-app-settings <APP_NAME>
```

2. Open `local.settings.json` file and locate the value named `AzureWebJobsStorage`, which is the Storage account connection string. You use the name `AzureWebJobsStorage` and the connection string in other sections of this article.

 **Important**

Because the `local.settings.json` file contains secrets downloaded from Azure, always exclude this file from source control. The `.gitignore` file created with a local functions project excludes the file by default.

Add an output binding definition to the function

Although a function can have only one trigger, it can have multiple input and output bindings, which lets you connect to other Azure services and resources without writing custom integration code.

You declare these bindings in the `function.json` file in your function folder. From the previous quickstart, your `function.json` file in the `HttpExample` folder contains two bindings in the `bindings` collection:

JSON

```
"bindings": [
  {
    "authLevel": "function",
    "type": "httpTrigger",
    "direction": "in",
    "name": "Request",
    "methods": [
      "get",
      "post"
    ]
  },
  {
    "type": "http",
    "direction": "out",
    "name": "Response"
  }
]
```

The second binding in the collection is named `res`. This `http` binding is an output binding (`out`) that is used to write the HTTP response.

To write to an Azure Storage queue from this function, add an `out` binding of type `queue` with the name `msg`, as shown in the code below:

JSON

```
{
  "authLevel": "function",
```

```
    "type": "httpTrigger",
    "direction": "in",
    "name": "Request",
    "methods": [
        "get",
        "post"
    ],
},
{
    "type": "http",
    "direction": "out",
    "name": "Response"
},
{
    "type": "queue",
    "direction": "out",
    "name": "msg",
    "queueName": "outqueue",
    "connection": "AzureWebJobsStorage"
}
]
```

For a `queue` type, you must specify the name of the queue in `queueName` and provide the *name* of the Azure Storage connection (from `local.settings.json` file) in `connection`.

For more information on the details of bindings, see [Azure Functions triggers and bindings concepts](#) and [queue output configuration](#).

Add code to use the output binding

With the queue binding defined, you can now update your function to receive the `msg` output parameter and write messages to the queue.

Add code that uses the `Push-OutputBinding` cmdlet to write text to the queue using the `msg` output binding. Add this code before you set the OK status in the `if` statement.

PowerShell

```
$outputMsg = $name
Push-OutputBinding -name msg -Value $outputMsg
```

At this point, your function must look as follows:

PowerShell

```
using namespace System.Net
```

```

# Input bindings are passed in via param block.
param($Request, $TriggerMetadata)

# Write to the Azure Functions log stream.
Write-Host "PowerShell HTTP trigger function processed a request."

# Interact with query parameters or the body of the request.
$name = $Request.Query.Name
if (-not $name) {
    $name = $Request.Body.Name
}

if ($name) {
    # Write the $name value to the queue,
    # which is the name passed to the function.
    $outputMsg = $name
    Push-OutputBinding -name msg -Value $outputMsg

    $status = [HttpStatusCode]::OK
    $body = "Hello $name"
}
else {
    $status = [HttpStatusCode]::BadRequest
    $body = "Please pass a name on the query string or in the request body."
}

# Associate values to output bindings by calling 'Push-OutputBinding'.
Push-OutputBinding -Name Response -Value ([HttpResponseContext]@{
    StatusCode = $status
    Body = $body
})

```

Observe that you *don't* need to write any code for authentication, getting a queue reference, or writing data. All these integration tasks are conveniently handled in the Azure Functions runtime and queue output binding.

Run the function locally

1. Run your function by starting the local Azure Functions runtime host from the *LocalFunctionProj* folder.

Console

func start

Toward the end of the output, the following lines must appear:

```
Azure Functions Core Tools
Core Tools Version:    4.0.5049 Commit hash: N/A  (64-bit)
Function Runtime Version: 4.15.2.20177

[2023-03-17T03:27:12.372Z] Worker process started and initialized.

Functions:

    HttpExample: [GET,POST] http://localhost:7071/api/HttpExample
```

ⓘ Note

If `HttpExample` doesn't appear as shown above, you likely started the host from outside the root folder of the project. In that case, use `Ctrl+C` to stop the host, go to the project's root folder, and run the previous command again.

2. Copy the URL of your HTTP function from this output to a browser and append the query string `?name=<YOUR_NAME>`, making the full URL like `http://localhost:7071/api/HttpExample?name=Functions`. The browser should display a response message that echoes back your query string value. The terminal in which you started your project also shows log output as you make requests.
3. When you're done, press `Ctrl + C` and type `y` to stop the functions host.

💡 Tip

During startup, the host downloads and installs the [Storage binding extension](#) and other Microsoft binding extensions. This installation happens because binding extensions are enabled by default in the `host.json` file with the following properties:

JSON

```
{
  "version": "2.0",
  "extensionBundle": {
    "id": "Microsoft.Azure.Functions.ExtensionBundle",
    "version": "[1.*, 2.0.0)"
  }
}
```

If you encounter any errors related to binding extensions, check that the above properties are present in `host.json`.

View the message in the Azure Storage queue

You can view the queue in the [Azure portal](#) or in the [Microsoft Azure Storage Explorer](#).

You can also view the queue in the Azure CLI, as described in the following steps:

1. Open the function project's `local.setting.json` file and copy the connection string value. In a terminal or command window, run the following command to create an environment variable named `AZURE_STORAGE_CONNECTION_STRING`, and paste your specific connection string in place of `<MY_CONNECTION_STRING>`. (This environment variable means you don't need to supply the connection string to each subsequent command using the `--connection-string` argument.)

```
bash
Bash
export AZURE_STORAGE_CONNECTION_STRING=<MY_CONNECTION_STRING>
```

2. (Optional) Use the `az storage queue list` command to view the Storage queues in your account. The output from this command must include a queue named `outqueue`, which was created when the function wrote its first message to that queue.

```
Azure CLI
az storage queue list --output tsv
```

3. Use the `az storage message get` command to read the message from this queue, which should be the value you supplied when testing the function earlier. The command reads and removes the first message from the queue.

```
bash
Azure CLI
echo `echo $(az storage message get --queue-name outqueue -o tsv --query '[].{Message:content}') | base64 --decode`
```

Because the message body is stored [base64 encoded](#), the message must be decoded before it's displayed. After you execute `az storage message get`, the message is removed from the queue. If there was only one message in `outqueue`,

you won't retrieve a message when you run this command a second time and instead get an error.

Redeploy the project to Azure

Now that you've verified locally that the function wrote a message to the Azure Storage queue, you can redeploy your project to update the endpoint running on Azure.

In the *LocalFunctionsProj* folder, use the `func azure functionapp publish` command to redeploy the project, replacing `<APP_NAME>` with the name of your app.

```
func azure functionapp publish <APP_NAME>
```

Verify in Azure

1. As in the previous quickstart, use a browser or CURL to test the redeployed function.

Browser

Copy the complete **Invoke URL** shown in the output of the publish command into a browser address bar, appending the query parameter `&name=Functions`. The browser should display the same output as when you ran the function locally.

2. Examine the Storage queue again, as described in the previous section, to verify that it contains the new message written to the queue.

Clean up resources

After you've finished, use the following command to delete the resource group and all its contained resources to avoid incurring further costs.

Azure CLI

```
az group delete --name AzureFunctionsQuickstart-rg
```

Next steps

You've updated your HTTP triggered function to write data to a Storage queue. Now you can learn more about developing Functions from the command line using Core Tools and Azure CLI:

- [Work with Azure Functions Core Tools](#)
- [Azure Functions triggers and bindings](#)
- [Examples of complete Function projects in PowerShell.](#)
- [Azure Functions PowerShell developer guide](#)

Connect Azure Functions to Azure Storage using Visual Studio Code

Article • 04/26/2024

Azure Functions lets you connect Azure services and other resources to functions without having to write your own integration code. These *bindings*, which represent both input and output, are declared within the function definition. Data from bindings is provided to the function as parameters. A *trigger* is a special type of input binding. Although a function has only one trigger, it can have multiple input and output bindings. To learn more, see [Azure Functions triggers and bindings concepts](#).

In this article, you learn how to use Visual Studio Code to connect Azure Storage to the function you created in the previous quickstart article. The output binding that you add to this function writes data from the HTTP request to a message in an Azure Queue storage queue.

Most bindings require a stored connection string that Functions uses to access the bound service. To make it easier, you use the storage account that you created with your function app. The connection to this account is already stored in an app setting named `AzureWebJobsStorage`.

Configure your local environment

Before you begin, you must meet the following requirements:

- Install the [Azure Storage extension for Visual Studio Code](#).
- Install [Azure Storage Explorer](#). Storage Explorer is a tool that you'll use to examine queue messages generated by your output binding. Storage Explorer is supported on macOS, Windows, and Linux-based operating systems.
- Complete the steps in [part 1 of the Visual Studio Code quickstart](#).

This article assumes that you're already signed in to your Azure subscription from Visual Studio Code. You can sign in by running `Azure: Sign In` from the command palette.

Download the function app settings

In the [previous quickstart article](#), you created a function app in Azure along with the required storage account. The connection string for this account is stored securely in the

app settings in Azure. In this article, you write messages to a Storage queue in the same account. To connect to your storage account when running the function locally, you must download app settings to the `local.settings.json` file.

1. Press `F1` to open the command palette, then search for and run the command `Azure Functions: Download Remote Settings....`
2. Choose the function app you created in the previous article. Select **Yes to all** to overwrite the existing local settings.

 **Important**

Because the `local.settings.json` file contains secrets, it never gets published, and is excluded from the source control.

3. Copy the value `AzureWebJobsStorage`, which is the key for the storage account connection string value. You use this connection to verify that the output binding works as expected.

Register binding extensions

Because you're using a Queue storage output binding, you must have the Storage bindings extension installed before you run the project.

Your project has been configured to use [extension bundles](#), which automatically installs a predefined set of extension packages.

Extension bundles is already enabled in the `host.json` file at the root of the project, which should look like the following example:

```
JSON

{
  "version": "2.0",
  "extensionBundle": {
    "id": "Microsoft.Azure.Functions.ExtensionBundle",
    "version": "[3.*, 4.0.0)"
  }
}
```

Now, you can add the storage output binding to your project.

Add an output binding

Binding attributes are defined by decorating specific function code in the `function_app.py` file. You use the `queue_output` decorator to add an [Azure Queue storage output binding](#).

By using the `queue_output` decorator, the binding direction is implicitly 'out' and type is Azure Storage Queue. Add the following decorator to your function code in `HttpExample\function_app.py`:

Python

```
@app.queue_output(arg_name="msg", queue_name="outqueue",
connection="AzureWebJobsStorage")
```

In this code, `arg_name` identifies the binding parameter referenced in your code, `queue_name` is name of the queue that the binding writes to, and `connection` is the name of an application setting that contains the connection string for the Storage account. In quickstarts you use the same storage account as the function app, which is in the `AzureWebJobsStorage` setting. When the `queue_name` doesn't exist, the binding creates it on first use.

Add code that uses the output binding

After the binding is defined, you can use the `name` of the binding to access it as an attribute in the function signature. By using an output binding, you don't have to use the Azure Storage SDK code for authentication, getting a queue reference, or writing data. The Functions runtime and queue output binding do those tasks for you.

Update `HttpExample\function_app.py` to match the following code, add the `msg` parameter to the function definition and `msg.set(name)` under the `if name:` statement:

Python

```
import azure.functions as func
import logging

app = func.FunctionApp(http_auth_level=func.AuthLevel.ANONYMOUS)

@app.route(route="HttpExample")
@app.queue_output(arg_name="msg", queue_name="outqueue",
connection="AzureWebJobsStorage")
def HttpExample(req: func.HttpRequest, msg: func.Out[func.QueueMessage]) ->
func.HttpResponse:
    logging.info('Python HTTP trigger function processed a request.')
    name = req.params.get('name')
```

```

if not name:
    try:
        req_body = req.get_json()
    except ValueError:
        pass
    else:
        name = req_body.get('name')

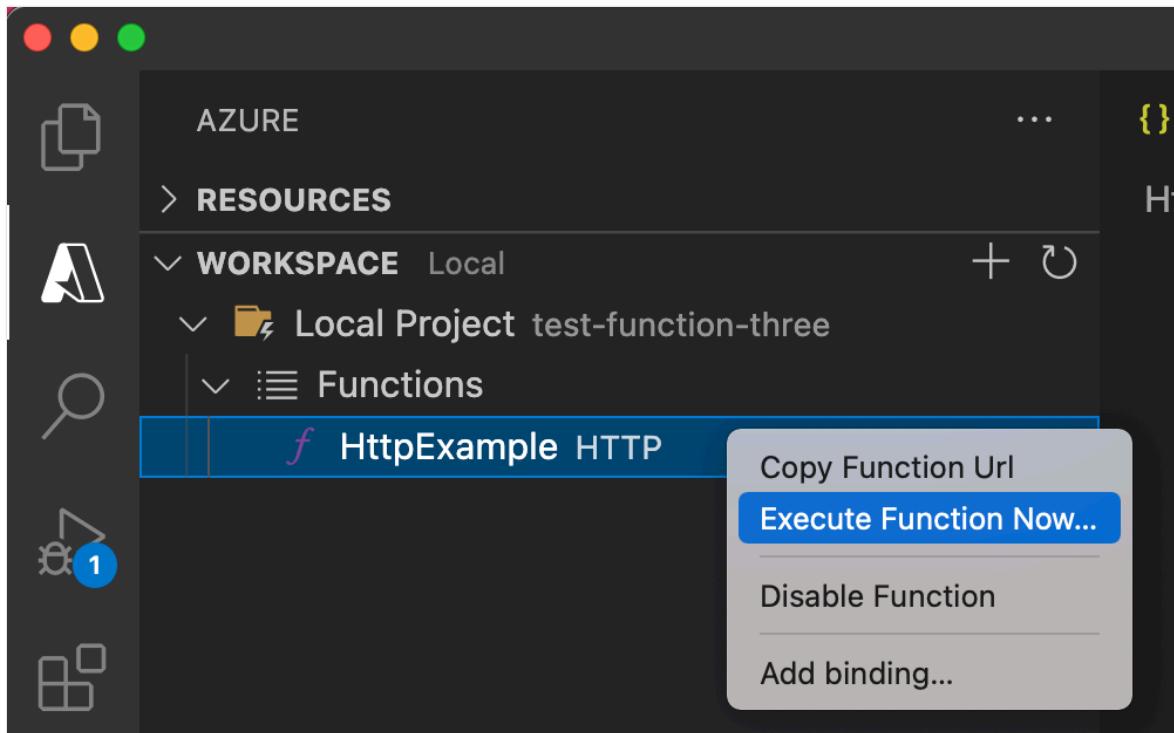

if name:
    msg.set(name)
    return func.HttpResponse(f"Hello, {name}. This HTTP triggered
function executed successfully.")
else:
    return func.HttpResponse(
        "This HTTP triggered function executed successfully. Pass a
name in the query string or in the request body for a personalized
response.",
        status_code=200
)

```

The `msg` parameter is an instance of the `azure.functions.Out class`. The `set` method writes a string message to the queue. In this case, it's the `name` passed to the function in the URL query string.

Run the function locally

1. As in the previous article, press `F5` to start the function app project and Core Tools.
2. With the Core Tools running, go to the **Azure: Functions** area. Under **Functions**, expand **Local Project > Functions**. Right-click (Ctrl-click on Mac) the `HttpExample` function and select **Execute Function Now....**

3. In the **Enter request body**, you see the request message body value of `{ "name": "Azure" }`. Press **Enter** to send this request message to your function.

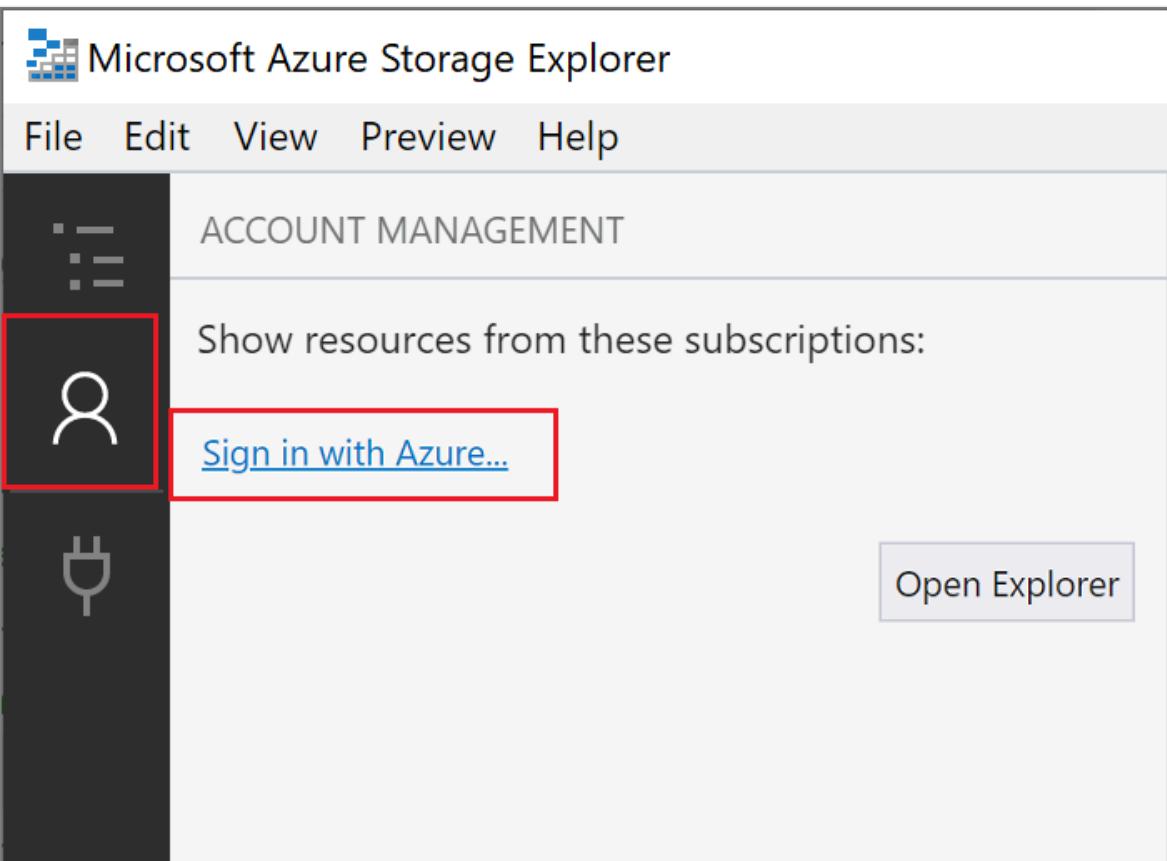

4. After a response is returned, press **Ctrl + C** to stop Core Tools.

Because you're using the storage connection string, your function connects to the Azure storage account when running locally. A new queue named **outqueue** is created in your storage account by the Functions runtime when the output binding is first used. You'll use Storage Explorer to verify that the queue was created along with the new message.

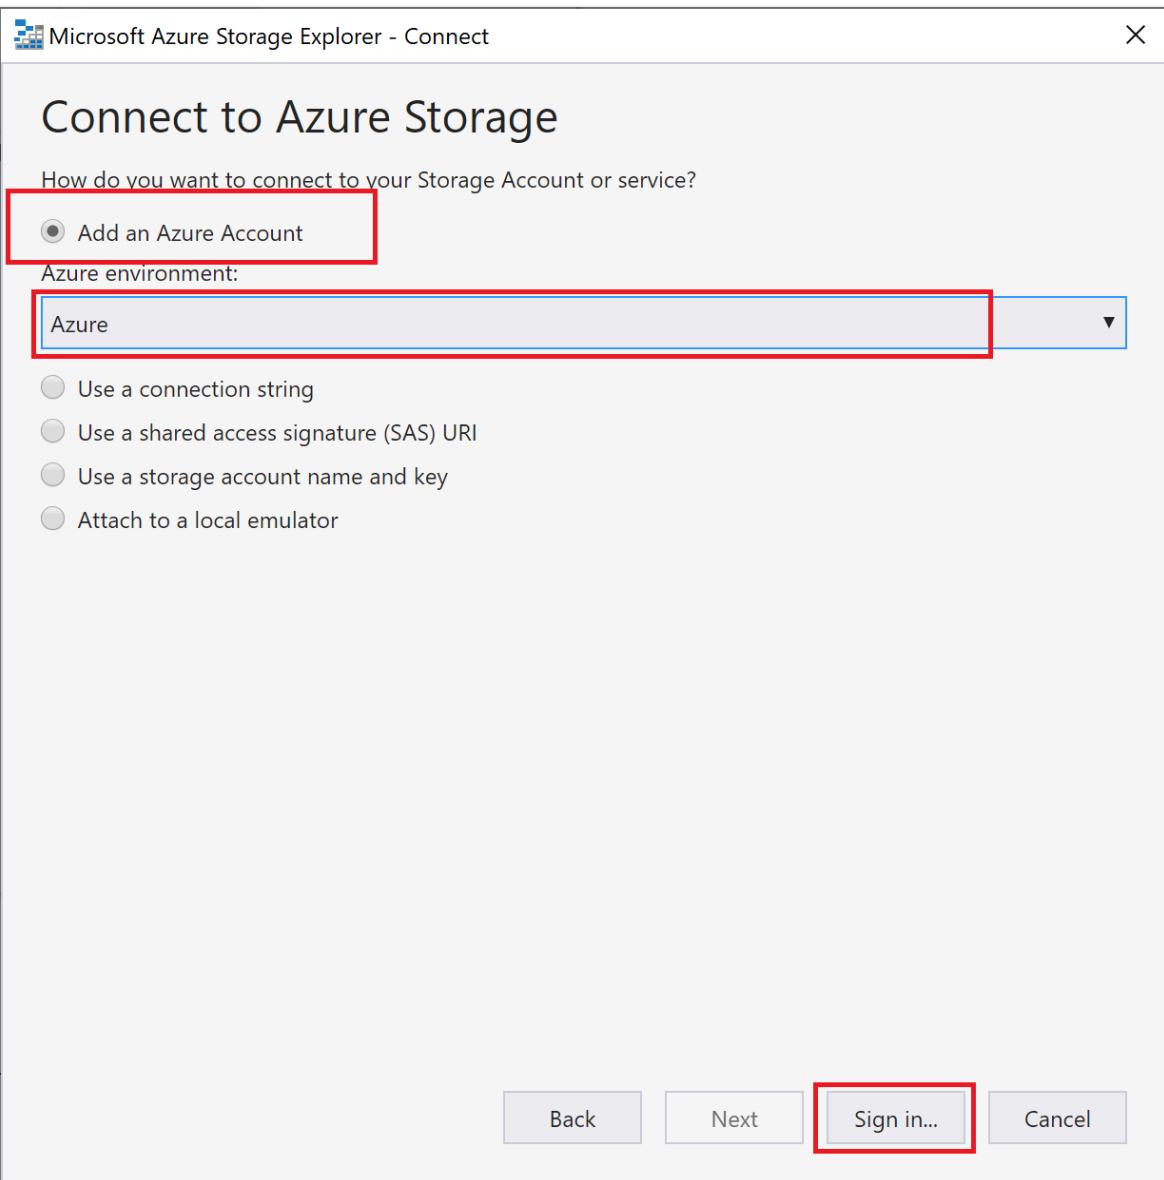

Connect Storage Explorer to your account

Skip this section if you've already installed Azure Storage Explorer and connected it to your Azure account.

1. Run the [Azure Storage Explorer](#) tool, select the connect icon on the left, and select **Add an account**.

2. In the **Connect** dialog, choose **Add an Azure account**, choose your **Azure environment**, and then select **Sign in....**

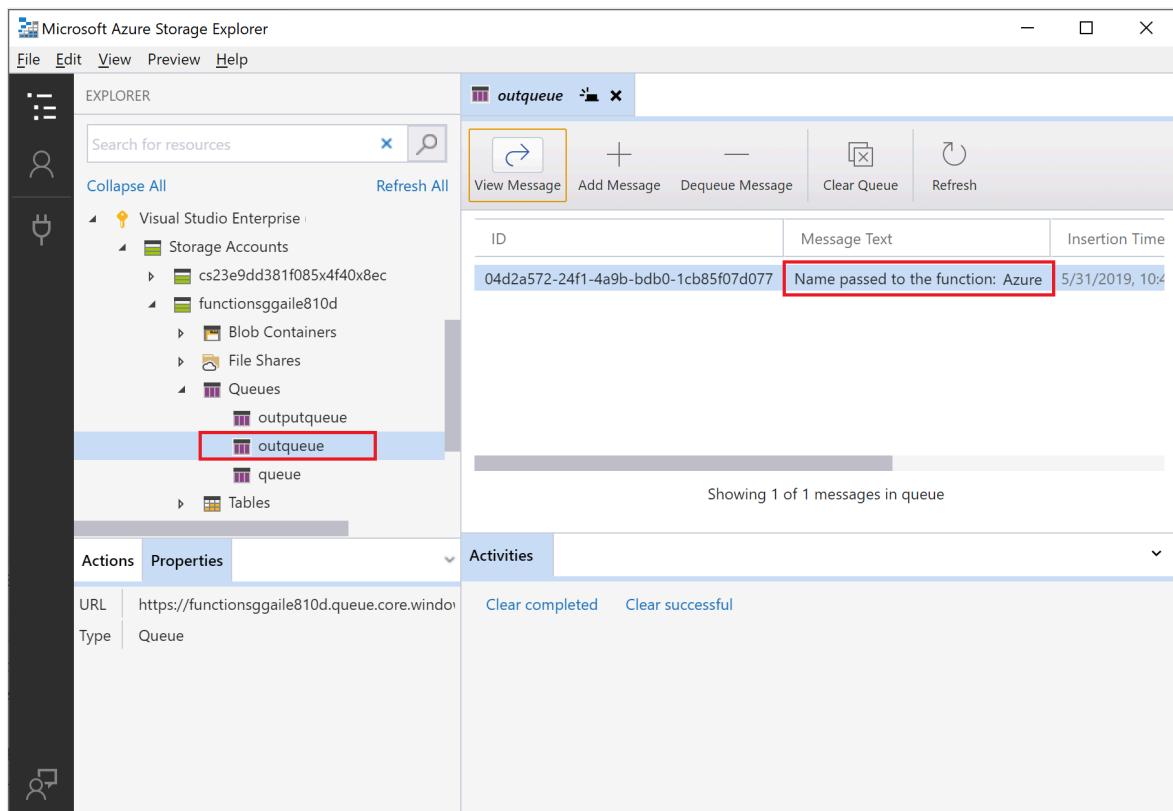

After you successfully sign in to your account, you see all of the Azure subscriptions associated with your account. Choose your subscription and select **Open Explorer**.

Examine the output queue

1. In Visual Studio Code, press **F1** to open the command palette, then search for and run the command **Azure Storage: Open in Storage Explorer** and choose your storage account name. Your storage account opens in the Azure Storage Explorer.
2. Expand the **Queues** node, and then select the queue named **outqueue**.

The queue contains the message that the queue output binding created when you ran the HTTP-triggered function. If you invoked the function with the default **name** value of *Azure*, the queue message is *Name passed to the function: Azure*.

3. Run the function again, send another request, and you see a new message in the queue.

Now, it's time to republish the updated function app to Azure.

Redeploy and verify the updated app

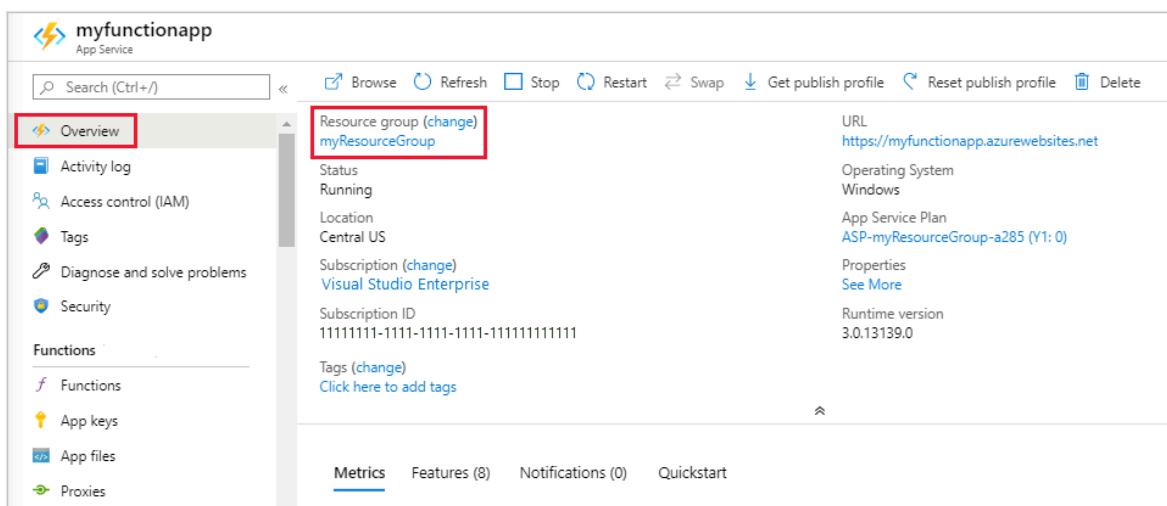

1. In Visual Studio Code, press **F1** to open the command palette. In the command palette, search for and select **Azure Functions: Deploy to function app....**
2. Choose the function app that you created in the first article. Because you're redeploying your project to the same app, select **Deploy** to dismiss the warning about overwriting files.
3. After the deployment completes, you can again use the **Execute Function Now...** feature to trigger the function in Azure.
4. Again [view the message in the storage queue](#) to verify that the output binding generates a new message in the queue.

Clean up resources

In Azure, *resources* refer to function apps, functions, storage accounts, and so forth. They're grouped into *resource groups*, and you can delete everything in a group by deleting the group.

You've created resources to complete these quickstarts. You may be billed for these resources, depending on your [account status](#) and [service pricing](#). If you don't need the resources anymore, here's how to delete them:

1. In Visual Studio Code, press `F1` to open the command palette. In the command palette, search for and select `Azure: Open in portal`.
2. Choose your function app and press `Enter`. The function app page opens in the Azure portal.
3. In the **Overview** tab, select the named link next to **Resource group**.

The screenshot shows the Azure portal interface for a function app named 'myfunctionapp'. The left sidebar has links for Activity log, Access control (IAM), Tags, Diagnose and solve problems, Security, Functions (with sub-links for Functions, App keys, App files, and Proxies), Metrics, Features (8), Notifications (0), and Quickstart. The main content area is the 'Overview' tab, which displays the following details:

- Resource group (change)**: myResourceGroup
- Status: Running
- Location: Central US
- Subscription (change): Visual Studio Enterprise
- Subscription ID: 11111111-1111-1111-1111-111111111111
- Tags (change): Click here to add tags
- URL: https://myfunctionapp.azurewebsites.net
- Operating System: Windows
- App Service Plan: ASP-myResourceGroup-a285 (Y1: 0)
- Properties: See More
- Runtime version: 3.0.13139.0

4. On the **Resource group** page, review the list of included resources, and verify that they're the ones you want to delete.
5. Select **Delete resource group**, and follow the instructions.

Deletion may take a couple of minutes. When it's done, a notification appears for a few seconds. You can also select the bell icon at the top of the page to view the notification.

Next steps

You've updated your HTTP triggered function to write data to a Storage queue. Now you can learn more about developing Functions using Visual Studio Code:

- [Develop Azure Functions using Visual Studio Code](#)
- [Azure Functions triggers and bindings](#).
- [Examples of complete Function projects in Python](#).

Connect Azure Functions to Azure Storage using command line tools

Article • 04/25/2024

In this article, you integrate an Azure Storage queue with the function and storage account you created in the previous quickstart article. You achieve this integration by using an *output binding* that writes data from an HTTP request to a message in the queue. Completing this article incurs no additional costs beyond the few USD cents of the previous quickstart. To learn more about bindings, see [Azure Functions triggers and bindings concepts](#).

Configure your local environment

Before you begin, you must complete the article, [Quickstart: Create an Azure Functions project from the command line](#). If you already cleaned up resources at the end of that article, go through the steps again to recreate the function app and related resources in Azure.

Retrieve the Azure Storage connection string

Earlier, you created an Azure Storage account for function app's use. The connection string for this account is stored securely in app settings in Azure. By downloading the setting into the `local.settings.json` file, you can use the connection to write to a Storage queue in the same account when running the function locally.

1. From the root of the project, run the following command, replace `<APP_NAME>` with the name of your function app from the previous step. This command overwrites any existing values in the file.

```
func azure functionapp fetch-app-settings <APP_NAME>
```

2. Open `local.settings.json` file and locate the value named `AzureWebJobsStorage`, which is the Storage account connection string. You use the name `AzureWebJobsStorage` and the connection string in other sections of this article.

 **Important**

Because the `local.settings.json` file contains secrets downloaded from Azure, always exclude this file from source control. The `.gitignore` file created with a local functions project excludes the file by default.

Add an output binding definition to the function

Although a function can have only one trigger, it can have multiple input and output bindings, which lets you connect to other Azure services and resources without writing custom integration code.

When using the [Python v2 programming model](#), binding attributes are defined directly in the `function_app.py` file as decorators. From the previous quickstart, your `function_app.py` file already contains one decorator-based binding:

Python

```
import azure.functions as func
import logging

app = func.FunctionApp()

@app.function_name(name="HttpTrigger1")
@app.route(route="hello", auth_level=func.AuthLevel.ANONYMOUS)
```

The `route` decorator adds `HttpTrigger` and `HttpOutput` binding to the function, which enables your function be triggered when http requests hit the specified route.

To write to an Azure Storage queue from this function, add the `queue_output` decorator to your function code:

Python

```
@app.queue_output(arg_name="msg", queue_name="outqueue",
connection="AzureWebJobsStorage")
```

In the decorator, `arg_name` identifies the binding parameter referenced in your code, `queue_name` is name of the queue that the binding writes to, and `connection` is the name of an application setting that contains the connection string for the Storage account. In quickstarts you use the same storage account as the function app, which is in the `AzureWebJobsStorage` setting (from `local.settings.json` file). When the `queue_name` doesn't exist, the binding creates it on first use.

For more information on the details of bindings, see [Azure Functions triggers and bindings concepts](#) and [queue output configuration](#).

Add code to use the output binding

With the queue binding defined, you can now update your function to receive the `msg` output parameter and write messages to the queue.

Update `HttpExample\function_app.py` to match the following code, add the `msg` parameter to the function definition and `msg.set(name)` under the `if name:` statement:

Python

```
import azure.functions as func
import logging

app = func.FunctionApp(http_auth_level=func.AuthLevel.ANONYMOUS)

@app.route(route="HttpExample")
@app.queue_output(arg_name="msg", queue_name="outqueue",
connection="AzureWebJobsStorage")
def HttpExample(req: func.HttpRequest, msg: func.Out[func.QueueMessage]) ->
func.HttpResponse:
    logging.info('Python HTTP trigger function processed a request.')

    name = req.params.get('name')
    if not name:
        try:
            req_body = req.get_json()
        except ValueError:
            pass
        else:
            name = req_body.get('name')

    if name:
        msg.set(name)
        return func.HttpResponse(f"Hello, {name}. This HTTP triggered
function executed successfully.")
    else:
        return func.HttpResponse(
            "This HTTP triggered function executed successfully. Pass a
name in the query string or in the request body for a personalized
response.",
            status_code=200
        )
```

The `msg` parameter is an instance of the `azure.functions.Out class`. The `set` method writes a string message to the queue. In this case, it's the `name` passed to the function in the URL query string.

Observe that you *don't* need to write any code for authentication, getting a queue reference, or writing data. All these integration tasks are conveniently handled in the Azure Functions runtime and queue output binding.

Run the function locally

1. Run your function by starting the local Azure Functions runtime host from the *LocalFunctionProj* folder.

```
Console  
func start
```

Toward the end of the output, the following lines must appear:

```
Azure Functions Core Tools  
Core Tools Version: 4.0.5049 Commit hash: N/A (64-bit)  
Function Runtime Version: 4.15.2.20177  
  
[2023-03-17T03:27:12.372Z] Worker process started and initialized.  
  
Functions:  
  
    HttpExample: [GET,POST] http://localhost:7071/api/HttpExample
```

ⓘ Note

If `HttpExample` doesn't appear as shown above, you likely started the host from outside the root folder of the project. In that case, use **Ctrl+C** to stop the host, go to the project's root folder, and run the previous command again.

2. Copy the URL of your HTTP function from this output to a browser and append the query string `?name=<YOUR_NAME>`, making the full URL like `http://localhost:7071/api/HttpExample?name=Functions`. The browser should display a response message that echoes back your query string value. The terminal in which you started your project also shows log output as you make requests.
3. When you're done, press `Ctrl + C` and type `y` to stop the functions host.

💡 Tip

During startup, the host downloads and installs the [Storage binding extension](#) and other Microsoft binding extensions. This installation happens because binding extensions are enabled by default in the `host.json` file with the following properties:

JSON

```
{  
    "version": "2.0",  
    "extensionBundle": {  
        "id": "Microsoft.Azure.Functions.ExtensionBundle",  
        "version": "[1.*, 2.0.0)"  
    }  
}
```

If you encounter any errors related to binding extensions, check that the above properties are present in *host.json*.

View the message in the Azure Storage queue

You can view the queue in the [Azure portal](#) or in the [Microsoft Azure Storage Explorer](#). You can also view the queue in the Azure CLI, as described in the following steps:

1. Open the function project's *local.setting.json* file and copy the connection string value. In a terminal or command window, run the following command to create an environment variable named `AZURE_STORAGE_CONNECTION_STRING`, and paste your specific connection string in place of `<MY_CONNECTION_STRING>`. (This environment variable means you don't need to supply the connection string to each subsequent command using the `--connection-string` argument.)

bash

Bash

```
export AZURE_STORAGE_CONNECTION_STRING=<MY_CONNECTION_STRING>"
```

2. (Optional) Use the [az storage queue list](#) command to view the Storage queues in your account. The output from this command must include a queue named `outqueue`, which was created when the function wrote its first message to that queue.

Azure CLI

```
az storage queue list --output tsv
```

3. Use the `az storage message get` command to read the message from this queue, which should be the value you supplied when testing the function earlier. The command reads and removes the first message from the queue.

bash

Azure CLI

```
echo `echo $(az storage message get --queue-name outqueue -o tsv --query '[].{Message:content}')` | base64 --decode`
```

Because the message body is stored [base64 encoded](#), the message must be decoded before it's displayed. After you execute `az storage message get`, the message is removed from the queue. If there was only one message in `outqueue`, you won't retrieve a message when you run this command a second time and instead get an error.

Redeploy the project to Azure

Now that you've verified locally that the function wrote a message to the Azure Storage queue, you can redeploy your project to update the endpoint running on Azure.

In the `LocalFunctionsProj` folder, use the `func azure functionapp publish` command to redeploy the project, replacing `<APP_NAME>` with the name of your app.

```
func azure functionapp publish <APP_NAME>
```

Verify in Azure

1. As in the previous quickstart, use a browser or CURL to test the redeployed function.

Browser

Copy the complete **Invoke URL** shown in the output of the publish command into a browser address bar, appending the query parameter `&name=Functions`.

The browser should display the same output as when you ran the function locally.

2. Examine the Storage queue again, as described in the previous section, to verify that it contains the new message written to the queue.

Clean up resources

After you've finished, use the following command to delete the resource group and all its contained resources to avoid incurring further costs.

Azure CLI

```
az group delete --name AzureFunctionsQuickstart-rg
```

Next steps

You've updated your HTTP triggered function to write data to a Storage queue. Now you can learn more about developing Functions from the command line using Core Tools and Azure CLI:

- [Work with Azure Functions Core Tools](#)
- [Azure Functions triggers and bindings](#)
- [Examples of complete Function projects in Python.](#)
- [Azure Functions Python developer guide](#)

Connect Azure Functions to Azure Storage using Visual Studio Code

Article • 04/26/2024

Azure Functions lets you connect Azure services and other resources to functions without having to write your own integration code. These *bindings*, which represent both input and output, are declared within the function definition. Data from bindings is provided to the function as parameters. A *trigger* is a special type of input binding. Although a function has only one trigger, it can have multiple input and output bindings. To learn more, see [Azure Functions triggers and bindings concepts](#).

In this article, you learn how to use Visual Studio Code to connect Azure Storage to the function you created in the previous quickstart article. The output binding that you add to this function writes data from the HTTP request to a message in an Azure Queue storage queue.

Most bindings require a stored connection string that Functions uses to access the bound service. To make it easier, you use the storage account that you created with your function app. The connection to this account is already stored in an app setting named `AzureWebJobsStorage`.

Configure your local environment

Before you begin, you must meet the following requirements:

- Install the [Azure Storage extension for Visual Studio Code](#).
- Install [Azure Storage Explorer](#). Storage Explorer is a tool that you'll use to examine queue messages generated by your output binding. Storage Explorer is supported on macOS, Windows, and Linux-based operating systems.
- Complete the steps in [part 1 of the Visual Studio Code quickstart](#).

This article assumes that you're already signed in to your Azure subscription from Visual Studio Code. You can sign in by running `Azure: Sign In` from the command palette.

Download the function app settings

In the [previous quickstart article](#), you created a function app in Azure along with the required storage account. The connection string for this account is stored securely in the

app settings in Azure. In this article, you write messages to a Storage queue in the same account. To connect to your storage account when running the function locally, you must download app settings to the `local.settings.json` file.

1. Press `F1` to open the command palette, then search for and run the command `Azure Functions: Download Remote Settings....`
2. Choose the function app you created in the previous article. Select **Yes to all** to overwrite the existing local settings.

 **Important**

Because the `local.settings.json` file contains secrets, it never gets published, and is excluded from the source control.

3. Copy the value `AzureWebJobsStorage`, which is the key for the storage account connection string value. You use this connection to verify that the output binding works as expected.

Register binding extensions

Because you're using a Queue storage output binding, you must have the Storage bindings extension installed before you run the project.

Your project has been configured to use [extension bundles](#), which automatically installs a predefined set of extension packages.

Extension bundles is already enabled in the `host.json` file at the root of the project, which should look like the following example:

```
JSON

{
  "version": "2.0",
  "logging": {
    "applicationInsights": {
      "samplingSettings": {
        "isEnabled": true,
        "excludedTypes": "Request"
      }
    }
  },
  "extensionBundle": {
    "id": "Microsoft.Azure.Functions.ExtensionBundle",
    "version": "[4.*, 5.0.0)"
  }
}
```

```
    }  
}
```

Now, you can add the storage output binding to your project.

Add an output binding

To write to an Azure Storage queue:

- Add an `extraOutputs` property to the binding configuration

TypeScript

```
{  
  methods: ['GET', 'POST'],  
  extraOutputs: [sendToQueue], // add output binding to HTTP trigger  
  authLevel: 'anonymous',  
  handler: () => {}  
}
```

- Add a `output.storageQueue` function above the `app.http` call

TypeScript

```
const sendToQueue: StorageQueueOutput = output.storageQueue({  
  queueName: 'outqueue',  
  connection: 'AzureWebJobsStorage',  
});
```

Add code that uses the output binding

After the binding is defined, you can use the `name` of the binding to access it as an attribute in the function signature. By using an output binding, you don't have to use the Azure Storage SDK code for authentication, getting a queue reference, or writing data. The Functions runtime and queue output binding do those tasks for you.

Add code that uses the output binding object on `context.extraOutputs` to create a queue message. Add this code before the return statement.

TypeScript

```
context.extraOutputs.set(sendToQueue, [msg]);
```

At this point, your function could look as follows:

TypeScript

```
import {
  app,
  output,
  HttpRequest,
  HttpResponseMessage,
  InvocationContext,
  StorageQueueOutput,
} from '@azure/functions';

const sendToQueue: StorageQueueOutput = output.storageQueue({
  queueName: 'outqueue',
  connection: 'AzureWebJobsStorage',
});

export async function HttpExample(
  request: HttpRequest,
  context: InvocationContext,
): Promise<HttpResponseInit> {
  try {
    context.log(`Http function processed request for url "${request.url}"`);

    const name = request.query.get('name') || (await request.text());
    context.log(`Name: ${name}`);

    if (name) {
      const msg = `Name passed to the function ${name}`;
      context.extraOutputs.set(sendToQueue, [msg]);
      return { body: msg };
    } else {
      context.log('Missing required data');
      return { status: 404, body: 'Missing required data' };
    }
  } catch (error) {
    context.log(`Error: ${error}`);
    return { status: 500, body: 'Internal Server Error' };
  }
}

app.http('HttpExample', {
  methods: ['GET', 'POST'],
  authLevel: 'anonymous',
  handler: HttpExample,
});
```

Run the function locally

1. As in the previous article, press `F5` to start the function app project and Core Tools.
2. With the Core Tools running, go to the **Azure: Functions** area. Under **Functions**, expand **Local Project > Functions**. Right-click (Ctrl-click on Mac) the `HttpExample` function and select **Execute Function Now....**

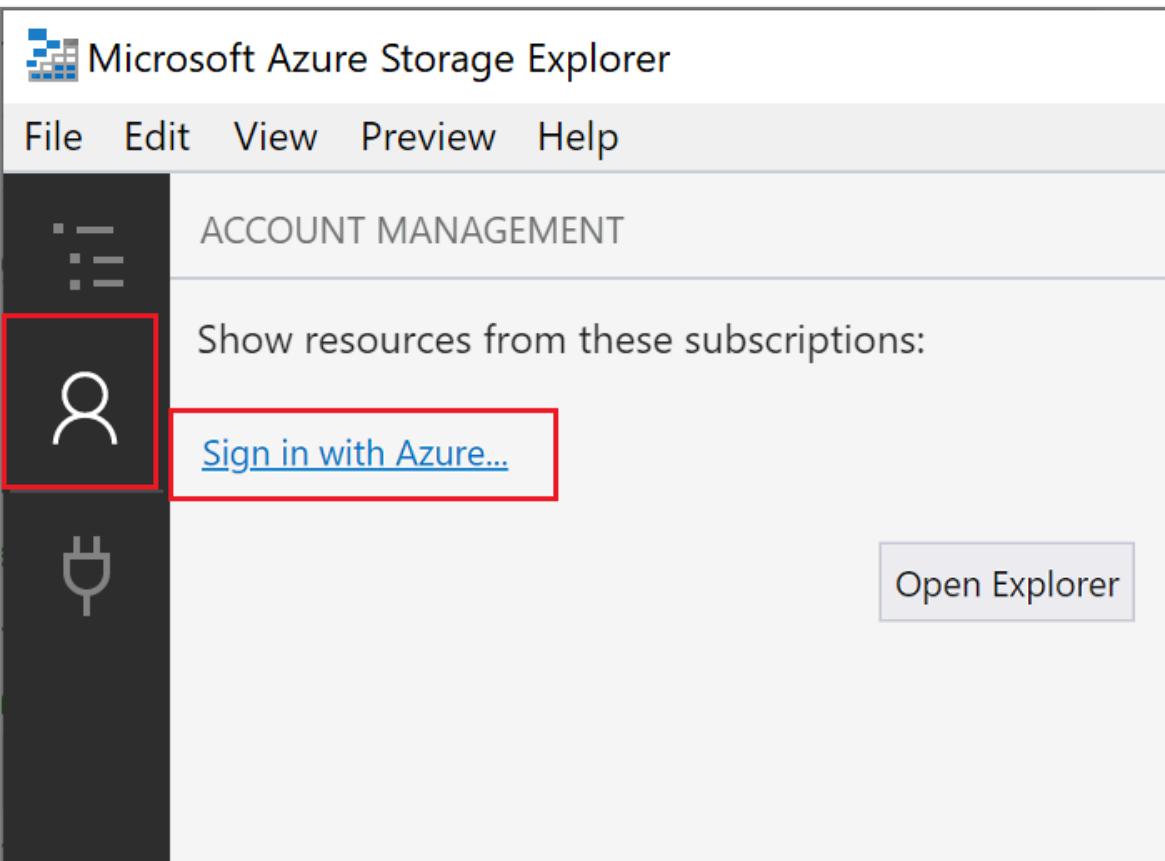

3. In the **Enter request body**, you see the request message body value of `{ "name": "Azure" }`. Press `Enter` to send this request message to your function.
4. After a response is returned, press `Ctrl + C` to stop Core Tools.

Because you're using the storage connection string, your function connects to the Azure storage account when running locally. A new queue named **outqueue** is created in your storage account by the Functions runtime when the output binding is first used. You'll use Storage Explorer to verify that the queue was created along with the new message.

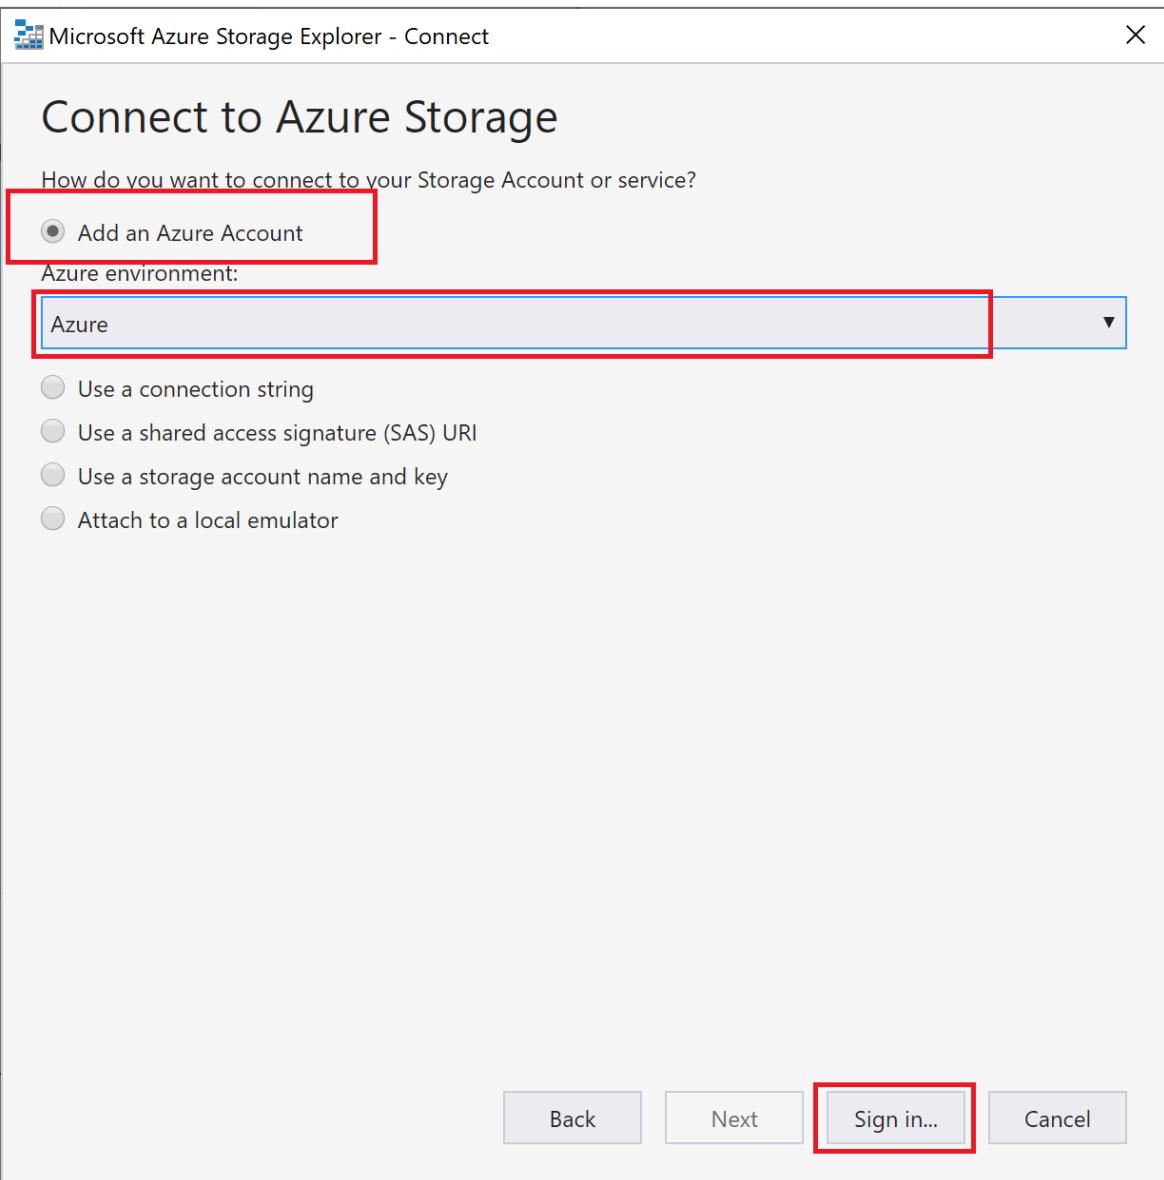

Connect Storage Explorer to your account

Skip this section if you've already installed Azure Storage Explorer and connected it to your Azure account.

1. Run the [Azure Storage Explorer](#) tool, select the connect icon on the left, and select **Add an account**.

2. In the **Connect** dialog, choose **Add an Azure account**, choose your **Azure environment**, and then select **Sign in....**

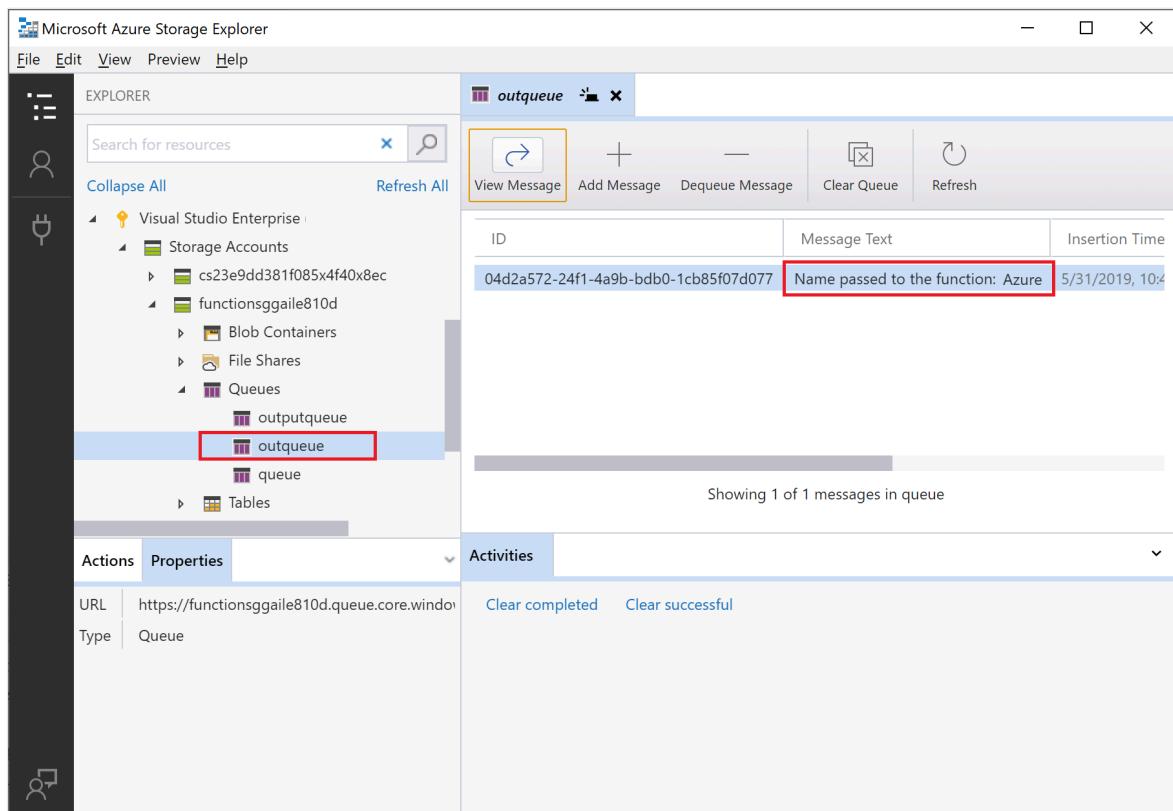

After you successfully sign in to your account, you see all of the Azure subscriptions associated with your account. Choose your subscription and select **Open Explorer**.

Examine the output queue

1. In Visual Studio Code, press **F1** to open the command palette, then search for and run the command **Azure Storage: Open in Storage Explorer** and choose your storage account name. Your storage account opens in the Azure Storage Explorer.
2. Expand the **Queues** node, and then select the queue named **outqueue**.

The queue contains the message that the queue output binding created when you ran the HTTP-triggered function. If you invoked the function with the default **name** value of *Azure*, the queue message is *Name passed to the function: Azure*.

3. Run the function again, send another request, and you see a new message in the queue.

Now, it's time to republish the updated function app to Azure.

Redeploy and verify the updated app

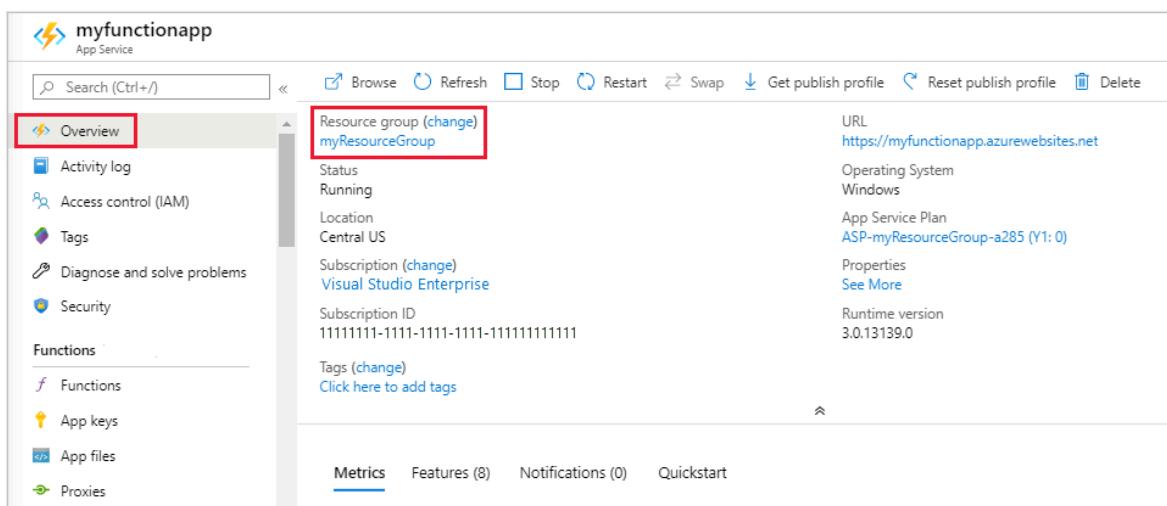

1. In Visual Studio Code, press **F1** to open the command palette. In the command palette, search for and select **Azure Functions: Deploy to function app....**
2. Choose the function app that you created in the first article. Because you're redeploying your project to the same app, select **Deploy** to dismiss the warning about overwriting files.
3. After the deployment completes, you can again use the **Execute Function Now...** feature to trigger the function in Azure.
4. Again [view the message in the storage queue](#) to verify that the output binding generates a new message in the queue.

Clean up resources

In Azure, *resources* refer to function apps, functions, storage accounts, and so forth. They're grouped into *resource groups*, and you can delete everything in a group by deleting the group.

You've created resources to complete these quickstarts. You may be billed for these resources, depending on your [account status](#) and [service pricing](#). If you don't need the resources anymore, here's how to delete them:

1. In Visual Studio Code, press `F1` to open the command palette. In the command palette, search for and select `Azure: Open in portal`.
2. Choose your function app and press `Enter`. The function app page opens in the Azure portal.
3. In the **Overview** tab, select the named link next to **Resource group**.

The screenshot shows the Azure portal interface for a function app named "myfunctionapp". The left sidebar has links for Activity log, Access control (IAM), Tags, Diagnose and solve problems, Security, Functions (with sub-links for Functions, App keys, App files, and Proxies), Metrics, Features (8), Notifications (0), and Quickstart. The main content area is the "Overview" tab, which displays details about the app: Status (Running), Location (Central US), Subscription (Visual Studio Enterprise), Subscription ID (11111111-1111-1111-1111-111111111111), and Tags (with a link to add tags). A red box highlights the "Resource group (change)" link, which points to "myResourceGroup". On the right, there are sections for URL (https://myfunctionapp.azurewebsites.net), Operating System (Windows), App Service Plan (ASP-myResourceGroup-a285 (Y1: 0)), Properties (See More), and Runtime version (3.0.13139.0).

4. On the **Resource group** page, review the list of included resources, and verify that they're the ones you want to delete.
5. Select **Delete resource group**, and follow the instructions.

Deletion may take a couple of minutes. When it's done, a notification appears for a few seconds. You can also select the bell icon at the top of the page to view the notification.

Next steps

You've updated your HTTP triggered function to write data to a Storage queue. Now you can learn more about developing Functions using Visual Studio Code:

- [Develop Azure Functions using Visual Studio Code](#)
- [Azure Functions triggers and bindings](#).
- [Examples of complete Function projects in TypeScript](#).
- [Azure Functions TypeScript developer guide](#)

Connect Azure Functions to Azure Storage using command line tools

Article • 04/25/2024

In this article, you integrate an Azure Storage queue with the function and storage account you created in the previous quickstart article. You achieve this integration by using an *output binding* that writes data from an HTTP request to a message in the queue. Completing this article incurs no additional costs beyond the few USD cents of the previous quickstart. To learn more about bindings, see [Azure Functions triggers and bindings concepts](#).

Configure your local environment

Before you begin, you must complete the article, [Quickstart: Create an Azure Functions project from the command line](#). If you already cleaned up resources at the end of that article, go through the steps again to recreate the function app and related resources in Azure.

Retrieve the Azure Storage connection string

Earlier, you created an Azure Storage account for function app's use. The connection string for this account is stored securely in app settings in Azure. By downloading the setting into the `local.settings.json` file, you can use the connection to write to a Storage queue in the same account when running the function locally.

1. From the root of the project, run the following command, replace `<APP_NAME>` with the name of your function app from the previous step. This command overwrites any existing values in the file.

```
func azure functionapp fetch-app-settings <APP_NAME>
```

2. Open `local.settings.json` file and locate the value named `AzureWebJobsStorage`, which is the Storage account connection string. You use the name `AzureWebJobsStorage` and the connection string in other sections of this article.

 **Important**

Because the `local.settings.json` file contains secrets downloaded from Azure, always exclude this file from source control. The `.gitignore` file created with a local functions project excludes the file by default.

Add an output binding definition to the function

Although a function can have only one trigger, it can have multiple input and output bindings, which lets you connect to other Azure services and resources without writing custom integration code.

When using the [Node.js v4 programming model](#), binding attributes are defined directly in the `./src/functions/HttpExample.js` file. From the previous quickstart, your file already contains an HTTP binding defined by the `app.http` method.

TypeScript

```
import {
  app,
  HttpRequest,
  HttpResponseMessage,
  InvocationContext,
} from '@azure/functions';

export async function httpTrigger1(
  request: HttpRequest,
  context: InvocationContext,
): Promise<HttpResponseMessage> {
  context.log(`Http function processed request for url "${request.url}"`);

  const name = request.query.get('name') || (await request.text()) ||
  'world';

  return { body: `Hello, ${name}!` };
}

app.http('httpTrigger1', {
  methods: ['GET', 'POST'],
  authLevel: 'anonymous',
  handler: httpTrigger1,
});
```

To write to an Azure Storage queue:

- Add an `extraOutputs` property to the binding configuration

TypeScript

```
{  
  methods: ['GET', 'POST'],  
  extraOutputs: [sendToQueue], // add output binding to HTTP trigger  
  authLevel: 'anonymous',  
  handler: () => {}  
}
```

- Add a `output.storageQueue` function above the `app.http` call

TypeScript

```
const sendToQueue: StorageQueueOutput = output.storageQueue({  
  queueName: 'outqueue',  
  connection: 'AzureWebJobsStorage',  
});
```

For a `queue` type, you must specify the name of the queue in `queueName` and provide the *name* of the Azure Storage connection (from `local.settings.json` file) in `connection`.

For more information on the details of bindings, see [Azure Functions triggers and bindings concepts](#) and [queue output configuration](#).

Add code to use the output binding

With the queue binding defined, you can now update your function to receive the `msg` output parameter and write messages to the queue.

Add code that uses the output binding object on `context.extraOutputs` to create a queue message. Add this code before the return statement.

TypeScript

```
context.extraOutputs.set(sendToQueue, [msg]);
```

At this point, your function could look as follows:

TypeScript

```
import {  
  app,  
  output,  
  HttpRequest,  
  HttpResponseMessage,  
  InvocationContext,
```

```

StorageQueueOutput,
} from '@azure/functions';

const sendToQueue: StorageQueueOutput = output.storageQueue({
  queueName: 'outqueue',
  connection: 'AzureWebJobsStorage',
});

export async function HttpExample(
  request: HttpRequest,
  context: InvocationContext,
): Promise<HttpResponseInit> {
  try {
    context.log(`Http function processed request for url "${request.url}"`);

    const name = request.query.get('name') || (await request.text());
    context.log(`Name: ${name}`);

    if (name) {
      const msg = `Name passed to the function ${name}`;
      context.extraOutputs.set(sendToQueue, [msg]);
      return { body: msg };
    } else {
      context.log('Missing required data');
      return { status: 404, body: 'Missing required data' };
    }
  } catch (error) {
    context.log(`Error: ${error}`);
    return { status: 500, body: 'Internal Server Error' };
  }
}

app.http('HttpExample', {
  methods: ['GET', 'POST'],
  authLevel: 'anonymous',
  handler: HttpExample,
});

```

Observe that you *don't* need to write any code for authentication, getting a queue reference, or writing data. All these integration tasks are conveniently handled in the Azure Functions runtime and queue output binding.

Run the function locally

1. Run your function by starting the local Azure Functions runtime host from the *LocalFunctionProj* folder.

Console

```
func start
```

Toward the end of the output, the following lines must appear:

```
Azure Functions Core Tools
Core Tools Version:      4.0.5049 Commit hash: N/A  (64-bit)
Function Runtime Version: 4.15.2.20177

[2023-03-17T03:27:12.372Z] Worker process started and initialized.

Functions:

    HttpExample: [GET,POST] http://localhost:7071/api/HttpExample
```

ⓘ Note

If `HttpExample` doesn't appear as shown above, you likely started the host from outside the root folder of the project. In that case, use **Ctrl+C** to stop the host, go to the project's root folder, and run the previous command again.

2. Copy the URL of your HTTP function from this output to a browser and append the query string `?name=<YOUR_NAME>`, making the full URL like `http://localhost:7071/api/HttpExample?name=Functions`. The browser should display a response message that echoes back your query string value. The terminal in which you started your project also shows log output as you make requests.
3. When you're done, press **Ctrl + C** and type **y** to stop the functions host.

💡 Tip

During startup, the host downloads and installs the [Storage binding extension](#) and other Microsoft binding extensions. This installation happens because binding extensions are enabled by default in the `host.json` file with the following properties:

JSON

```
{
  "version": "2.0",
  "extensionBundle": {
    "id": "Microsoft.Azure.Functions.ExtensionBundle",
    "version": "[1.*, 2.0.0)"
  }
}
```

If you encounter any errors related to binding extensions, check that the above properties are present in `host.json`.

View the message in the Azure Storage queue

You can view the queue in the [Azure portal](#) or in the [Microsoft Azure Storage Explorer](#). You can also view the queue in the Azure CLI, as described in the following steps:

1. Open the function project's `local.setting.json` file and copy the connection string value. In a terminal or command window, run the following command to create an environment variable named `AZURE_STORAGE_CONNECTION_STRING`, and paste your specific connection string in place of `<MY_CONNECTION_STRING>`. (This environment variable means you don't need to supply the connection string to each subsequent command using the `--connection-string` argument.)

```
bash
Bash
export AZURE_STORAGE_CONNECTION_STRING=<MY_CONNECTION_STRING>
```

2. (Optional) Use the `az storage queue list` command to view the Storage queues in your account. The output from this command must include a queue named `outqueue`, which was created when the function wrote its first message to that queue.

```
Azure CLI
az storage queue list --output tsv
```

3. Use the `az storage message get` command to read the message from this queue, which should be the value you supplied when testing the function earlier. The command reads and removes the first message from the queue.

```
bash
Azure CLI
```

```
echo `echo $(az storage message get --queue-name outqueue -o tsv --query '[].{Message:content}') | base64 --decode`
```

Because the message body is stored [base64 encoded](#), the message must be decoded before it's displayed. After you execute `az storage message get`, the message is removed from the queue. If there was only one message in `outqueue`, you won't retrieve a message when you run this command a second time and instead get an error.

Redeploy the project to Azure

Now that you've verified locally that the function wrote a message to the Azure Storage queue, you can redeploy your project to update the endpoint running on Azure.

In the `LocalFunctionsProj` folder, use the [func azure functionapp publish](#) command to redeploy the project, replacing `<APP_NAME>` with the name of your app.

```
func azure functionapp publish <APP_NAME>
```

Verify in Azure

1. As in the previous quickstart, use a browser or CURL to test the redeployed function.

Browser

Copy the complete **Invoke URL** shown in the output of the publish command into a browser address bar, appending the query parameter `&name=Functions`. The browser should display the same output as when you ran the function locally.

2. Examine the Storage queue again, as described in the previous section, to verify that it contains the new message written to the queue.

Clean up resources

After you've finished, use the following command to delete the resource group and all its contained resources to avoid incurring further costs.

Azure CLI

```
az group delete --name AzureFunctionsQuickstart-rg
```

Next steps

You've updated your HTTP triggered function to write data to a Storage queue. Now you can learn more about developing Functions from the command line using Core Tools and Azure CLI:

- [Azure Functions triggers and bindings](#)
- [Examples of complete Function projects in TypeScript.](#)
- [Azure Functions TypeScript developer guide](#)

Connect Azure Functions to Azure Cosmos DB using Visual Studio Code

Article • 04/26/2024

Azure Functions lets you connect Azure services and other resources to functions without having to write your own integration code. These *bindings*, which represent both input and output, are declared within the function definition. Data from bindings is provided to the function as parameters. A *trigger* is a special type of input binding. Although a function has only one trigger, it can have multiple input and output bindings. To learn more, see [Azure Functions triggers and bindings concepts](#).

This article shows you how to use Visual Studio Code to connect [Azure Cosmos DB](#) to the function you created in the previous quickstart article. The output binding that you add to this function writes data from the HTTP request to a JSON document stored in an Azure Cosmos DB container.

Before you begin, you must complete the [quickstart: Create a C# function in Azure using Visual Studio Code](#). If you already cleaned up resources at the end of that article, go through the steps again to recreate the function app and related resources in Azure.

Configure your environment

Before you get started, make sure to install the [Azure Databases extension](#) for Visual Studio Code.

Create your Azure Cosmos DB account

Now, you create an Azure Cosmos DB account as a [serverless account type](#). This consumption-based mode makes Azure Cosmos DB a strong option for serverless workloads.

1. In Visual Studio Code, select **View > Command Palette...** then in the command palette search for `Azure Databases: Create Server...`
2. Provide the following information at the prompts:

[] [Expand table](#)

Prompt	Selection
Select an Azure Database Server	Choose Core (NoSQL) to create a document database that you can query by using a SQL syntax or a Query Copilot (Preview) converting natural language prompts to queries. Learn more about the Azure Cosmos DB .
Account name	Enter a unique name to identify your Azure Cosmos DB account. The account name can use only lowercase letters, numbers, and hyphens (-), and must be between 3 and 31 characters long.
Select a capacity model	Select Serverless to create an account in serverless mode .
Select a resource group for new resources	Choose the resource group where you created your function app in the previous article .
Select a location for new resources	Select a geographic location to host your Azure Cosmos DB account. Use the location that's closest to you or your users to get the fastest access to your data.

After your new account is provisioned, a message is displayed in notification area.

Create an Azure Cosmos DB database and container

1. Select the Azure icon in the Activity bar, expand **Resources > Azure Cosmos DB**, right-click (Ctrl+select on macOS) your account, and select **Create database...**
2. Provide the following information at the prompts:

[\[+\] Expand table](#)

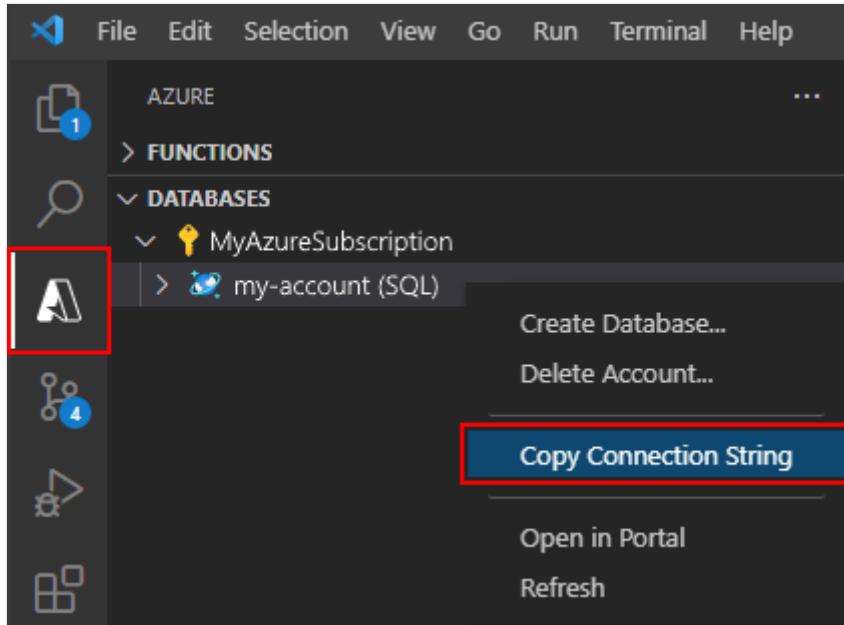

Prompt	Selection
Database name	Type <code>my-database</code> .
Enter and ID for your collection	Type <code>my-container</code> .
Enter the partition key for the collection	Type <code>/id</code> as the partition key .

3. Select **OK** to create the container and database.

Update your function app settings

In the [previous quickstart article](#), you created a function app in Azure. In this article, you update your app to write JSON documents to the Azure Cosmos DB container you've created. To connect to your Azure Cosmos DB account, you must add its connection string to your app settings. You then download the new setting to your local.settings.json file so you can connect to your Azure Cosmos DB account when running locally.

1. In Visual Studio Code, right-click (Ctrl+select on macOS) on your new Azure Cosmos DB account, and select **Copy Connection String**.

2. Press **F1** to open the command palette, then search for and run the command `Azure Functions: Add New Setting...`

3. Choose the function app you created in the previous article. Provide the following information at the prompts:

[+] Expand table

Prompt	Selection
Enter new app setting name	Type <code>CosmosDbConnectionSetting</code> .
Enter value for "CosmosDbConnectionSetting"	Paste the connection string of your Azure Cosmos DB account you copied. You can also configure Microsoft Entra identity as an alternative.

This creates an application setting named connection `CosmosDbConnectionSetting` in your function app in Azure. Now, you can download this setting to your local.settings.json file.

4. Press **F1** again to open the command palette, then search for and run the command `Azure Functions: Download Remote Settings....`.
5. Choose the function app you created in the previous article. Select **Yes to all** to overwrite the existing local settings.

This downloads all of the setting from Azure to your local project, including the new connection string setting. Most of the downloaded settings aren't used when running locally.

Register binding extensions

Because you're using an Azure Cosmos DB output binding, you must have the corresponding bindings extension installed before you run the project.

Except for HTTP and timer triggers, bindings are implemented as extension packages. Run the following `dotnet add package` command in the Terminal window to add the Azure Cosmos DB extension package to your project.

```
command
```

```
dotnet add package Microsoft.Azure.Functions.Worker.Extensions.CosmosDB
```

Now, you can add the Azure Cosmos DB output binding to your project.

Add an output binding

In a C# class library project, the bindings are defined as binding attributes on the function method.

Open the `HttpExample.cs` project file and add the following classes:

```
C#
```

```
public class MultiResponse
{
    [CosmosDBOutput("my-database", "my-container",
        Connection = "CosmosDbConnectionString", CreateIfNotExists = true)]
    public MyDocument Document { get; set; }
    public HttpResponseMessage HttpResponseMessage { get; set; }
}
public class MyDocument {
    public string id { get; set; }
```

```
    public string message { get; set; }  
}
```

The `MyDocument` class defines an object that gets written to the database. The connection string for the Storage account is set by the `Connection` property. In this case, you could omit `Connection` because you're already using the default storage account.

The `MultiResponse` class allows you to both write to the specified collection in the Azure Cosmos DB and return an HTTP success message. Because you need to return a `MultiResponse` object, you need to also update the method signature.

Specific attributes specify the name of the container and the name of its parent database. The connection string for your Azure Cosmos DB account is set by the `CosmosDbConnectionStringSetting`.

Add code that uses the output binding

Replace the existing Run method with the following code:

C#

```
[Function("HttpExample")]  
public static MultiResponse Run([HttpTrigger(AuthorizationLevel.Anonymous,  
"get", "post")] HttpRequestData req,  
    FunctionContext executionContext)  
{  
    var logger = executionContext.GetLogger("HttpExample");  
    logger.LogInformation("C# HTTP trigger function processed a request.");  
  
    var message = "Welcome to Azure Functions!";  
  
    var response = req.CreateResponse(HttpStatusCode.OK);  
    response.Headers.Add("Content-Type", "text/plain; charset=utf-8");  
    response.WriteString(message);  
  
    // Return a response to both HTTP trigger and Azure Cosmos DB output  
    // binding.  
    return new MultiResponse()  
    {  
        Document = new MyDocument  
        {  
            id = System.Guid.NewGuid().ToString(),  
            message = message  
        },  
        HttpResponseMessage = response  
    };  
}
```

Run the function locally

Visual Studio Code integrates with [Azure Functions Core tools](#) to let you run this project on your local development computer before you publish to Azure. If you don't already have Core Tools installed locally, you are prompted to install it the first time you run your project.

1. To call your function, press **F5** to start the function app project. The **Terminal** panel displays the output from Core Tools. Your app starts in the **Terminal** panel. You can see the URL endpoint of your HTTP-triggered function running locally.

```
PROBLEMS    OUTPUT    DEBUG CONSOLE    TERMINAL    AZURE: ACTIVITY LOG    ⚙ host start - Task ✓    +    □    🗑    ^    ×

Functions:

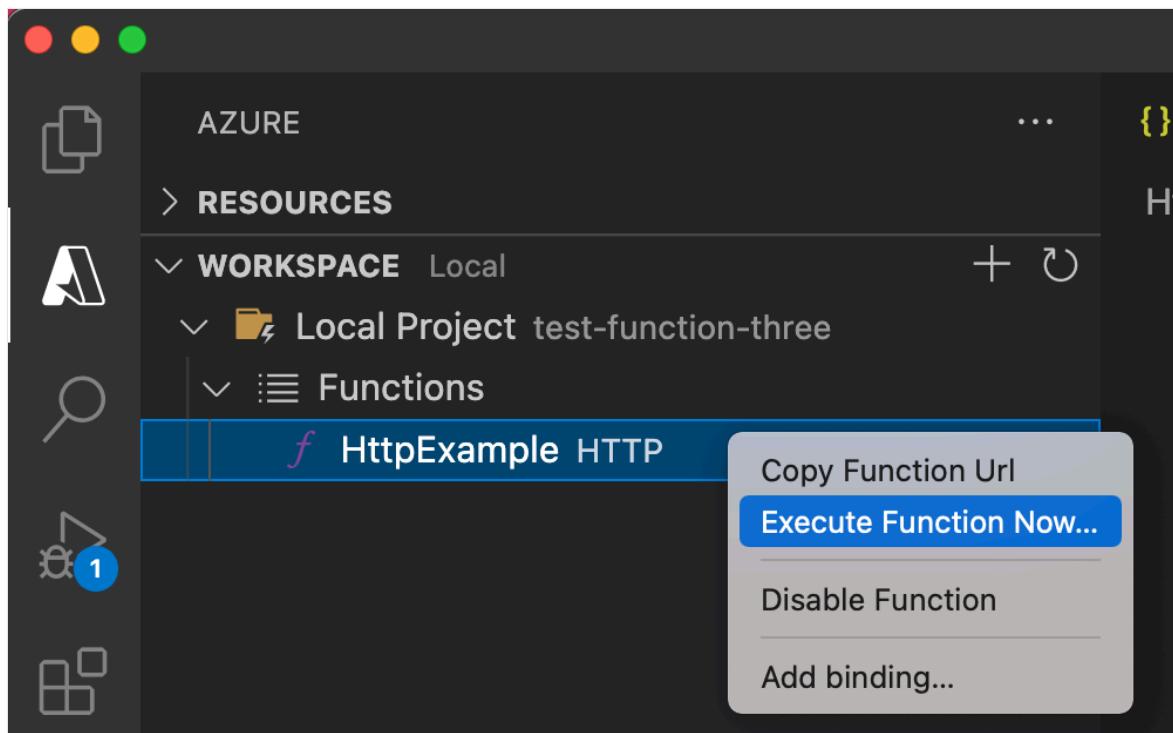

HttpExample: [GET,POST] http://localhost:7071/api/HttpExample

For detailed output, run func with --verbose flag.
[2022-05-25T18:45:53.470Z] Worker process started and initialized.
[2022-05-25T18:45:54.960Z] Host lock lease acquired by instance ID '00000000000000000000E24CCCAC'.
```

If you don't already have Core Tools installed, select **Install** to install Core Tools when prompted to do so.

If you have trouble running on Windows, make sure that the default terminal for Visual Studio Code isn't set to **WSL Bash**.

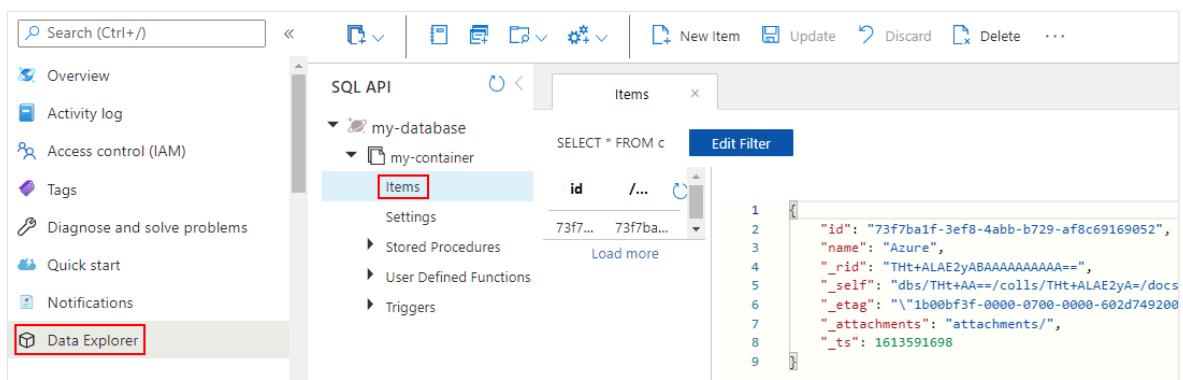

- With the Core Tools running, go to the **Azure: Functions** area. Under **Functions**, expand **Local Project > Functions**. Right-click (Windows) or `ctrl -` click (macOS) the **HttpExample** function and choose **Execute Function Now....**

3. In the **Enter request body**, press **Enter** to send a request message to your function.
4. When the function executes locally and returns a response, a notification is raised in Visual Studio Code. Information about the function execution is shown in the **Terminal** panel.
5. Press **Ctrl + C** to stop Core Tools and disconnect the debugger.

Verify that a JSON document has been created

1. On the Azure portal, go back to your Azure Cosmos DB account and select **Data Explorer**.
2. Expand your database and container, and select **Items** to list the documents created in your container.
3. Verify that a new JSON document has been created by the output binding.

The screenshot shows the Azure portal's Data Explorer interface. On the left, there's a sidebar with various options like Overview, Activity log, Access control (IAM), Tags, Diagnose and solve problems, Quick start, Notifications, and Data Explorer. The Data Explorer option is highlighted with a red box. The main area shows a hierarchical tree structure under SQL API > my-database > my-container. The 'Items' node is selected and highlighted with a red box. To the right, there's a table with columns 'id' and '_...'. Below the table, there's a code editor window displaying a JSON document:

```

1 "id": "73f7ba1f-3ef8-4abb-b729-af8c69169052",
2 "name": "Azure",
3 "_rid": "THT+ALAE2yABAAAAAAA==",
4 "_self": "dbs/THT+AA==/colls/THT+ALAE2yA=/docs",
5 "_etag": "\\"1b00bf3f-0000-0700-0000-602d749200
6
7 "_attachments": "attachments/",
8
9 "_ts": 1613591698

```

Redeploy and verify the updated app

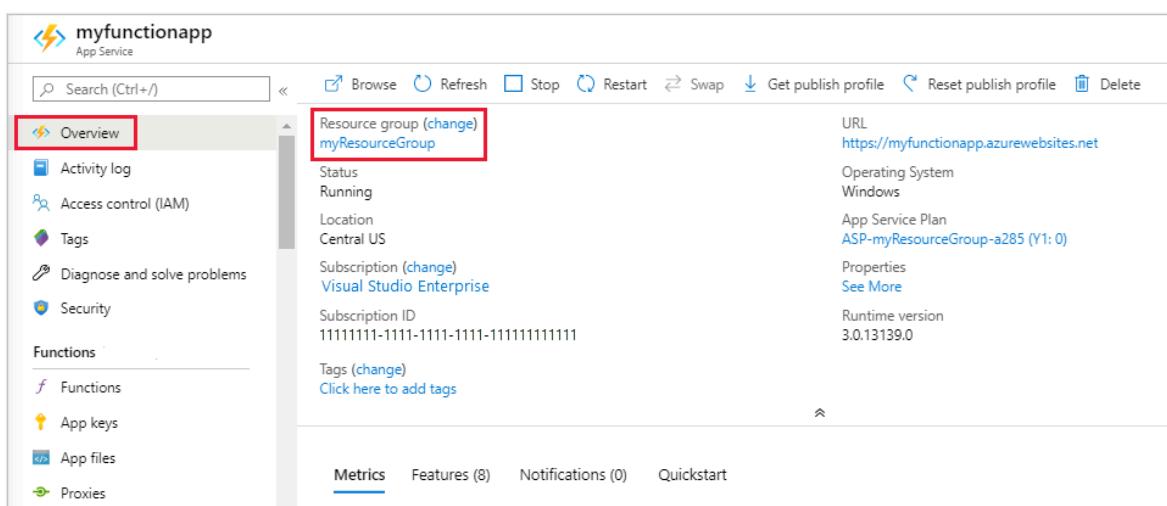

1. In Visual Studio Code, press F1 to open the command palette. In the command palette, search for and select **Azure Functions: Deploy to function app....**
2. Choose the function app that you created in the first article. Because you're redeploying your project to the same app, select **Deploy** to dismiss the warning about overwriting files.
3. After deployment completes, you can again use the **Execute Function Now...** feature to trigger the function in Azure.
4. Again [check the documents created in your Azure Cosmos DB container](#) to verify that the output binding again generates a new JSON document.

Clean up resources

In Azure, *resources* refer to function apps, functions, storage accounts, and so forth. They're grouped into *resource groups*, and you can delete everything in a group by deleting the group.

You created resources to complete these quickstarts. You might be billed for these resources, depending on your [account status](#) and [service pricing](#). If you don't need the resources anymore, here's how to delete them:

1. In Visual Studio Code, press `F1` to open the command palette. In the command palette, search for and select `Azure: Open in portal`.
2. Choose your function app and press `Enter`. The function app page opens in the Azure portal.
3. In the **Overview** tab, select the named link next to **Resource group**.

The screenshot shows the Azure portal interface for a function app named "myfunctionapp". The left sidebar has links for Overview, Activity log, Access control (IAM), Tags, Diagnose and solve problems, Security, Functions (Functions, App keys, App files, Proxies), Metrics, Features (8), Notifications (0), and Quickstart. The Overview tab is selected. On the right, there is a summary card with details: Status (Running), Location (Central US), Subscription (Visual Studio Enterprise), Subscription ID (11111111-1111-1111-1111-111111111111), and Tags (Click here to add tags). A red box highlights the "Resource group (change)" link under the "myResourceGroup" section. Below the card, there are sections for URL (<https://myfunctionapp.azurewebsites.net>), Operating System (Windows), App Service Plan (ASP-myResourceGroup-a285 (Y1: 0)), Properties (See More), and Runtime version (3.0.13139.0).

4. On the **Resource group** page, review the list of included resources, and verify that they're the ones you want to delete.
5. Select **Delete resource group**, and follow the instructions.

Deletion may take a couple of minutes. When it's done, a notification appears for a few seconds. You can also select the bell icon at the top of the page to view the notification.

Next steps

You've updated your HTTP triggered function to write JSON documents to an Azure Cosmos DB container. Now you can learn more about developing Functions using Visual Studio Code:

- Develop Azure Functions using Visual Studio Code
- Azure Functions triggers and bindings.
- Examples of complete Function projects in C#.
- Azure Functions C# developer reference

Connect Azure Functions to Azure SQL Database using Visual Studio Code

Article • 04/25/2024

Azure Functions lets you connect Azure services and other resources to functions without having to write your own integration code. These *bindings*, which represent both input and output, are declared within the function definition. Data from bindings is provided to the function as parameters. A *trigger* is a special type of input binding. Although a function has only one trigger, it can have multiple input and output bindings. To learn more, see [Azure Functions triggers and bindings concepts](#).

This article shows you how to use Visual Studio Code to connect [Azure SQL Database](#) to the function you created in the previous quickstart article. The output binding that you add to this function writes data from the HTTP request to a table in Azure SQL Database.

Before you begin, you must complete the [quickstart: Create a C# function in Azure using Visual Studio Code](#). If you already cleaned up resources at the end of that article, go through the steps again to recreate the function app and related resources in Azure.

More details on the settings for [Azure SQL bindings and trigger for Azure Functions](#) are available in the Azure Functions documentation.

Create your Azure SQL Database

1. Follow the [Azure SQL Database create quickstart](#) to create a serverless Azure SQL Database. The database can be empty or created from the sample dataset AdventureWorksLT.
2. Provide the following information at the prompts:

[] Expand table

Prompt	Selection
Resource group	Choose the resource group where you created your function app in the previous article .
Database name	Enter <code>mySampleDatabase</code> .
Server name	Enter a unique name for your server. We can't provide an exact server name to use because server names must be globally

Prompt	Selection
	unique for all servers in Azure, not just unique within a subscription.
Authentication method	Select SQL Server authentication .
Server admin login	Enter <code>azureuser</code> .
Password	Enter a password that meets the complexity requirements.
Allow Azure services and resources to access this server	Select Yes .

3. Once the creation has completed, navigate to the database blade in the Azure portal, and, under **Settings**, select **Connection strings**. Copy the **ADO.NET** connection string for **SQL authentication**. Paste the connection string into a temporary document for later use.

The screenshot shows the 'mySampleDatabase - Connection strings' blade in the Azure portal. On the left, there's a sidebar with various options like Overview, Activity log, Tags, etc., and a 'Connection strings' option which is highlighted with a red box. The main area shows three connection strings under the ADO.NET tab:

- ADO.NET (SQL authentication)**: Contains the connection string: `Server=tcp:myserver99.database.windows.net,1433;Initial Catalog=mySampleDatabase;Persist Security Info=False;User ID=(your_username);Password=(your_password);MultipleActiveResultSets=False;Encrypt=True;TrustServerCertificate=False;Connection Timeout=30;`
- ADO.NET (Active Directory password authentication)**: Contains the connection string: `Server=tcp:myserver99.database.windows.net,1433;Initial Catalog=mySampleDatabase;Persist Security Info=False;User ID=(your_username);Password=(your_password);MultipleActiveResultSets=False;Encrypt=True;TrustServerCertificate=False;Authentication="Active Directory Password";`
- ADO.NET (Active Directory integrated authentication)**: Contains the connection string: `Server=tcp:myserver99.database.windows.net,1433;Initial Catalog=mySampleDatabase;Persist Security Info=False;User ID=(your_username);MultipleActiveResultSets=False;Encrypt=True;TrustServerCertificate=False;Authentication="Active Directory Integrated";`

4. Create a table to store the data from the HTTP request. In the Azure portal, navigate to the database blade and select **Query editor**. Enter the following query to create a table named `dbo.ToDo`:

```
CREATE TABLE dbo.ToDo (
    [Id] UNIQUEIDENTIFIER PRIMARY KEY,
    [order] INT NULL,
    [title] NVARCHAR(200) NOT NULL,
    [url] NVARCHAR(200) NOT NULL,
    [completed] BIT NOT NULL
);
```

5. Verify that your Azure Function will be able to access the Azure SQL Database by checking the [server's firewall settings](#). Navigate to the **server blade** on the Azure portal, and under **Security**, select **Networking**. The exception for **Allow Azure services and resources to access this server** should be checked.

The screenshot shows the Azure portal interface for managing a SQL server named 'mydocsamplesqlserver'. The left sidebar lists various security features: Microsoft Defender for Cloud, Transparent data encryption, Identity, Auditing, Intelligent Performance, Automatic tuning, and Recommendations. The 'Networking' option is selected and highlighted with a red box. The main content area shows the 'Networking' blade with tabs for Public access, Private access, and Connectivity. Under the 'Public access' tab, there is a section for 'Firewall rules' with options to add client IPv4 addresses or firewall rules. Below this is an 'Exceptions' section, also highlighted with a red box, containing a checkbox labeled 'Allow Azure services and resources to access this server'.

Update your function app settings

In the [previous quickstart article](#), you created a function app in Azure. In this article, you update your app to write data to the Azure SQL Database you've just created. To connect to your Azure SQL Database, you must add its connection string to your app settings. You then download the new setting to your local.settings.json file so you can connect to your Azure SQL Database when running locally.

1. Edit the connection string in the temporary document you created earlier. Replace the value of `Password` with the password you used when creating the Azure SQL Database. Copy the updated connection string.
2. Press `Ctrl/Cmd+shift+P` to open the command palette, then search for and run the command `Azure Functions: Add New Setting...`.
3. Choose the function app you created in the previous article. Provide the following information at the prompts:

[\[+\] Expand table](#)

Prompt	Selection
Enter new app setting name	Type <code>SqlConnectionString</code> .
Enter value for "SqlConnectionString"	Paste the connection string of your Azure SQL Database you just copied.

This creates an application setting named connection `SqlConnectionString` in your function app in Azure. Now, you can download this setting to your `local.settings.json` file.

4. Press `Ctrl/Cmd+shift+P` again to open the command palette, then search for and run the command `Azure Functions: Download Remote Settings....`
5. Choose the function app you created in the previous article. Select **Yes to all** to overwrite the existing local settings.

This downloads all of the setting from Azure to your local project, including the new connection string setting. Most of the downloaded settings aren't used when running locally.

Register binding extensions

Because you're using an Azure SQL output binding, you must have the corresponding bindings extension installed before you run the project.

With the exception of HTTP and timer triggers, bindings are implemented as extension packages. Run the following `dotnet add package` command in the Terminal window to add the Azure SQL extension package to your project.

Bash

```
dotnet add package Microsoft.Azure.Functions.Worker.Extensions.Sql
```

Now, you can add the Azure SQL output binding to your project.

Add an output binding

In Functions, each type of binding requires a `direction`, `type`, and a unique `name` to be defined in the `function.json` file. The way you define these attributes depends on the language of your function app.

Open the *HttpExample.cs* project file and add the following `ToDoItem` class, which defines the object that is written to the database:

```
C#  
  
namespace AzureSQL.ToDo  
{  
    public class ToDoItem  
    {  
        public Guid Id { get; set; }  
        public int? order { get; set; }  
        public string title { get; set; }  
        public string url { get; set; }  
        public bool? completed { get; set; }  
    }  
}
```

In a C# class library project, the bindings are defined as binding attributes on the function method. The *function.json* file required by Functions is then auto-generated based on these attributes.

Open the *HttpExample.cs* project file and add the following output type class, which defines the combined objects that will be output from our function for both the HTTP response and the SQL output:

```
cs  
  
public static class OutputType  
{  
    [SqlOutput("dbo.ToDo", connectionStringSetting: "SqlConnectionString")]  
    public ToDoItem ToDoItem { get; set; }  
    public HttpResponseMessage HttpResponseMessage { get; set; }  
}
```

Add a using statement to the `Microsoft.Azure.Functions.Worker.Extensions.Sql` library to the top of the file:

```
cs  
  
using Microsoft.Azure.Functions.Worker.Extensions.Sql;
```

Add code that uses the output binding

Replace the existing Run method with the following code:

CS

```
[Function("HttpExample")]
public static OutputType Run([HttpTrigger(AuthorizationLevel.Anonymous,
"get", "post")] HttpRequestData req,
    FunctionContext executionContext)
{
    var logger = executionContext.GetLogger("HttpExample");
    logger.LogInformation("C# HTTP trigger function processed a request.");

    var message = "Welcome to Azure Functions!";

    var response = req.CreateResponse(HttpStatusCode.OK);
    response.Headers.Add("Content-Type", "text/plain; charset=utf-8");
    response.WriteString(message);

    // Return a response to both HTTP trigger and Azure SQL output binding.
    return new OutputType()
    {
        ToDoItem = new ToDoItem
        {
            id = System.Guid.NewGuid().ToString(),
            title = message,
            completed = false,
            url = ""
        },
        HttpResponseMessage = response
    };
}
```

Run the function locally

Visual Studio Code integrates with [Azure Functions Core tools](#) to let you run this project on your local development computer before you publish to Azure. If you don't already have Core Tools installed locally, you are prompted to install it the first time you run your project.

1. To call your function, press **F5** to start the function app project. The **Terminal** panel displays the output from Core Tools. Your app starts in the **Terminal** panel. You can see the URL endpoint of your HTTP-triggered function running locally.

The screenshot shows the Visual Studio Code interface with the Terminal tab selected. The terminal window displays the following output:

```
PROBLEMS OUTPUT DEBUG CONSOLE TERMINAL AZURE: ACTIVITY LOG
✖ host start - Task ✓ + □ ⌂ ⌂ ×

Functions:

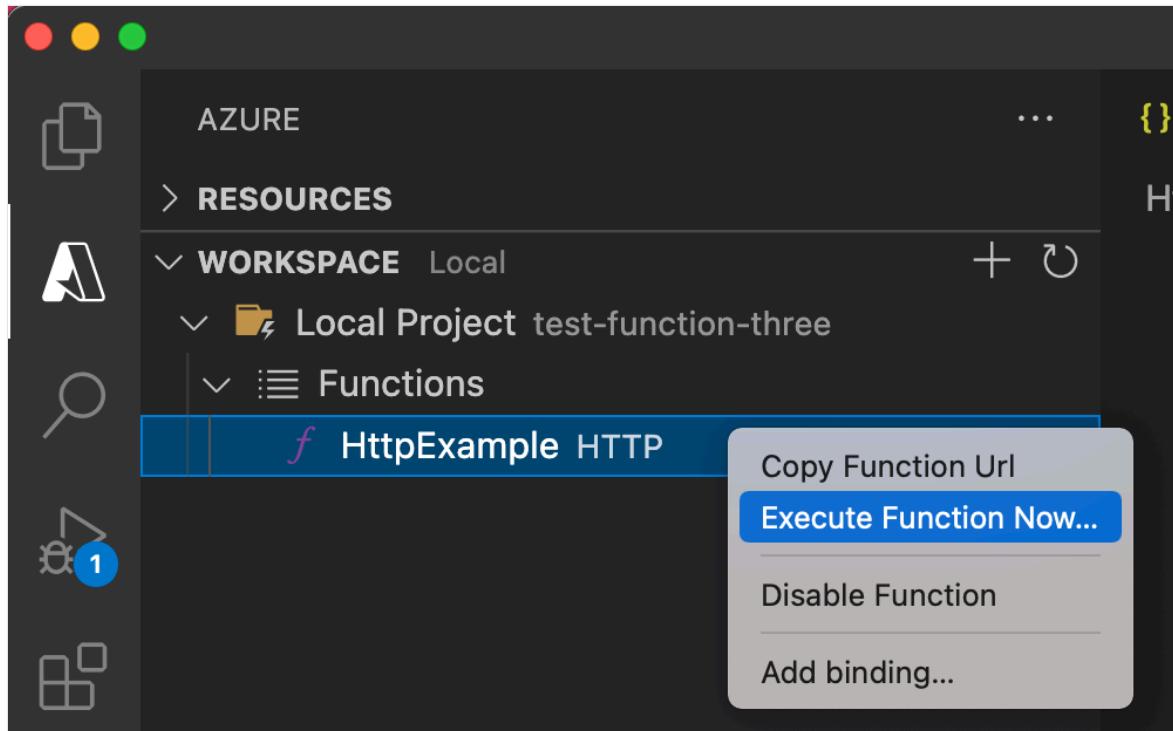

HttpExample: [GET,POST] http://localhost:7071/api/HttpExample

For detailed output, run func with --verbose flag.
[2022-05-25T18:45:53.470Z] Worker process started and initialized.
[2022-05-25T18:45:54.960Z] Host lock lease acquired by instance ID '00000000000000000000E24CCCAC'.
```

If you don't already have Core Tools installed, select **Install** to install Core Tools when prompted to do so.

If you have trouble running on Windows, make sure that the default terminal for Visual Studio Code isn't set to **WSL Bash**.

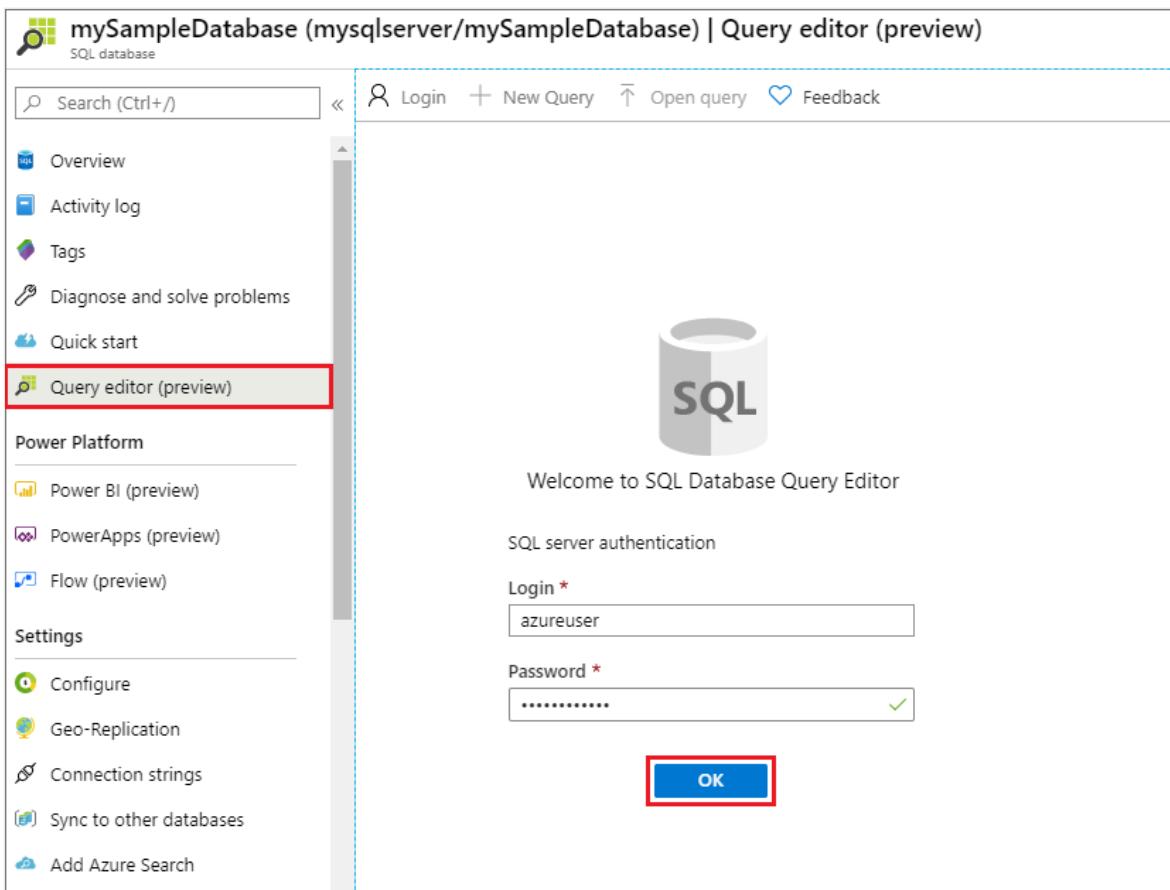

- With the Core Tools running, go to the **Azure: Functions** area. Under **Functions**, expand **Local Project > Functions**. Right-click (Windows) or `ctrl -` click (macOS) the `HttpExample` function and choose **Execute Function Now....**

- In the **Enter request body**, press `Enter` to send a request message to your function.
- When the function executes locally and returns a response, a notification is raised in Visual Studio Code. Information about the function execution is shown in the **Terminal** panel.
- Press `Ctrl + C` to stop Core Tools and disconnect the debugger.

Verify that information has been written to the database

- On the Azure portal, go back to your Azure SQL Database and select **Query editor**.

2. Connect to your database and expand the **Tables** node in object explorer on the left. Right-click on the `dbo.ToDo` table and select **Select Top 1000 Rows**.
3. Verify that the new information has been written to the database by the output binding.

Redeploy and verify the updated app

1. In Visual Studio Code, press F1 to open the command palette. In the command palette, search for and select `Azure Functions: Deploy to function app....`.
2. Choose the function app that you created in the first article. Because you're redeploying your project to the same app, select **Deploy** to dismiss the warning about overwriting files.
3. After deployment completes, you can again use the **Execute Function Now...** feature to trigger the function in Azure.
4. Again [check the data written to your Azure SQL Database](#) to verify that the output binding again generates a new JSON document.

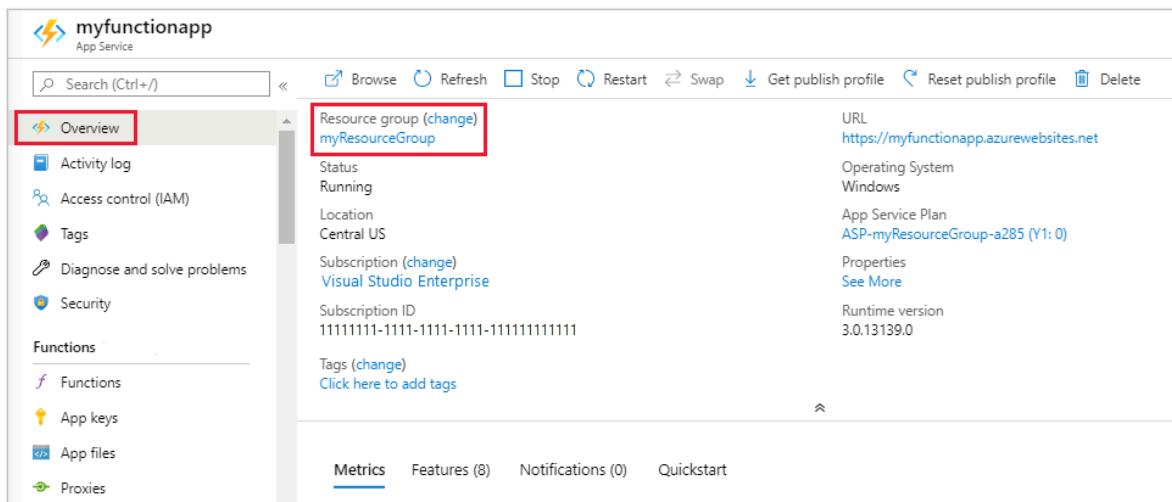

Clean up resources

In Azure, *resources* refer to function apps, functions, storage accounts, and so forth.

They're grouped into *resource groups*, and you can delete everything in a group by deleting the group.

You created resources to complete these quickstarts. You may be billed for these resources, depending on your [account status](#) and [service pricing](#). If you don't need the resources anymore, here's how to delete them:

1. In Visual Studio Code, press `F1` to open the command palette. In the command palette, search for and select `Azure: Open in portal`.
2. Choose your function app and press `Enter`. The function app page opens in the Azure portal.
3. In the **Overview** tab, select the named link next to **Resource group**.

4. On the **Resource group** page, review the list of included resources, and verify that they're the ones you want to delete.
5. Select **Delete resource group**, and follow the instructions.

Deletion may take a couple of minutes. When it's done, a notification appears for a few seconds. You can also select the bell icon at the top of the page to view the notification.

Next steps

You've updated your HTTP triggered function to write data to Azure SQL Database. Now you can learn more about developing Functions using Visual Studio Code:

Connect Azure Functions to Azure Cosmos DB using Visual Studio Code

Article • 04/26/2024

Azure Functions lets you connect Azure services and other resources to functions without having to write your own integration code. These *bindings*, which represent both input and output, are declared within the function definition. Data from bindings is provided to the function as parameters. A *trigger* is a special type of input binding. Although a function has only one trigger, it can have multiple input and output bindings. To learn more, see [Azure Functions triggers and bindings concepts](#).

This article shows you how to use Visual Studio Code to connect [Azure Cosmos DB](#) to the function you created in the previous quickstart article. The output binding that you add to this function writes data from the HTTP request to a JSON document stored in an Azure Cosmos DB container.

Before you begin, you must complete the [quickstart: Create a JavaScript function in Azure using Visual Studio Code](#). If you already cleaned up resources at the end of that article, go through the steps again to recreate the function app and related resources in Azure.

ⓘ Note

This article currently only supports [Node.js v3 for Functions](#).

Configure your environment

Before you get started, make sure to install the [Azure Databases extension](#) for Visual Studio Code.

Create your Azure Cosmos DB account

Now, you create an Azure Cosmos DB account as a [serverless account type](#). This consumption-based mode makes Azure Cosmos DB a strong option for serverless workloads.

1. In Visual Studio Code, select **View > Command Palette...** then in the command palette search for `Azure Databases: Create Server...`

- Provide the following information at the prompts:

[+] Expand table

Prompt	Selection
Select an Azure Database Server	Choose Core (NoSQL) to create a document database that you can query by using a SQL syntax or a Query Copilot (Preview) converting natural language prompts to queries. Learn more about the Azure Cosmos DB.
Account name	Enter a unique name to identify your Azure Cosmos DB account. The account name can use only lowercase letters, numbers, and hyphens (-), and must be between 3 and 31 characters long.
Select a capacity model	Select Serverless to create an account in serverless mode.
Select a resource group for new resources	Choose the resource group where you created your function app in the previous article .
Select a location for new resources	Select a geographic location to host your Azure Cosmos DB account. Use the location that's closest to you or your users to get the fastest access to your data.

After your new account is provisioned, a message is displayed in notification area.

Create an Azure Cosmos DB database and container

- Select the Azure icon in the Activity bar, expand **Resources > Azure Cosmos DB**, right-click (Ctrl+select on macOS) your account, and select **Create database...**
- Provide the following information at the prompts:

[+] Expand table

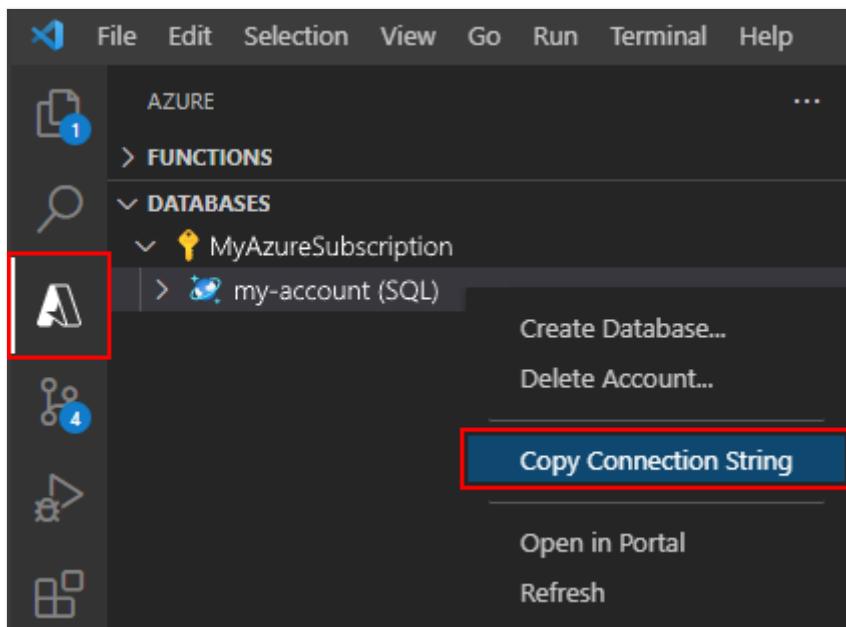

Prompt	Selection
Database name	Type <code>my-database</code> .
Enter and ID for your collection	Type <code>my-container</code> .
Enter the partition key for the collection	Type <code>/id</code> as the partition key .

- Select **OK** to create the container and database.

Update your function app settings

In the [previous quickstart article](#), you created a function app in Azure. In this article, you update your app to write JSON documents to the Azure Cosmos DB container you've created. To connect to your Azure Cosmos DB account, you must add its connection string to your app settings. You then download the new setting to your local.settings.json file so you can connect to your Azure Cosmos DB account when running locally.

1. In Visual Studio Code, right-click (Ctrl+select on macOS) on your new Azure Cosmos DB account, and select **Copy Connection String**.

2. Press **F1** to open the command palette, then search for and run the command `Azure Functions: Add New Setting....`
3. Choose the function app you created in the previous article. Provide the following information at the prompts:

 Expand table

Prompt	Selection
Enter new app setting name	Type <code>CosmosDbConnectionSetting</code> .
Enter value for "CosmosDbConnectionSetting"	Paste the connection string of your Azure Cosmos DB account you copied. You can also configure Microsoft Entra identity as an alternative.

This creates an application setting named connection `CosmosDbConnectionSetting` in your function app in Azure. Now, you can download this setting to your

`local.settings.json` file.

4. Press **F1** again to open the command palette, then search for and run the command `Azure Functions: Download Remote Settings....`
5. Choose the function app you created in the previous article. Select **Yes to all** to overwrite the existing local settings.

This downloads all of the setting from Azure to your local project, including the new connection string setting. Most of the downloaded settings aren't used when running locally.

Register binding extensions

Because you're using an Azure Cosmos DB output binding, you must have the corresponding bindings extension installed before you run the project.

Your project has been configured to use [extension bundles](#), which automatically installs a predefined set of extension packages.

Extension bundles usage is enabled in the `host.json` file at the root of the project, which appears as follows:

```
JSON

{
  "version": "2.0",
  "logging": {
    "applicationInsights": {
      "samplingSettings": {
        "isEnabled": true,
        "excludedTypes": "Request"
      }
    }
  },
  "extensionBundle": {
    "id": "Microsoft.Azure.Functions.ExtensionBundle",
    "version": "[4.*, 5.0.0)"
  },
  "concurrency": {
    "dynamicConcurrencyEnabled": true,
    "snapshotPersistenceEnabled": true
  },
  "extensions": {
    "cosmosDB": {
      "connectionMode": "Gateway"
    }
  }
}
```

```
}
```

Now, you can add the Azure Cosmos DB output binding to your project.

Add an output binding

Binding attributes are defined directly in your function code. The [Azure Cosmos DB output configuration](#) describes the fields required for an Azure Cosmos DB output binding.

For this `MultiResponse` scenario, you need to add an `extraOutputs` output binding to the function.

JavaScript

```
app.http('HttpExample', {
  methods: ['GET', 'POST'],
  extraOutputs: [sendToCosmosDb],
  handler: async (request, context) => {
```

Add the following properties to the binding configuration:

JavaScript

```
const sendToCosmosDb = output.cosmosDB({
  databaseName: 'my-database',
  containerName: 'my-container',
  createIfNotExists: false,
  connection: 'CosmosDBConnectionString',
});
```

Add code that uses the output binding

Add code that uses the `extraInputs` output binding object on `context` to send a JSON document to the named output binding function, `sendToCosmosDb`. Add this code before the `return` statement.

JavaScript

```
context.extraOutputs.set(sendToCosmosDb, {
  // create a random ID
  id:
    new Date().toISOString() + Math.random().toString().substring(2, 10),
```

```
    name: name,  
});
```

At this point, your function should look as follows:

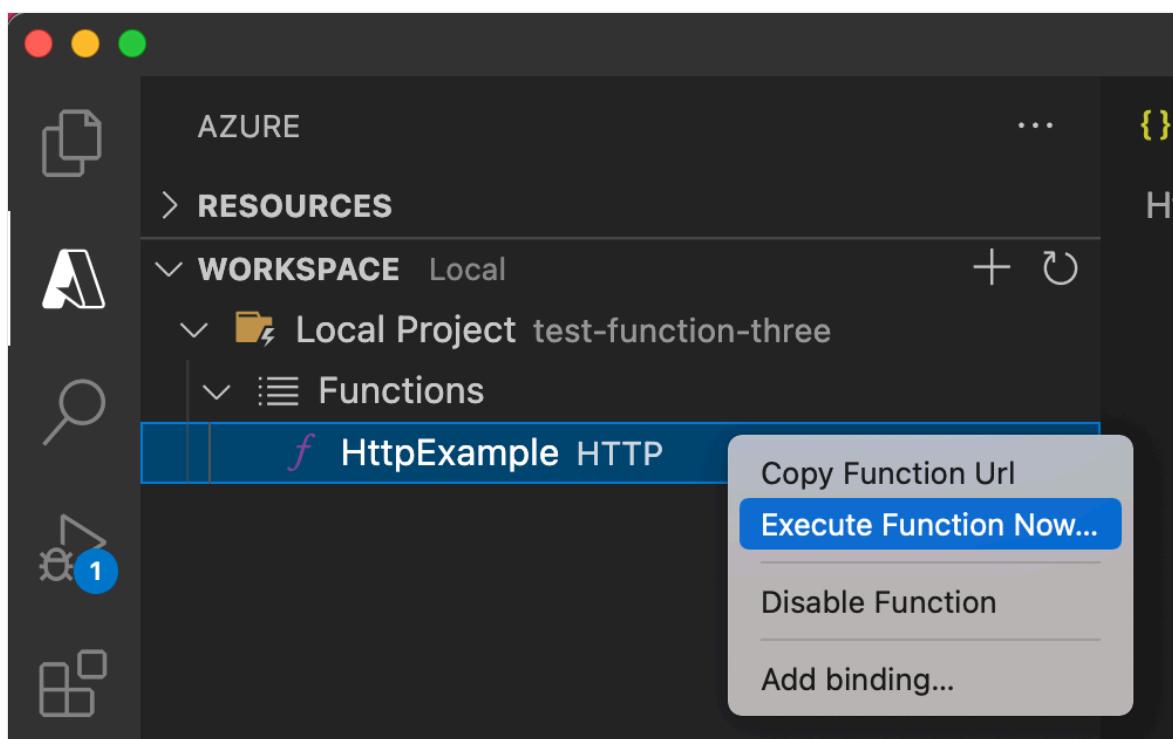

```
JavaScript  
  
const { app, output } = require('@azure/functions');  
  
const sendToCosmosDb = output.cosmosDB({  
  databaseName: 'my-database',  
  containerName: 'my-container',  
  createIfNotExists: false,  
  connection: 'CosmosDBConnectionString',  
});  
  
app.http('HttpExampleToCosmosDB', {  
  methods: ['GET', 'POST'],  
  extraOutputs: [sendToCosmosDb],  
  handler: async (request, context) => {  
    try {  
      context.log(`Http function processed request for url  
"${request.url}"`);  
  
      const name = request.query.get('name') || (await request.text());  
  
      if (!name) {  
        return { status: 404, body: 'Missing required data' };  
      }  
  
      // Output to Database  
      context.extraOutputs.set(sendToCosmosDb, {  
        // create a random ID  
        id:  
          new Date().toISOString() + Math.random().toString().substring(2,  
10),  
        name: name,  
      });  
  
      const responseMessage = name  
        ? `Hello, ${name}  
        . This HTTP triggered function executed successfully.  
        : 'This HTTP triggered function executed successfully. Pass a name  
        in the query string or in the request body for a personalized response.';  
  
      // Return to HTTP client  
      return { body: responseMessage };  
    } catch (error) {  
      context.log(`Error: ${error}`);  
      return { status: 500, body: 'Internal Server Error' };  
    }  
  }  
});
```

```
 },  
});
```

This code now returns a `MultiResponse` object that contains both a document and an HTTP response.

Run the function locally

1. As in the previous article, press `F5` to start the function app project and Core Tools.
2. With Core Tools running, go to the **Azure: Functions** area. Under **Functions**, expand **Local Project > Functions**. Right-click (Ctrl-click on Mac) the `HttpExample` function and choose **Execute Function Now...**

3. In **Enter request body** you see the request message body value of `{ "name": "Azure" }`. Press Enter to send this request message to your function.
4. After a response is returned, press `Ctrl + C` to stop Core Tools.

Verify that a JSON document has been created

1. On the Azure portal, go back to your Azure Cosmos DB account and select **Data Explorer**.

2. Expand your database and container, and select **Items** to list the documents created in your container.

3. Verify that a new JSON document has been created by the output binding.

The screenshot shows the Azure portal interface with the 'Data Explorer' blade open. On the left, there's a sidebar with various options like Overview, Activity log, Access control (IAM), Tags, Diagnose and solve problems, Quick start, Notifications, and Data Explorer. The 'Data Explorer' option is highlighted with a red box. The main area shows the 'SQL API' for a database named 'my-database' and a container named 'my-container'. The 'Items' tab is selected, and a single document is listed with the ID '73f7ba1f-3ef8-4abb-b729-af8c69169052'. The JSON content of the document is displayed in a code editor-like pane:

```
1 "id": "73f7ba1f-3ef8-4abb-b729-af8c69169052",
2 "name": "Azure",
3 "_rid": "THT+ALAE2yABAAAAAA==",
4 "_self": "dbs/THT+AA==/colls/THT+ALAE2yA=/docs",
5 "_etag": "\\"1b00bf3f-0000-0700-0000-602d749200",
6 "_attachments": "attachments/",
7 "_ts": 1613591698
```

Redeploy and verify the updated app

1. In Visual Studio Code, press F1 to open the command palette. In the command palette, search for and select **Azure Functions: Deploy to function app...**.

2. Choose the function app that you created in the first article. Because you're redeploying your project to the same app, select **Deploy** to dismiss the warning about overwriting files.

3. After deployment completes, you can again use the **Execute Function Now...** feature to trigger the function in Azure.

4. Again [check the documents created in your Azure Cosmos DB container](#) to verify that the output binding again generates a new JSON document.

Clean up resources

In Azure, *resources* refer to function apps, functions, storage accounts, and so forth. They're grouped into *resource groups*, and you can delete everything in a group by deleting the group.

You created resources to complete these quickstarts. You might be billed for these resources, depending on your [account status](#) and [service pricing](#). If you don't need the resources anymore, here's how to delete them:

1. In Visual Studio Code, press F1 to open the command palette. In the command palette, search for and select **Azure: Open in portal**.

2. Choose your function app and press **Enter**. The function app page opens in the Azure portal.

3. In the **Overview** tab, select the named link next to **Resource group**.

The screenshot shows the Azure portal's Overview page for an App Service named 'myfunctionapp'. The left sidebar has links for Activity log, Access control (IAM), Tags, Diagnose and solve problems, Security, Functions (with sub-links for Functions, App keys, App files, and Proxies), Metrics, Features (8), Notifications (0), and Quickstart. The main content area shows the following details:

Setting	Value
Status	Running
Location	Central US
Subscription (change)	Visual Studio Enterprise
Subscription ID	11111111-1111-1111-1111-111111111111
Tags (change)	Click here to add tags
URL	https://myfunctionapp.azurewebsites.net
Operating System	Windows
App Service Plan	ASP-myResourceGroup-a285 (Y1: 0)
Properties	See More
Runtime version	3.0.13139.0

4. On the **Resource group** page, review the list of included resources, and verify that they're the ones you want to delete.

5. Select **Delete resource group**, and follow the instructions.

Deletion may take a couple of minutes. When it's done, a notification appears for a few seconds. You can also select the bell icon at the top of the page to view the notification.

Next steps

You've updated your HTTP triggered function to write JSON documents to an Azure Cosmos DB container. Now you can learn more about developing Functions using Visual Studio Code:

Connect Azure Functions to Azure SQL Database using Visual Studio Code

Article • 04/25/2024

Azure Functions lets you connect Azure services and other resources to functions without having to write your own integration code. These *bindings*, which represent both input and output, are declared within the function definition. Data from bindings is provided to the function as parameters. A *trigger* is a special type of input binding. Although a function has only one trigger, it can have multiple input and output bindings. To learn more, see [Azure Functions triggers and bindings concepts](#).

This article shows you how to use Visual Studio Code to connect [Azure SQL Database](#) to the function you created in the previous quickstart article. The output binding that you add to this function writes data from the HTTP request to a table in Azure SQL Database.

Before you begin, you must complete the [quickstart: Create a JavaScript function in Azure using Visual Studio Code](#). If you already cleaned up resources at the end of that article, go through the steps again to recreate the function app and related resources in Azure.

More details on the settings for [Azure SQL bindings and trigger for Azure Functions](#) are available in the Azure Functions documentation.

Create your Azure SQL Database

1. Follow the [Azure SQL Database create quickstart](#) to create a serverless Azure SQL Database. The database can be empty or created from the sample dataset AdventureWorksLT.
2. Provide the following information at the prompts:

[+] [Expand table](#)

Prompt	Selection
Resource group	Choose the resource group where you created your function app in the previous article .
Database name	Enter <code>mySampleDatabase</code> .
Server name	Enter a unique name for your server. We can't provide an exact server name to use because server names must be globally

Prompt	Selection
	unique for all servers in Azure, not just unique within a subscription.
Authentication method	Select SQL Server authentication .
Server admin login	Enter <code>azureuser</code> .
Password	Enter a password that meets the complexity requirements.
Allow Azure services and resources to access this server	Select Yes .

3. Once the creation has completed, navigate to the database blade in the Azure portal, and, under **Settings**, select **Connection strings**. Copy the **ADO.NET** connection string for **SQL authentication**. Paste the connection string into a temporary document for later use.

The screenshot shows the 'mySampleDatabase - Connection strings' blade in the Azure portal. The left sidebar includes links for Overview, Activity log, Tags, Diagnose and solve problems, Quick start, Query editor (preview), Settings (Configure, Geo-Replication), and Connection strings. The 'Connection strings' link is highlighted with a red box. The main area shows tabs for ADO.NET, JDBC, ODBC, and PHP. The ADO.NET tab is active, displaying the 'ADO.NET (SQL authentication)' section with a connection string. This string is also highlighted with a red box. Below it are sections for 'ADO.NET (Active Directory password authentication)' and 'ADO.NET (Active Directory integrated authentication)', each with its own connection string. At the bottom, there's a link to 'Download ADO.NET driver for SQL server'.

4. Create a table to store the data from the HTTP request. In the Azure portal, navigate to the database blade and select **Query editor**. Enter the following query to create a table named `dbo.ToDo`:

```
CREATE TABLE dbo.ToDo (
    [Id] UNIQUEIDENTIFIER PRIMARY KEY,
    [order] INT NULL,
    [title] NVARCHAR(200) NOT NULL,
    [url] NVARCHAR(200) NOT NULL,
    [completed] BIT NOT NULL
);
```

5. Verify that your Azure Function will be able to access the Azure SQL Database by checking the [server's firewall settings](#). Navigate to the **server blade** on the Azure portal, and under **Security**, select **Networking**. The exception for **Allow Azure services and resources to access this server** should be checked.

The screenshot shows the Azure portal interface for managing a SQL server named 'mydocsamplesqlserver'. The left sidebar lists various security features: Microsoft Defender for Cloud, Transparent data encryption, Identity, Auditing, Intelligent Performance, Automatic tuning, and Recommendations. The 'Networking' option is selected and highlighted with a red box. The main content area shows the 'Networking' blade with tabs for Public access, Private access, and Connectivity. Under the 'Public access' tab, there is a section for 'Firewall rules' with options to add client IPv4 addresses or firewall rules. Below this is an 'Exceptions' section, also highlighted with a red box, containing a checkbox labeled 'Allow Azure services and resources to access this server'.

Update your function app settings

In the [previous quickstart article](#), you created a function app in Azure. In this article, you update your app to write data to the Azure SQL Database you've just created. To connect to your Azure SQL Database, you must add its connection string to your app settings. You then download the new setting to your local.settings.json file so you can connect to your Azure SQL Database when running locally.

1. Edit the connection string in the temporary document you created earlier. Replace the value of `Password` with the password you used when creating the Azure SQL Database. Copy the updated connection string.
2. Press `Ctrl/Cmd+shift+P` to open the command palette, then search for and run the command `Azure Functions: Add New Setting...`.
3. Choose the function app you created in the previous article. Provide the following information at the prompts:

[\[+\] Expand table](#)

Prompt	Selection
Enter new app setting name	Type <code>SqlConnectionString</code> .
Enter value for "SqlConnectionString"	Paste the connection string of your Azure SQL Database you just copied.

This creates an application setting named connection `SqlConnectionString` in your function app in Azure. Now, you can download this setting to your `local.settings.json` file.

4. Press `Ctrl/Cmd+shift+P` again to open the command palette, then search for and run the command `Azure Functions: Download Remote Settings....`
5. Choose the function app you created in the previous article. Select **Yes to all** to overwrite the existing local settings.

This downloads all of the setting from Azure to your local project, including the new connection string setting. Most of the downloaded settings aren't used when running locally.

Register binding extensions

Because you're using an Azure SQL output binding, you must have the corresponding bindings extension installed before you run the project.

Your project has been configured to use [extension bundles](#), which automatically installs a predefined set of extension packages.

Extension bundles usage is enabled in the `host.json` file at the root of the project, which appears as follows:

```
JSON

{
  "version": "2.0",
  "logging": {
    "applicationInsights": {
      "samplingSettings": {
        "isEnabled": true,
        "excludedTypes": "Request"
      }
    }
  },
  "extensionBundle": {
    "id": "Microsoft.Azure.Functions.ExtensionBundle",
    "version": "[4.*, 5.0.0)"
  }
}
```

```
  },
  "concurrency": {
    "dynamicConcurrencyEnabled": true,
    "snapshotPersistenceEnabled": true
  }
}
```

...

Now, you can add the Azure SQL output binding to your project.

Add an output binding

In Functions, each type of binding requires a `direction`, `type`, and a unique `name` to be defined in the `function.json` file. The way you define these attributes depends on the language of your function app.

Binding attributes are defined directly in your code. The [Azure SQL output configuration](#) describes the fields required for an Azure SQL output binding.

For this `MultiResponse` scenario, you need to add an `extraOutputs` output binding to the function.

JavaScript

```
app.http('HttpExample', {
  methods: ['GET', 'POST'],
  extraOutputs: [sendToSql],
  handler: async (request, context) => {
```

Add the following properties to the binding configuration:

JavaScript

```
const sendToSql = output.sql({
  commandText: 'dboToDo',
  connectionStringSetting: 'SqlConnectionString',
});
```

Add code that uses the output binding

Add code that uses the `extraInputs` output binding object on `context` to send a JSON document to the named output binding function, `sendToSql`. Add this code before the `return` statement.

```
JavaScript
```

```
const data = JSON.stringify([
  {
    // create a random ID
    Id: crypto.randomUUID(),
    title: name,
    completed: false,
    url: '',
  },
]);

// Output to Database
context.extraOutputs.set(sendToSql, data);
```

To utilize the `crypto` module, add the following line to the top of the file:

```
JavaScript
```

```
const crypto = require("crypto");
```

At this point, your function should look as follows:

```
JavaScript
```

```
const { app, output } = require('@azure/functions');
const crypto = require('crypto');

const sendToSql = output.sql({
  commandText: 'dbo.ToDo',
  connectionStringSetting: 'SqlConnectionString',
});

app.http('HttpExample', {
  methods: ['GET', 'POST'],
  extraOutputs: [sendToSql],
  handler: async (request, context) => {
    try {
      context.log(`Http function processed request for url
      "${request.url}"`);

      const name = request.query.get('name') || (await request.text());

      if (!name) {
        return { status: 404, body: 'Missing required data' };
      }

      // Stringified array of objects to be inserted into the database
      const data = JSON.stringify([
        {
          // create a random ID
```

```
    Id: crypto.randomUUID(),
    title: name,
    completed: false,
    url: '',
  },
]);

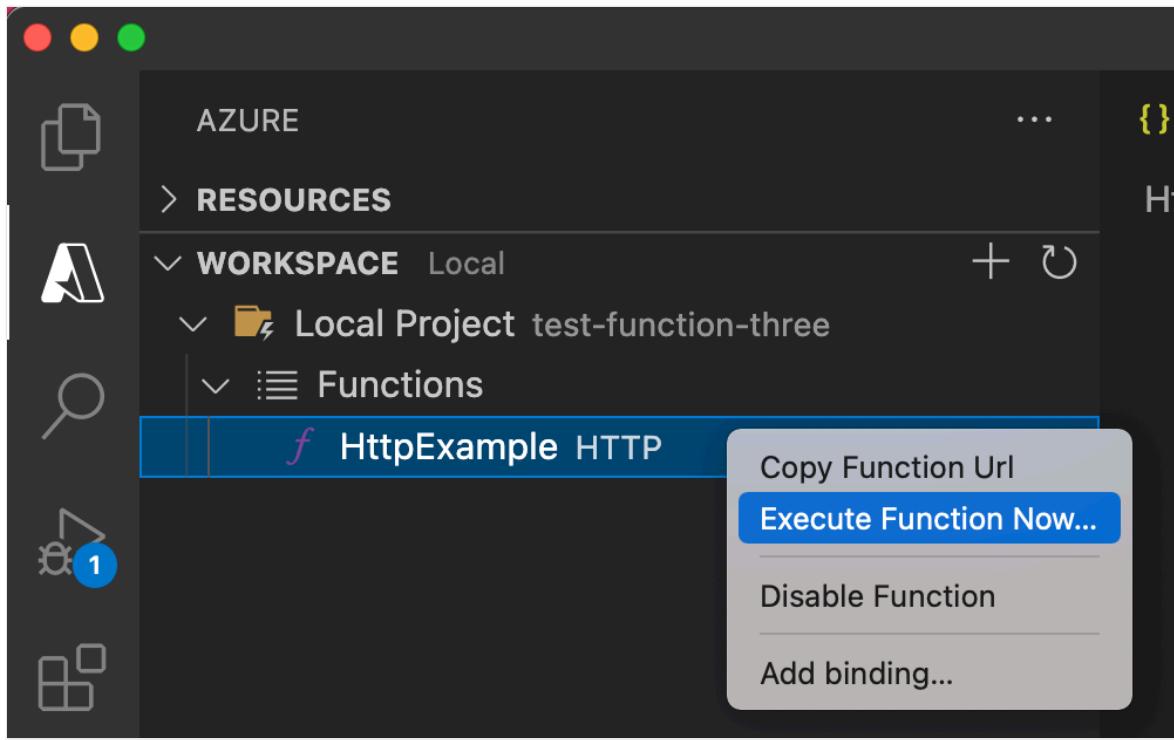

// Output to Database
context.extraOutputs.set(sendToSql, data);

const responseMessage = name
? 'Hello, ' +
  name +
  '. This HTTP triggered function executed successfully.'
: 'This HTTP triggered function executed successfully. Pass a name
in the query string or in the request body for a personalized response.';

// Return to HTTP client
return { body: responseMessage };
} catch (error) {
  context.log(`Error: ${error}`);
  return { status: 500, body: 'Internal Server Error' };
}
},
));
}
```

Run the function locally

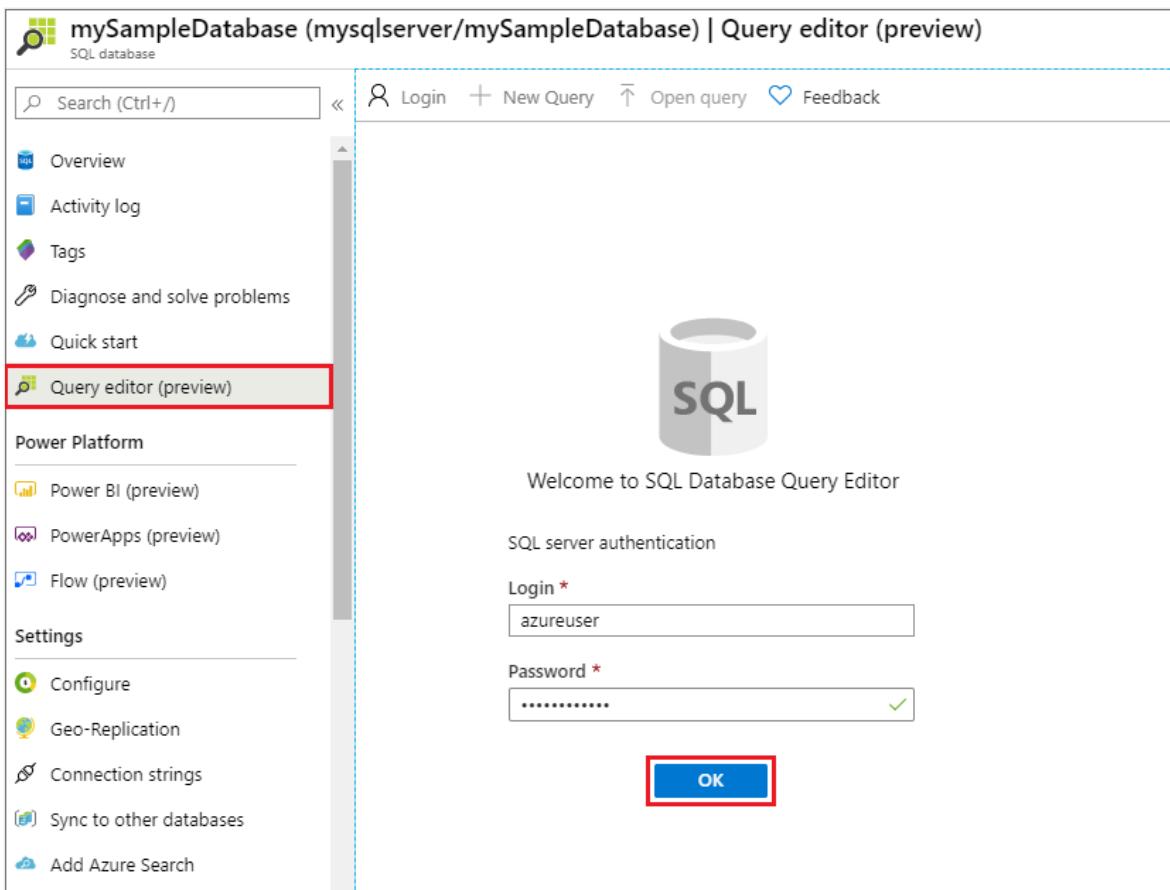

1. As in the previous article, press **F5** to start the function app project and Core Tools.
2. With Core Tools running, go to the **Azure: Functions** area. Under **Functions**, expand **Local Project > Functions**. Right-click (Ctrl-click on Mac) the **HttpExample** function and choose **Execute Function Now...**

3. In **Enter request body** you see the request message body value of `{ "name": "Azure" }`. Press Enter to send this request message to your function.
4. After a response is returned, press `Ctrl + C` to stop Core Tools.

Verify that information has been written to the database

1. On the Azure portal, go back to your Azure SQL Database and select **Query editor**.

2. Connect to your database and expand the **Tables** node in object explorer on the left. Right-click on the `dbo.ToDo` table and select **Select Top 1000 Rows**.
3. Verify that the new information has been written to the database by the output binding.

Redeploy and verify the updated app

1. In Visual Studio Code, press F1 to open the command palette. In the command palette, search for and select `Azure Functions: Deploy to function app....`.
2. Choose the function app that you created in the first article. Because you're redeploying your project to the same app, select **Deploy** to dismiss the warning about overwriting files.
3. After deployment completes, you can again use the **Execute Function Now...** feature to trigger the function in Azure.
4. Again [check the data written to your Azure SQL Database](#) to verify that the output binding again generates a new JSON document.

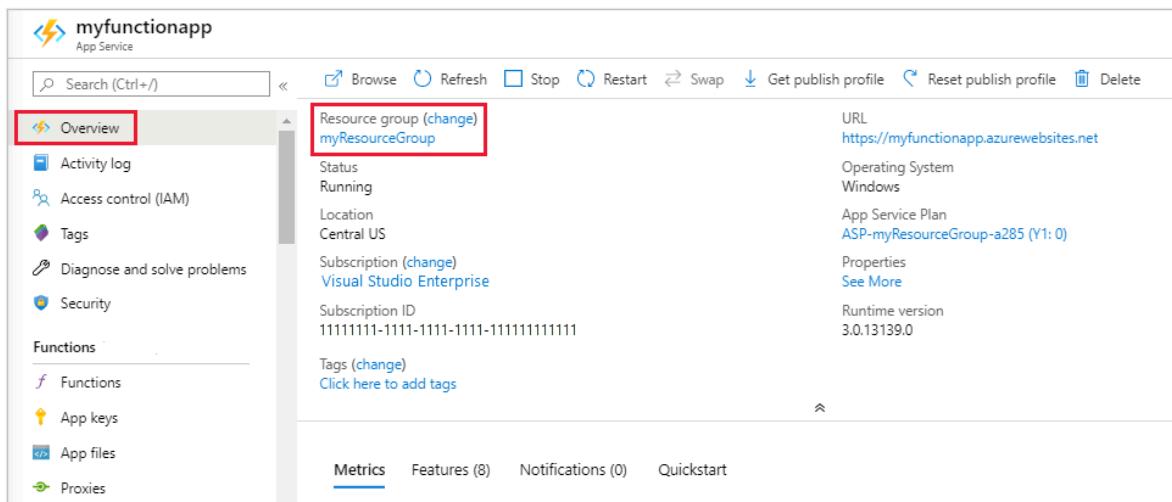

Clean up resources

In Azure, *resources* refer to function apps, functions, storage accounts, and so forth.

They're grouped into *resource groups*, and you can delete everything in a group by deleting the group.

You created resources to complete these quickstarts. You may be billed for these resources, depending on your [account status](#) and [service pricing](#). If you don't need the resources anymore, here's how to delete them:

1. In Visual Studio Code, press `F1` to open the command palette. In the command palette, search for and select `Azure: Open in portal`.
2. Choose your function app and press `Enter`. The function app page opens in the Azure portal.
3. In the **Overview** tab, select the named link next to **Resource group**.

4. On the **Resource group** page, review the list of included resources, and verify that they're the ones you want to delete.
5. Select **Delete resource group**, and follow the instructions.

Deletion may take a couple of minutes. When it's done, a notification appears for a few seconds. You can also select the bell icon at the top of the page to view the notification.

Next steps

You've updated your HTTP triggered function to write data to Azure SQL Database. Now you can learn more about developing Functions using Visual Studio Code:

Connect Azure Functions to Azure Cosmos DB using Visual Studio Code

Article • 04/26/2024

Azure Functions lets you connect Azure services and other resources to functions without having to write your own integration code. These *bindings*, which represent both input and output, are declared within the function definition. Data from bindings is provided to the function as parameters. A *trigger* is a special type of input binding. Although a function has only one trigger, it can have multiple input and output bindings. To learn more, see [Azure Functions triggers and bindings concepts](#).

This article shows you how to use Visual Studio Code to connect [Azure Cosmos DB](#) to the function you created in the previous quickstart article. The output binding that you add to this function writes data from the HTTP request to a JSON document stored in an Azure Cosmos DB container.

Before you begin, you must complete the [quickstart: Create a Python function in Azure using Visual Studio Code](#). If you already cleaned up resources at the end of that article, go through the steps again to recreate the function app and related resources in Azure.

Configure your environment

Before you get started, make sure to install the [Azure Databases extension](#) for Visual Studio Code.

Create your Azure Cosmos DB account

Now, you create an Azure Cosmos DB account as a [serverless account type](#). This consumption-based mode makes Azure Cosmos DB a strong option for serverless workloads.

1. In Visual Studio Code, select **View > Command Palette...** then in the command palette search for `Azure Databases: Create Server...`
2. Provide the following information at the prompts:

[] [Expand table](#)

Prompt	Selection
Select an Azure Database Server	Choose Core (NoSQL) to create a document database that you can query by using a SQL syntax or a Query Copilot (Preview) converting natural language prompts to queries. Learn more about the Azure Cosmos DB .
Account name	Enter a unique name to identify your Azure Cosmos DB account. The account name can use only lowercase letters, numbers, and hyphens (-), and must be between 3 and 31 characters long.
Select a capacity model	Select Serverless to create an account in serverless mode.
Select a resource group for new resources	Choose the resource group where you created your function app in the previous article .
Select a location for new resources	Select a geographic location to host your Azure Cosmos DB account. Use the location that's closest to you or your users to get the fastest access to your data.

After your new account is provisioned, a message is displayed in notification area.

Create an Azure Cosmos DB database and container

1. Select the Azure icon in the Activity bar, expand **Resources > Azure Cosmos DB**, right-click (Ctrl+select on macOS) your account, and select **Create database...**
2. Provide the following information at the prompts:

[\[+\] Expand table](#)

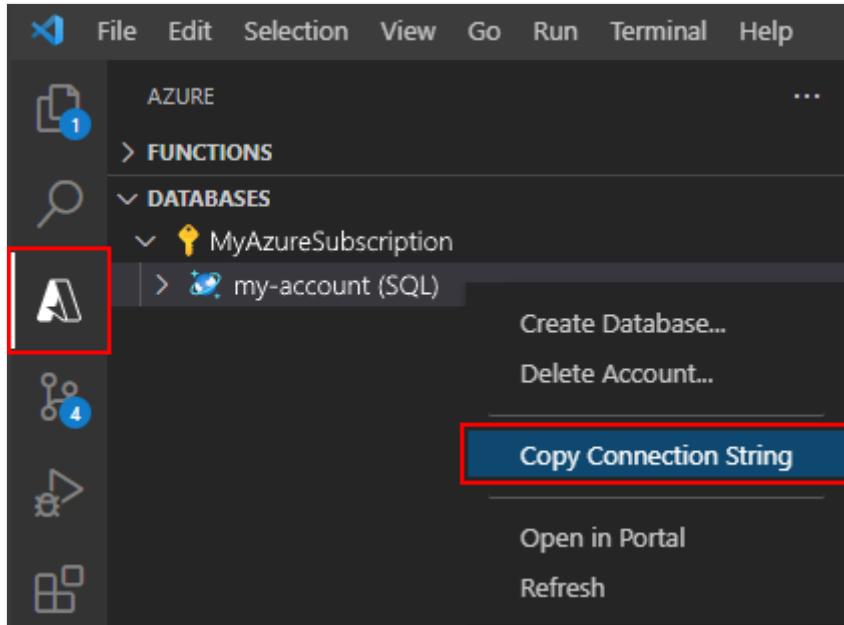

Prompt	Selection
Database name	Type <code>my-database</code> .
Enter and ID for your collection	Type <code>my-container</code> .
Enter the partition key for the collection	Type <code>/id</code> as the partition key .

3. Select **OK** to create the container and database.

Update your function app settings

In the [previous quickstart article](#), you created a function app in Azure. In this article, you update your app to write JSON documents to the Azure Cosmos DB container you've created. To connect to your Azure Cosmos DB account, you must add its connection string to your app settings. You then download the new setting to your local.settings.json file so you can connect to your Azure Cosmos DB account when running locally.

1. In Visual Studio Code, right-click (Ctrl+select on macOS) on your new Azure Cosmos DB account, and select **Copy Connection String**.

2. Press **F1** to open the command palette, then search for and run the command `Azure Functions: Add New Setting...`

3. Choose the function app you created in the previous article. Provide the following information at the prompts:

[+] [Expand table](#)

Prompt	Selection
Enter new app setting name	Type <code>CosmosDbConnectionSetting</code> .
Enter value for "CosmosDbConnectionSetting"	Paste the connection string of your Azure Cosmos DB account you copied. You can also configure Microsoft Entra identity as an alternative.

This creates an application setting named connection `CosmosDbConnectionSetting` in your function app in Azure. Now, you can download this setting to your local.settings.json file.

4. Press **F1** again to open the command palette, then search for and run the command `Azure Functions: Download Remote Settings....`.
5. Choose the function app you created in the previous article. Select **Yes to all** to overwrite the existing local settings.

This downloads all of the setting from Azure to your local project, including the new connection string setting. Most of the downloaded settings aren't used when running locally.

Register binding extensions

Because you're using an Azure Cosmos DB output binding, you must have the corresponding bindings extension installed before you run the project.

Your project has been configured to use [extension bundles](#), which automatically installs a predefined set of extension packages.

Extension bundles usage is enabled in the `host.json` file at the root of the project, which appears as follows:

```
JSON

{
  "version": "2.0",
  "extensionBundle": {
    "id": "Microsoft.Azure.Functions.ExtensionBundle",
    "version": "[3.*, 4.0.0)"
  }
}
```

Now, you can add the Azure Cosmos DB output binding to your project.

Add an output binding

Binding attributes are defined directly in the `function_app.py` file. You use the `cosmos_db_output` decorator to add an [Azure Cosmos DB output binding](#):

```
Python

@app.cosmos_db_output(arg_name="outputDocument", database_name="my-
database",
                      container_name="my-container", connection="CosmosDbConnectionString")
```

In this code, `arg_name` identifies the binding parameter referenced in your code, `database_name` and `container_name` are the database and collection names that the binding writes to, and `connection` is the name of an application setting that contains the connection string for the Azure Cosmos DB account, which is in the `CosmosDbConnectionSetting` setting in the `local.settings.json` file.

Add code that uses the output binding

Update `HttpExample\function_app.py` to match the following code. Add the `outputDocument` parameter to the function definition and `outputDocument.set()` under the `if name:` statement:

```
Python

import azure.functions as func
import logging

app = func.FunctionApp()

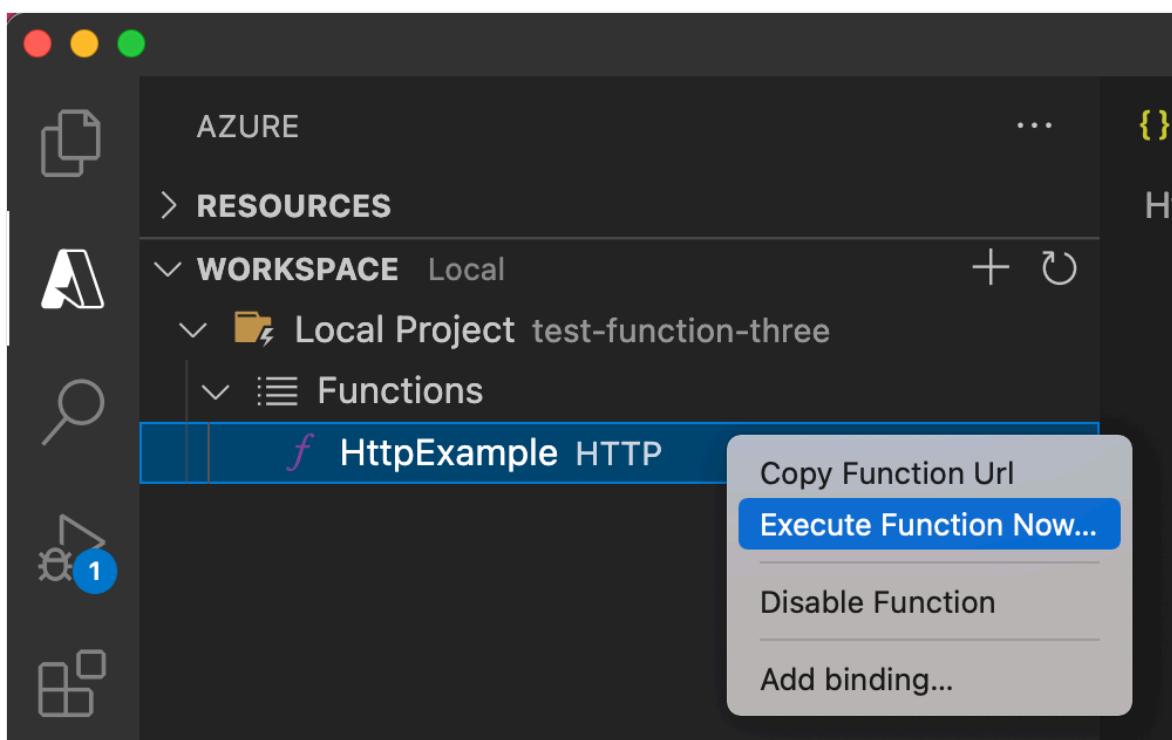

@app.function_name(name="HttpTrigger1")
@app.route(route="hello", auth_level=func.AuthLevel.ANONYMOUS)
@app.queue_output(arg_name="msg", queue_name="outqueue",
connection="AzureWebJobsStorage")
@app.cosmos_db_output(arg_name="outputDocument", database_name="my-
database", container_name="my-container",
connection="CosmosDbConnectionSetting")
def test_function(req: func.HttpRequest, msg: func.Out[func.QueueMessage],
outputDocument: func.Out[func.Document]) -> func.HttpResponse:
    logging.info('Python HTTP trigger function processed a request.')
    logging.info('Python Cosmos DB trigger function processed a request.')
    name = req.params.get('name')
    if not name:
        try:
            req_body = req.get_json()
        except ValueError:
            pass
        else:
            name = req_body.get('name')

    if name:
        outputDocument.set(func.Document.from_dict({"id": name}))
        msg.set(name)
        return func.HttpResponse(f"Hello {name}!")
    else:
        return func.HttpResponse(
            "Please pass a name on the query string or in the
request body",
            status_code=400
        )
```

The document `{"id": "name"}` is created in the database collection specified in the binding.

Run the function locally

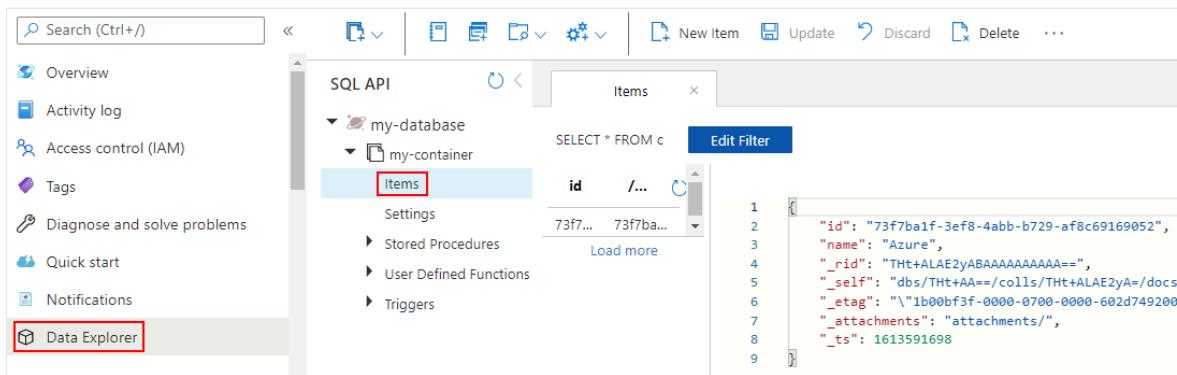

1. As in the previous article, press `F5` to start the function app project and Core Tools.
2. With Core Tools running, go to the **Azure: Functions** area. Under **Functions**, expand **Local Project > Functions**. Right-click (Ctrl-click on Mac) the `HttpExample` function and choose **Execute Function Now....**

3. In **Enter request body** you see the request message body value of `{ "name": "Azure" }`. Press Enter to send this request message to your function.
4. After a response is returned, press `ctrl + c` to stop Core Tools.

Verify that a JSON document has been created

1. On the Azure portal, go back to your Azure Cosmos DB account and select **Data Explorer**.
2. Expand your database and container, and select **Items** to list the documents created in your container.
3. Verify that a new JSON document has been created by the output binding.

Redeploy and verify the updated app

1. In Visual Studio Code, press F1 to open the command palette. In the command palette, search for and select **Azure Functions: Deploy to function app...**.
2. Choose the function app that you created in the first article. Because you're redeploying your project to the same app, select **Deploy** to dismiss the warning about overwriting files.
3. After deployment completes, you can again use the **Execute Function Now...** feature to trigger the function in Azure.
4. Again [check the documents created in your Azure Cosmos DB container](#) to verify that the output binding again generates a new JSON document.

Clean up resources

In Azure, *resources* refer to function apps, functions, storage accounts, and so forth. They're grouped into *resource groups*, and you can delete everything in a group by deleting the group.

You created resources to complete these quickstarts. You might be billed for these resources, depending on your [account status](#) and [service pricing](#). If you don't need the resources anymore, here's how to delete them:

1. In Visual Studio Code, press **F1** to open the command palette. In the command palette, search for and select **Azure: Open in portal**.
2. Choose your function app and press **Enter**. The function app page opens in the Azure portal.
3. In the **Overview** tab, select the named link next to **Resource group**.

The screenshot shows the Azure portal's 'Overview' page for a resource group. The left sidebar has a red box around the 'Overview' link. The main area shows a card for 'myResourceGroup' with a red box around its title. The card contains details like 'Status: Running', 'Location: Central US', and 'Subscription: Visual Studio Enterprise'. At the bottom of the card, there's a link 'Click here to add tags'. To the right, there's a detailed view of properties: URL (<https://myfunctionapp.azurewebsites.net>), Operating System (Windows), App Service Plan (ASP-myResourceGroup-a285 (Y1: 0)), Properties (See More), and Runtime version (3.0.13139.0). Below the card, there are tabs for Metrics, Features (8), Notifications (0), and Quickstart.

4. On the **Resource group** page, review the list of included resources, and verify that they're the ones you want to delete.

5. Select **Delete resource group**, and follow the instructions.

Deletion may take a couple of minutes. When it's done, a notification appears for a few seconds. You can also select the bell icon at the top of the page to view the notification.

Next steps

You've updated your HTTP triggered function to write JSON documents to an Azure Cosmos DB container. Now you can learn more about developing Functions using Visual Studio Code:

Connect Azure Functions to Azure SQL Database using Visual Studio Code

Article • 04/25/2024

Azure Functions lets you connect Azure services and other resources to functions without having to write your own integration code. These *bindings*, which represent both input and output, are declared within the function definition. Data from bindings is provided to the function as parameters. A *trigger* is a special type of input binding. Although a function has only one trigger, it can have multiple input and output bindings. To learn more, see [Azure Functions triggers and bindings concepts](#).

This article shows you how to use Visual Studio Code to connect [Azure SQL Database](#) to the function you created in the previous quickstart article. The output binding that you add to this function writes data from the HTTP request to a table in Azure SQL Database.

Before you begin, you must complete the [quickstart: Create a Python function in Azure using Visual Studio Code](#). If you already cleaned up resources at the end of that article, go through the steps again to recreate the function app and related resources in Azure.

More details on the settings for [Azure SQL bindings and trigger for Azure Functions](#) are available in the Azure Functions documentation.

Create your Azure SQL Database

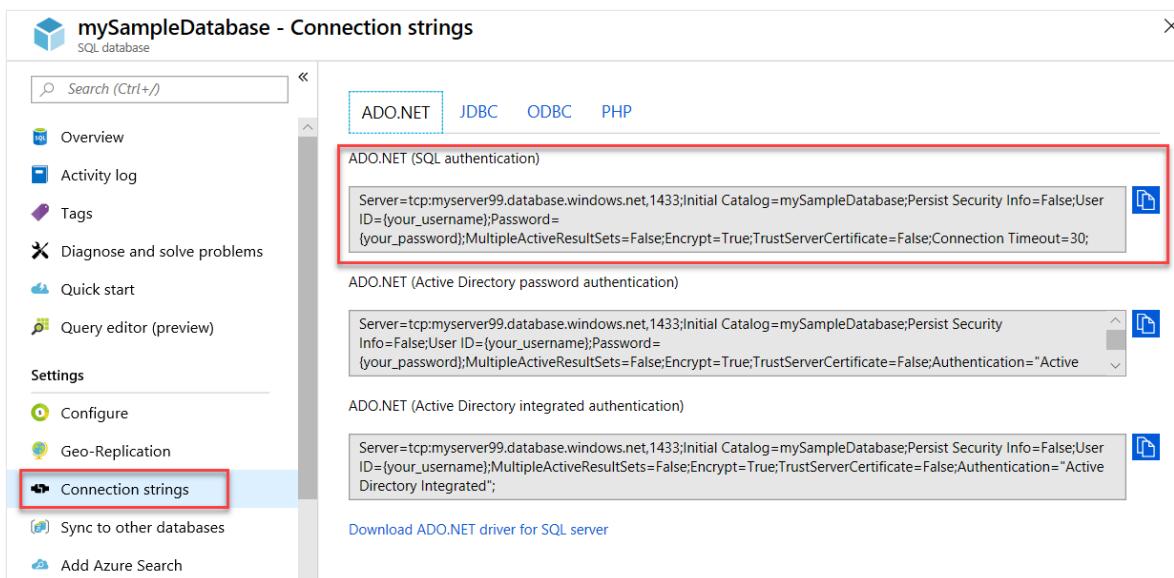

1. Follow the [Azure SQL Database create quickstart](#) to create a serverless Azure SQL Database. The database can be empty or created from the sample dataset AdventureWorksLT.
2. Provide the following information at the prompts:

[] Expand table

Prompt	Selection
Resource group	Choose the resource group where you created your function app in the previous article .
Database name	Enter <code>mySampleDatabase</code> .
Server name	Enter a unique name for your server. We can't provide an exact server name to use because server names must be globally

Prompt	Selection
	unique for all servers in Azure, not just unique within a subscription.
Authentication method	Select SQL Server authentication .
Server admin login	Enter <code>azureuser</code> .
Password	Enter a password that meets the complexity requirements.
Allow Azure services and resources to access this server	Select Yes .

3. Once the creation has completed, navigate to the database blade in the Azure portal, and, under **Settings**, select **Connection strings**. Copy the **ADO.NET** connection string for **SQL authentication**. Paste the connection string into a temporary document for later use.

4. Create a table to store the data from the HTTP request. In the Azure portal, navigate to the database blade and select **Query editor**. Enter the following query to create a table named `dbo.ToDo`:

```
SQL

CREATE TABLE dbo.ToDo (
    [Id] UNIQUEIDENTIFIER PRIMARY KEY,
    [order] INT NULL,
    [title] NVARCHAR(200) NOT NULL,
    [url] NVARCHAR(200) NOT NULL,
    [completed] BIT NOT NULL
);
```

5. Verify that your Azure Function will be able to access the Azure SQL Database by checking the [server's firewall settings](#). Navigate to the **server blade** on the Azure portal, and under **Security**, select **Networking**. The exception for **Allow Azure services and resources to access this server** should be checked.

The screenshot shows the Azure portal interface for managing a SQL server named 'mydocsamplesqlserver'. The left sidebar lists various security features: Microsoft Defender for Cloud, Transparent data encryption, Identity, Auditing, Intelligent Performance, Automatic tuning, and Recommendations. The 'Networking' option is selected and highlighted with a red box. On the right, the 'Networking' blade is displayed with tabs for Public access, Private access, and Connectivity. Under the Public access tab, there is a section for Firewall rules with options to add client IPv4 addresses or firewall rules. Below this is an 'Exceptions' section, which is also highlighted with a red box, containing a checkbox labeled 'Allow Azure services and resources to access this server'.

Update your function app settings

In the [previous quickstart article](#), you created a function app in Azure. In this article, you update your app to write data to the Azure SQL Database you've just created. To connect to your Azure SQL Database, you must add its connection string to your app settings. You then download the new setting to your local.settings.json file so you can connect to your Azure SQL Database when running locally.

1. Edit the connection string in the temporary document you created earlier. Replace the value of `Password` with the password you used when creating the Azure SQL Database. Copy the updated connection string.
2. Press `Ctrl/Cmd+shift+P` to open the command palette, then search for and run the command `Azure Functions: Add New Setting...`.
3. Choose the function app you created in the previous article. Provide the following information at the prompts:

[] [Expand table](#)

Prompt	Selection
Enter new app setting name	Type <code>SqlConnectionString</code> .
Enter value for "SqlConnectionString"	Paste the connection string of your Azure SQL Database you just copied.

This creates an application setting named connection `SqlConnectionString` in your function app in Azure. Now, you can download this setting to your `local.settings.json` file.

4. Press `Ctrl/Cmd+shift+P` again to open the command palette, then search for and run the command `Azure Functions: Download Remote Settings....`
5. Choose the function app you created in the previous article. Select **Yes to all** to overwrite the existing local settings.

This downloads all of the setting from Azure to your local project, including the new connection string setting. Most of the downloaded settings aren't used when running locally.

Register binding extensions

Because you're using an Azure SQL output binding, you must have the corresponding bindings extension installed before you run the project.

Your project has been configured to use [extension bundles](#), which automatically installs a predefined set of extension packages.

Extension bundles usage is enabled in the `host.json` file at the root of the project, which appears as follows:

```
JSON

{
  "version": "2.0",
  "logging": {
    "applicationInsights": {
      "samplingSettings": {
        "isEnabled": true,
        "excludedTypes": "Request"
      }
    }
  },
  "extensionBundle": {
    "id": "Microsoft.Azure.Functions.ExtensionBundle",
    "version": "[4.*, 5.0.0)"
  }
}
```

```
        },
        "concurrency": {
            "dynamicConcurrencyEnabled": true,
            "snapshotPersistenceEnabled": true
        }
    }
}
```

:::

Now, you can add the Azure SQL output binding to your project.

Add an output binding

In Functions, each type of binding requires a `direction`, `type`, and a unique `name` to be defined in the `function.json` file. The way you define these attributes depends on the language of your function app.

Binding attributes are defined directly in the `function_app.py` file. You use the `generic_output_binding` decorator to add an [Azure SQL output binding](#):

Python

```
@app.generic_output_binding(arg_name="ToDoItems", type="sql",
    CommandText="dbo.ToDo", ConnectionStringSetting="SqlConnectionString"
    data_type=DataType.STRING)
```

In this code, `arg_name` identifies the binding parameter referenced in your code, `type` denotes the output binding is a SQL output binding, `CommandText` is the table that the binding writes to, and `ConnectionStringSetting` is the name of an application setting that contains the Azure SQL connection string. The connection string is in the `SqlConnectionString` setting in the `local.settings.json` file.

Add code that uses the output binding

Update `HttpExample\function_app.py` to match the following code. Add the `ToDoItems` parameter to the function definition and `ToDoItems.set()` under the `if name: __main__` statement:

Python

```
import azure.functions as func
import logging
from azure.functions.decorators.core import DataType
import uuid
```

```

app = func.FunctionApp()

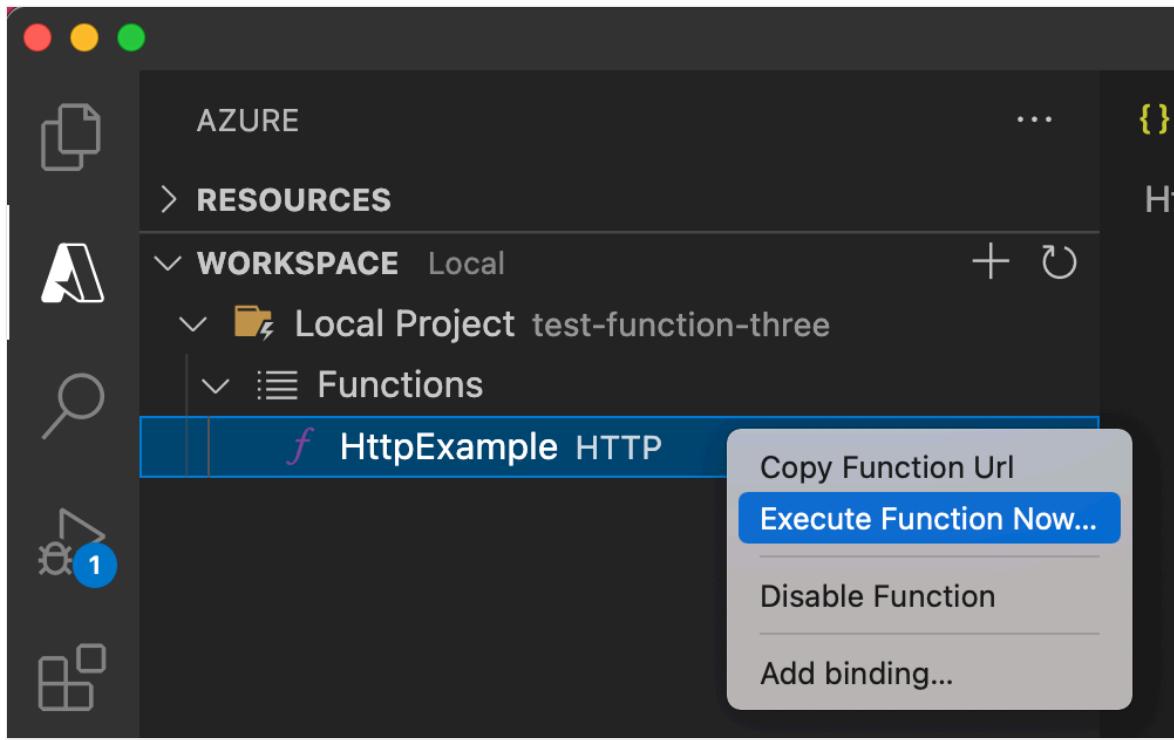

@app.function_name(name="HttpTrigger1")
@app.route(route="hello", auth_level=func.AuthLevel.ANONYMOUS)
@app.generic_output_binding(arg_name="ToDoItems", type="sql",
CommandText="dbo.ToDo",
ConnectionStringSetting="SqlConnectionString", data_type=DataType.STRING)
def test_function(req: func.HttpRequest, ToDoItems: func.Out[func.SqlRow]) -
> func.HttpResponse:
    logging.info('Python HTTP trigger function processed a request.')
    name = req.get_json().get('name')
    if not name:
        try:
            req_body = req.get_json()
        except ValueError:
            pass
    else:
        name = req_body.get('name')

    if name:
        ToDoItems.set(func.SqlRow({"Id": str(uuid.uuid4()), "title": name,
"completed": False, "url": ""}))
        return func.HttpResponse(f"Hello {name}!")
    else:
        return func.HttpResponse(
            "Please pass a name on the query string or in the
request body",
            status_code=400
        )

```

Run the function locally

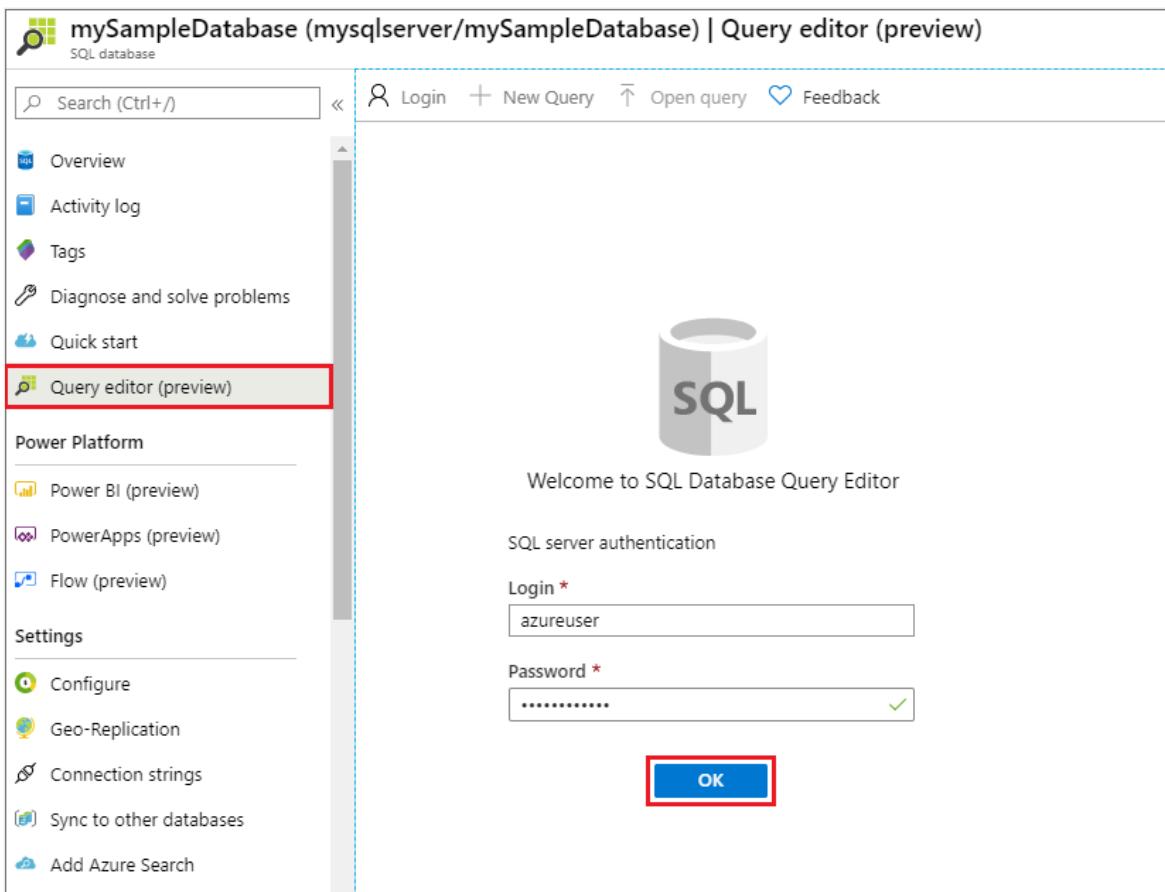

1. As in the previous article, press **F5** to start the function app project and Core Tools.
2. With Core Tools running, go to the **Azure: Functions** area. Under **Functions**, expand **Local Project > Functions**. Right-click (Ctrl-click on Mac) the **HttpExample** function and choose **Execute Function Now...**

3. In **Enter request body** you see the request message body value of `{ "name": "Azure" }`. Press Enter to send this request message to your function.
4. After a response is returned, press `Ctrl + C` to stop Core Tools.

Verify that information has been written to the database

1. On the Azure portal, go back to your Azure SQL Database and select **Query editor**.

2. Connect to your database and expand the **Tables** node in object explorer on the left. Right-click on the `dbo.ToDo` table and select **Select Top 1000 Rows**.
3. Verify that the new information has been written to the database by the output binding.

Redeploy and verify the updated app

1. In Visual Studio Code, press F1 to open the command palette. In the command palette, search for and select `Azure Functions: Deploy to function app....`.
2. Choose the function app that you created in the first article. Because you're redeploying your project to the same app, select **Deploy** to dismiss the warning about overwriting files.
3. After deployment completes, you can again use the **Execute Function Now...** feature to trigger the function in Azure.
4. Again [check the data written to your Azure SQL Database](#) to verify that the output binding again generates a new JSON document.

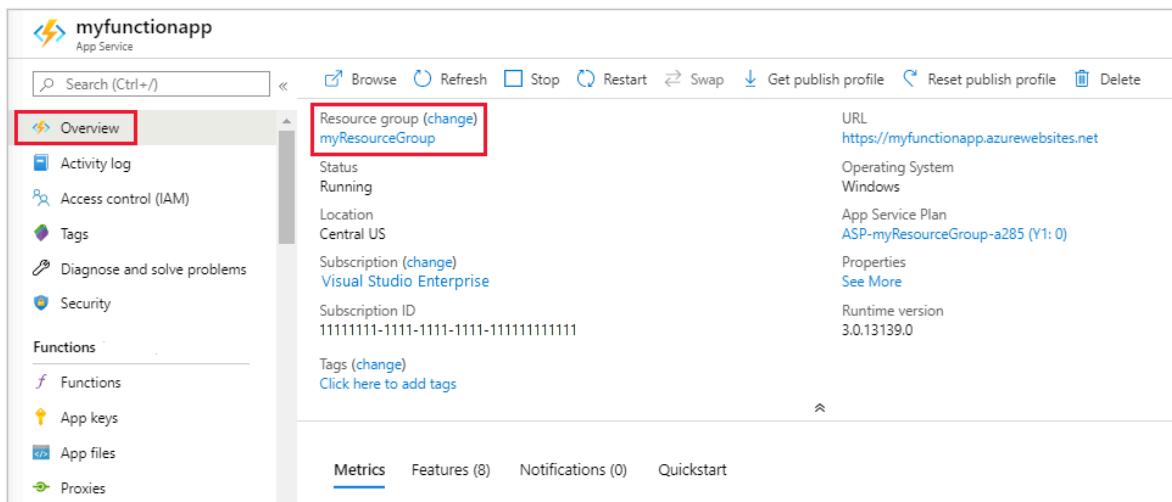

Clean up resources

In Azure, *resources* refer to function apps, functions, storage accounts, and so forth.

They're grouped into *resource groups*, and you can delete everything in a group by deleting the group.

You created resources to complete these quickstarts. You may be billed for these resources, depending on your [account status](#) and [service pricing](#). If you don't need the resources anymore, here's how to delete them:

1. In Visual Studio Code, press `F1` to open the command palette. In the command palette, search for and select `Azure: Open in portal`.
2. Choose your function app and press `Enter`. The function app page opens in the Azure portal.
3. In the **Overview** tab, select the named link next to **Resource group**.

4. On the **Resource group** page, review the list of included resources, and verify that they're the ones you want to delete.
5. Select **Delete resource group**, and follow the instructions.

Deletion may take a couple of minutes. When it's done, a notification appears for a few seconds. You can also select the bell icon at the top of the page to view the notification.

Next steps

You've updated your HTTP triggered function to write data to Azure SQL Database. Now you can learn more about developing Functions using Visual Studio Code:

Tutorial: Add Azure OpenAI text completion hints to your functions in Visual Studio Code

Article • 07/12/2024

This article shows you how to use Visual Studio Code to add an HTTP endpoint to the function app you created in the previous quickstart article. When triggered, this new HTTP endpoint uses an [Azure OpenAI text completion input binding](#) to get text completion hints from your data model.

During this tutorial, you learn how to accomplish these tasks:

- ✓ Create resources in Azure OpenAI.
- ✓ Deploy a model in OpenAI the resource.
- ✓ Set access permissions to the model resource.
- ✓ Enable your function app to connect to OpenAI.
- ✓ Add OpenAI bindings to your HTTP triggered function.

1. Check prerequisites

- Complete the steps in [part 1 of the Visual Studio Code quickstart](#).
- Obtain access to Azure OpenAI in your Azure subscription. If you haven't already been granted access, complete [this form](#) to request access.
- Install [.NET Core CLI tools](#).
- The [Azurite storage emulator](#). While you can also use an actual Azure Storage account, the article assumes you're using this emulator.

2. Create your Azure OpenAI resources

The following steps show how to create an Azure OpenAI data model in the Azure portal.

1. Sign in with your Azure subscription in the [Azure portal](#).
2. Select **Create a resource** and search for the **Azure OpenAI**. When you locate the service, select **Create**.

3. On the **Create Azure OpenAI** page, provide the following information for the fields on the **Basics** tab:

[] [Expand table](#)

Field	Description
Subscription	Your subscription, which has been onboarded to use Azure OpenAI.
Resource group	The resource group you created for the function app in the previous article. You can find this resource group name by right-clicking the function app in the Azure Resources browser, selecting properties, and then searching for the <code>resourceGroup</code> setting in the returned JSON resource file.
Region	Ideally, the same location as the function app.
Name	A descriptive name for your Azure OpenAI Service resource, such as <i>mySampleOpenAI</i> .
Pricing Tier	The pricing tier for the resource. Currently, only the Standard tier is available for the Azure OpenAI Service. For more info on pricing visit the Azure OpenAI pricing page ↗

Content review policy

To detect and mitigate harmful use of the Azure OpenAI Service, Microsoft logs the content you send to the Completions and image generations APIs as well as the content it sends back. If content is flagged by the service's filters, it may be reviewed by a Microsoft full-time employee.

[Learn more about how Microsoft processes, uses, and stores your data](#)

[Apply for modified content filters and abuse monitoring](#)

[Review the Azure OpenAI code of conduct](#)

[Previous](#)

[Next](#)

4. Select **Next** twice to accept the default values for both the **Network** and **Tags** tabs.

The service you create doesn't have any network restrictions, including from the internet.

5. Select **Next** a final time to move to the final stage in the process: **Review + submit**.

6. Confirm your configuration settings, and select **Create**.

The Azure portal displays a notification when the new resource is available. Select **Go to resource** in the notification or search for your new Azure OpenAI resource by name.

7. In the Azure OpenAI resource page for your new resource, select **Click here to view endpoints** under **Essentials > Endpoints**. Copy the **endpoint URL** and the **keys**. Save these values, you need them later.

Now that you have the credentials to connect to your model in Azure OpenAI, you need to set these access credentials in application settings.

3. Deploy a model

Now you can deploy a model. You can select from one of several available models in Azure OpenAI Studio.

To deploy a model, follow these steps:

1. Sign in to [Azure OpenAI Studio](#).
2. Choose the subscription and the Azure OpenAI resource you created, and select **Use resource**.
3. Under **Management** select **Deployments**.
4. Select **Create new deployment** and configure the following fields:

[] [Expand table](#)

Field	Description
Deployment name	Choose a name carefully. The deployment name is used in your code to call the model by using the client libraries and the REST APIs, so you must save for use later on.
Select a model	Model availability varies by region. For a list of available models per region, see Model summary table and region availability .

i Important

When you access the model via the API, you need to refer to the deployment name rather than the underlying model name in API calls, which is one of the key differences between OpenAI and Azure OpenAI. OpenAI only requires the model name. Azure OpenAI always requires deployment name, even when using the model parameter. In our docs, we often have examples where deployment names are represented as identical to model names to help indicate which model works with a particular API endpoint. Ultimately your

deployment names can follow whatever naming convention is best for your use case.

5. Accept the default values for the rest of the setting and select **Create**.

The deployments table shows a new entry that corresponds to your newly created model.

You now have everything you need to add Azure OpenAI-based text completion to your function app.

4. Update application settings

1. In Visual Studio Code, open the local code project you created when you completed the [previous article](#).
2. In the local.settings.json file in the project root folder, update the `AzureWebJobsStorage` setting to `UseDevelopmentStorage=true`. You can skip this step if the `AzureWebJobsStorage` setting in *local.settings.json* is set to the connection string for an existing Azure Storage account instead of `UseDevelopmentStorage=true`.
3. In the local.settings.json file, add these settings values:
 - `AZURE_OPENAI_ENDPOINT`: required by the binding extension. Set this value to the endpoint of the Azure OpenAI resource you created earlier.
 - `AZURE_OPENAI_KEY`: required by the binding extension. Set this value to the key for the Azure OpenAI resource.
 - `CHAT_MODEL_DEPLOYMENT_NAME`: used to define the input binding. Set this value to the name you chose for your model deployment.
4. Save the file. When you deploy to Azure, you must also add these settings to your function app.

5. Register binding extensions

Because you're using an Azure OpenAI output binding, you must have the corresponding bindings extension installed before you run the project.

Except for HTTP and timer triggers, bindings are implemented as extension packages. To add the Azure OpenAI extension package to your project, run this [dotnet add package](#) command in the **Terminal** window:

Bash

```
dotnet add package Microsoft.Azure.Functions.Worker.Extensions.OpenAI --  
prerelease
```

Now, you can use the Azure OpenAI output binding in your project.

6. Return text completion from the model

The code you add creates a `whois` HTTP function endpoint in your existing project. In this function, data passed in a URL `name` parameter of a GET request is used to dynamically create a completion prompt. This dynamic prompt is bound to a text completion input binding, which returns a response from the model based on the prompt. The completion from the model is returned in the HTTP response.

1. In your existing `HttpExample` class file, add this `using` statement:

C#

```
using  
Microsoft.Azure.Functions.Worker.Extensions.OpenAI.TextCompletion;
```

2. In the same file, add this code that defines a new HTTP trigger endpoint named `whois`:

C#

```
[Function(nameof(WhoIs))]  
public IActionResult WhoIs([HttpTrigger(AuthorizationLevel.Function,  
Route = "whois/{name}")] HttpRequest req,  
[TextCompletionInput("Who is {name}?", Model =  
"%CHAT_MODEL_DEPLOYMENT_NAME%")] TextCompletionResponse response)  
{  
    if(!String.IsNullOrEmpty(response.Content))  
    {  
        return new OkObjectResult(response.Content);  
    }  
    else  
    {  
        return new NotFoundObjectResult("Something went wrong.");  
    }  
}
```

7. Run the function

1. In Visual Studio Code, Press F1 and in the command palette type `Azurite: Start` and press Enter to start the Azurite storage emulator.
2. Press `F5` to start the function app project and Core Tools in debug mode.
3. With the Core Tools running, send a GET request to the `whois` endpoint function, with a name in the path, like this URL:

```
http://localhost:7071/api/whois/<NAME>
```

Replace the `<NAME>` string with the value you want passed to the `"Who is {name}?"` prompt. The `<NAME>` must be the URL-encoded name of a public figure, like `Abraham%20Lincoln`.

The response you see is the text completion response from your Azure OpenAI model.

4. After a response is returned, press `Ctrl + C` to stop Core Tools.

8. Clean up resources

In Azure, *resources* refer to function apps, functions, storage accounts, and so forth. They're grouped into *resource groups*, and you can delete everything in a group by deleting the group.

You created resources to complete these quickstarts. You could be billed for these resources, depending on your [account status](#) and [service pricing](#). If you don't need the resources anymore, here's how to delete them:

1. In Visual Studio Code, press `F1` to open the command palette. In the command palette, search for and select `Azure: Open in portal`.
2. Choose your function app and press `Enter`. The function app page opens in the Azure portal.
3. In the **Overview** tab, select the named link next to **Resource group**.

The screenshot shows the Azure portal interface for an App Service named 'myfunctionapp'. The left sidebar has a 'Functions' section with 'Overview', 'Activity log', 'Access control (IAM)', 'Tags', 'Diagnose and solve problems', and 'Security'. Below that is another 'Functions' section with 'Functions', 'App keys', 'App files', and 'Proxies'. The main pane shows the 'Overview' tab for a resource group named 'myResourceGroup'. The resource group details include: Status (Running), Location (Central US), Subscription (Visual Studio Enterprise), Subscription ID (11111111-1111-1111-1111-111111111111), and Tags (Click here to add tags). At the bottom of the main pane are tabs for Metrics, Features (8), Notifications (0), and Quickstart.

4. On the **Resource group** page, review the list of included resources, and verify that they're the ones you want to delete.

5. Select **Delete resource group**, and follow the instructions.

Deletion may take a couple of minutes. When it's done, a notification appears for a few seconds. You can also select the bell icon at the top of the page to view the notification.

Tutorial: Add Azure OpenAI text completion hints to your functions in Visual Studio Code

Article • 07/12/2024

This article shows you how to use Visual Studio Code to add an HTTP endpoint to the function app you created in the previous quickstart article. When triggered, this new HTTP endpoint uses an [Azure OpenAI text completion input binding](#) to get text completion hints from your data model.

During this tutorial, you learn how to accomplish these tasks:

- ✓ Create resources in Azure OpenAI.
- ✓ Deploy a model in OpenAI the resource.
- ✓ Set access permissions to the model resource.
- ✓ Enable your function app to connect to OpenAI.
- ✓ Add OpenAI bindings to your HTTP triggered function.

1. Check prerequisites

- Complete the steps in [part 1 of the Visual Studio Code quickstart](#).
- Obtain access to Azure OpenAI in your Azure subscription. If you haven't already been granted access, complete [this form](#) to request access.
- The [Azurite storage emulator](#). While you can also use an actual Azure Storage account, the article assumes you're using this emulator.

2. Create your Azure OpenAI resources

The following steps show how to create an Azure OpenAI data model in the Azure portal.

1. Sign in with your Azure subscription in the [Azure portal](#).
2. Select **Create a resource** and search for the **Azure OpenAI**. When you locate the service, select **Create**.
3. On the **Create Azure OpenAI** page, provide the following information for the fields on the **Basics** tab:

[+] [Expand table](#)

Field	Description
Subscription	Your subscription, which has been onboarded to use Azure OpenAI.
Resource group	The resource group you created for the function app in the previous article. You can find this resource group name by right-clicking the function app in the Azure Resources browser, selecting properties, and then searching for the <code>resourceGroup</code> setting in the returned JSON resource file.
Region	Ideally, the same location as the function app.
Name	A descriptive name for your Azure OpenAI Service resource, such as <i>mySampleOpenAI</i> .
Pricing Tier	The pricing tier for the resource. Currently, only the Standard tier is available for the Azure OpenAI Service. For more info on pricing visit the Azure OpenAI pricing page ↗

4. Select **Next** twice to accept the default values for both the **Network** and **Tags** tabs.

The service you create doesn't have any network restrictions, including from the internet.

5. Select **Next** a final time to move to the final stage in the process: **Review + submit**.

6. Confirm your configuration settings, and select **Create**.

The Azure portal displays a notification when the new resource is available. Select **Go to resource** in the notification or search for your new Azure OpenAI resource by name.

7. In the Azure OpenAI resource page for your new resource, select **Click here to view endpoints** under **Essentials > Endpoints**. Copy the **endpoint URL** and the **keys**. Save these values, you need them later.

Now that you have the credentials to connect to your model in Azure OpenAI, you need to set these access credentials in application settings.

3. Deploy a model

Now you can deploy a model. You can select from one of several available models in Azure OpenAI Studio.

To deploy a model, follow these steps:

1. Sign in to [Azure OpenAI Studio](#).
2. Choose the subscription and the Azure OpenAI resource you created, and select **Use resource**.
3. Under **Management** select **Deployments**.
4. Select **Create new deployment** and configure the following fields:

[] [Expand table](#)

Field	Description
Deployment name	Choose a name carefully. The deployment name is used in your code to call the model by using the client libraries and the REST APIs, so you must save for use later on.
Select a model	Model availability varies by region. For a list of available models per region, see Model summary table and region availability .

i Important

When you access the model via the API, you need to refer to the deployment name rather than the underlying model name in API calls, which is one of the key differences between OpenAI and Azure OpenAI. OpenAI only requires the model name. Azure OpenAI always requires deployment name, even when using the model parameter. In our docs, we often have examples where deployment names are represented as identical to model names to help indicate which model works with a particular API endpoint. Ultimately your

deployment names can follow whatever naming convention is best for your use case.

- Accept the default values for the rest of the setting and select **Create**.

The deployments table shows a new entry that corresponds to your newly created model.

You now have everything you need to add Azure OpenAI-based text completion to your function app.

4. Update application settings

- In Visual Studio Code, open the local code project you created when you completed the [previous article](#).
- In the `local.settings.json` file in the project root folder, update the `AzureWebJobsStorage` setting to `UseDevelopmentStorage=true`. You can skip this step if the `AzureWebJobsStorage` setting in `local.settings.json` is set to the connection string for an existing Azure Storage account instead of `UseDevelopmentStorage=true`.
- In the `local.settings.json` file, add these settings values:
 - `AZURE_OPENAI_ENDPOINT`: required by the binding extension. Set this value to the endpoint of the Azure OpenAI resource you created earlier.
 - `AZURE_OPENAI_KEY`: required by the binding extension. Set this value to the key for the Azure OpenAI resource.
 - `CHAT_MODEL_DEPLOYMENT_NAME`: used to define the input binding. Set this value to the name you chose for your model deployment.
- Save the file. When you deploy to Azure, you must also add these settings to your function app.

5. Update the extension bundle

To access the preview Azure OpenAI bindings, you must use a preview version of the extension bundle that contains this extension.

Replace the `extensionBundle` setting in your current `host.json` file with this JSON:

JSON

```
"extensionBundle": {  
    "id": "Microsoft.Azure.Functions.ExtensionBundle.Preview",  
    "version": "[4.*, 5.0.0)"  
}
```

Now, you can use the Azure OpenAI output binding in your project.

6. Return text completion from the model

The code you add creates a `whois` HTTP function endpoint in your existing project. In this function, data passed in a URL `name` parameter of a GET request is used to dynamically create a completion prompt. This dynamic prompt is bound to a text completion input binding, which returns a response from the model based on the prompt. The completion from the model is returned in the HTTP response.

1. Update the `pom.xml` project file to add this reference to the `properties` collection:

XML

```
<azure-functions-java-library-openai>0.3.0-preview</azure-functions-  
java-library-openai>
```

2. In the same file, add this dependency to the `dependencies` collection:

XML

```
<dependency>  
    <groupId>com.microsoft.azure.functions</groupId>  
    <artifactId>azure-functions-java-library-openai</artifactId>  
    <version>${azure-functions-java-library-openai}</version>  
</dependency>
```

3. In the existing `Function.java` project file, add these `import` statements:

Java

```
import  
com.microsoft.azure.functions.openai.annotation.textcompletion.TextComp  
letion;  
import  
com.microsoft.azure.functions.openai.annotation.textcompletion.TextComp  
letionResponse;
```

4. In the same file, add this code that defines a new HTTP trigger endpoint named

`whois`:

```
Java

@FunctionName("WhoIs")
public HttpResponseMessage whoIs(
    @HttpTrigger(
        name = "req",
        methods = {HttpMethod.GET},
        authLevel = AuthorizationLevel.ANONYMOUS,
        route = "whois/{name}")
    HttpRequestMessage<Optional<String>> request,
    @BindingName("name") String name,
    @TextCompletion(prompt = "Who is {name}?", model =
"%CHAT_MODEL_DEPLOYMENT_NAME%", name = "response")
    TextCompletionResponse response,
    final ExecutionContext context) {
    return request.createResponseBuilder(HttpStatus.OK)
        .header("Content-Type", "application/json")
        .body(response.getContent())
        .build();
}
```

7. Run the function

1. In Visual Studio Code, Press F1 and in the command palette type `Azurite: Start` and press Enter to start the Azurite storage emulator.

2. Press `F5` to start the function app project and Core Tools in debug mode.

3. With the Core Tools running, send a GET request to the `whois` endpoint function, with a name in the path, like this URL:

`http://localhost:7071/api/whois/<NAME>`

Replace the `<NAME>` string with the value you want passed to the `"Who is {name}?"` prompt. The `<NAME>` must be the URL-encoded name of a public figure, like `Abraham%20Lincoln`.

The response you see is the text completion response from your Azure OpenAI model.

4. After a response is returned, press `Ctrl + C` to stop Core Tools.

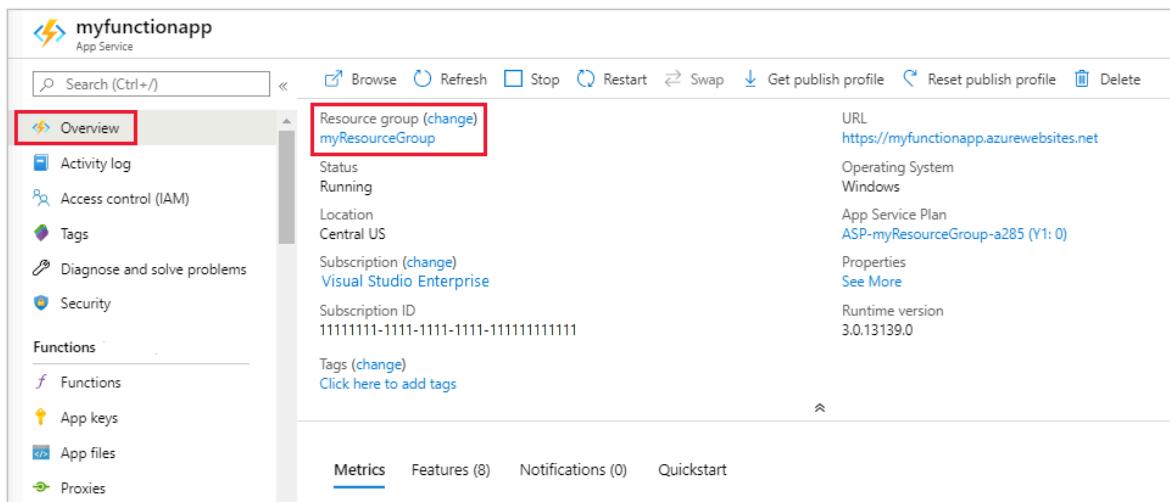

8. Clean up resources

In Azure, *resources* refer to function apps, functions, storage accounts, and so forth.

They're grouped into *resource groups*, and you can delete everything in a group by deleting the group.

You created resources to complete these quickstarts. You could be billed for these resources, depending on your [account status](#) and [service pricing](#). If you don't need the resources anymore, here's how to delete them:

1. In Visual Studio Code, press `F1` to open the command palette. In the command palette, search for and select `Azure: Open in portal`.
2. Choose your function app and press `Enter`. The function app page opens in the Azure portal.
3. In the **Overview** tab, select the named link next to **Resource group**.

4. On the **Resource group** page, review the list of included resources, and verify that they're the ones you want to delete.
5. Select **Delete resource group**, and follow the instructions.

Deletion may take a couple of minutes. When it's done, a notification appears for a few seconds. You can also select the bell icon at the top of the page to view the notification.

Now that you have the credentials to connect to your model in Azure OpenAI, you need to set these access credentials in application settings.

3. Deploy a model

Now you can deploy a model. You can select from one of several available models in Azure OpenAI Studio.

To deploy a model, follow these steps:

1. Sign in to [Azure OpenAI Studio](#).
2. Choose the subscription and the Azure OpenAI resource you created, and select **Use resource**.
3. Under **Management** select **Deployments**.
4. Select **Create new deployment** and configure the following fields:

[] [Expand table](#)

Field	Description
Deployment name	Choose a name carefully. The deployment name is used in your code to call the model by using the client libraries and the REST APIs, so you must save for use later on.
Select a model	Model availability varies by region. For a list of available models per region, see Model summary table and region availability .

i Important

When you access the model via the API, you need to refer to the deployment name rather than the underlying model name in API calls, which is one of the key differences between OpenAI and Azure OpenAI. OpenAI only requires the model name. Azure OpenAI always requires deployment name, even when using the model parameter. In our docs, we often have examples where deployment names are represented as identical to model names to help indicate which model works with a particular API endpoint. Ultimately your

deployment names can follow whatever naming convention is best for your use case.

- Accept the default values for the rest of the setting and select **Create**.

The deployments table shows a new entry that corresponds to your newly created model.

You now have everything you need to add Azure OpenAI-based text completion to your function app.

4. Update application settings

- In Visual Studio Code, open the local code project you created when you completed the [previous article](#).
- In the `local.settings.json` file in the project root folder, update the `AzureWebJobsStorage` setting to `UseDevelopmentStorage=true`. You can skip this step if the `AzureWebJobsStorage` setting in `local.settings.json` is set to the connection string for an existing Azure Storage account instead of `UseDevelopmentStorage=true`.
- In the `local.settings.json` file, add these settings values:
 - `AZURE_OPENAI_ENDPOINT`: required by the binding extension. Set this value to the endpoint of the Azure OpenAI resource you created earlier.
 - `AZURE_OPENAI_KEY`: required by the binding extension. Set this value to the key for the Azure OpenAI resource.
 - `CHAT_MODEL_DEPLOYMENT_NAME`: used to define the input binding. Set this value to the name you chose for your model deployment.
- Save the file. When you deploy to Azure, you must also add these settings to your function app.

5. Update the extension bundle

To access the preview Azure OpenAI bindings, you must use a preview version of the extension bundle that contains this extension.

Replace the `extensionBundle` setting in your current `host.json` file with this JSON:

JSON

```
"extensionBundle": {  
  "id": "Microsoft.Azure.Functions.ExtensionBundle.Preview",  
  "version": "[4.*, 5.0.0)"  
}
```

Now, you can use the Azure OpenAI output binding in your project.

6. Return text completion from the model

The code you add creates a `whois` HTTP function endpoint in your existing project. In this function, data passed in a URL `name` parameter of a GET request is used to dynamically create a completion prompt. This dynamic prompt is bound to a text completion input binding, which returns a response from the model based on the prompt. The completion from the model is returned in the HTTP response.

1. In Visual Studio Code, Press F1 and in the command palette type `Azure Functions: Create Function...`, select **HTTP trigger**, type the function name `whois`, and press Enter.
2. In the new `whois.js` code file, replace the contents of the file with this code:

```
JavaScript  
  
const { app, input } = require("@azure/functions");  
  
// This OpenAI completion input requires a {name} binding value.  
const openAICompletionInput = input.generic({  
  prompt: 'Who is {name}?',  
  maxTokens: '100',  
  type: 'textCompletion',  
  model: '%CHAT_MODEL_DEPLOYMENT_NAME%'  
})  
  
app.http('whois', {  
  methods: ['GET'],  
  route: 'whois/{name}',  
  authLevel: 'function',  
  extraInputs: [openAICompletionInput],  
  handler: async (_request, context) => {  
    var response = context.extraInputs.get(openAICompletionInput)  
    return { body: response.content.trim() }  
  }  
});
```

7. Run the function

1. In Visual Studio Code, Press F1 and in the command palette type `Azurite: Start` and press Enter to start the Azurite storage emulator.
2. Press `F5` to start the function app project and Core Tools in debug mode.
3. With the Core Tools running, send a GET request to the `whois` endpoint function, with a name in the path, like this URL:

```
http://localhost:7071/api/whois/<NAME>
```

Replace the `<NAME>` string with the value you want passed to the `"Who is {name}?"` prompt. The `<NAME>` must be the URL-encoded name of a public figure, like `Abraham%20Lincoln`.

The response you see is the text completion response from your Azure OpenAI model.

4. After a response is returned, press `Ctrl + C` to stop Core Tools.

8. Clean up resources

In Azure, *resources* refer to function apps, functions, storage accounts, and so forth. They're grouped into *resource groups*, and you can delete everything in a group by deleting the group.

You created resources to complete these quickstarts. You could be billed for these resources, depending on your [account status](#) and [service pricing](#). If you don't need the resources anymore, here's how to delete them:

1. In Visual Studio Code, press `F1` to open the command palette. In the command palette, search for and select `Azure: Open in portal`.
2. Choose your function app and press `Enter`. The function app page opens in the Azure portal.
3. In the **Overview** tab, select the named link next to **Resource group**.

The screenshot shows the Azure portal's Overview page for a resource group. The left sidebar has a red box around the 'Overview' tab. The main content area has a red box around the 'myResourceGroup' resource card. Resource details shown include status, location, subscription, tags, and various service properties.

4. On the **Resource group** page, review the list of included resources, and verify that they're the ones you want to delete.

5. Select **Delete resource group**, and follow the instructions.

Deletion may take a couple of minutes. When it's done, a notification appears for a few seconds. You can also select the bell icon at the top of the page to view the notification.

Tutorial: Add Azure OpenAI text completion hints to your functions in Visual Studio Code

Article • 07/12/2024

This article shows you how to use Visual Studio Code to add an HTTP endpoint to the function app you created in the previous quickstart article. When triggered, this new HTTP endpoint uses an [Azure OpenAI text completion input binding](#) to get text completion hints from your data model.

During this tutorial, you learn how to accomplish these tasks:

- ✓ Create resources in Azure OpenAI.
- ✓ Deploy a model in OpenAI the resource.
- ✓ Set access permissions to the model resource.
- ✓ Enable your function app to connect to OpenAI.
- ✓ Add OpenAI bindings to your HTTP triggered function.

1. Check prerequisites

- Complete the steps in [part 1 of the Visual Studio Code quickstart](#).
- Obtain access to Azure OpenAI in your Azure subscription. If you haven't already been granted access, complete [this form](#) to request access.
- The [Azurite storage emulator](#). While you can also use an actual Azure Storage account, the article assumes you're using this emulator.

2. Create your Azure OpenAI resources

The following steps show how to create an Azure OpenAI data model in the Azure portal.

1. Sign in with your Azure subscription in the [Azure portal](#).
2. Select **Create a resource** and search for the **Azure OpenAI**. When you locate the service, select **Create**.
3. On the **Create Azure OpenAI** page, provide the following information for the fields on the **Basics** tab:

[+] [Expand table](#)

Field	Description
Subscription	Your subscription, which has been onboarded to use Azure OpenAI.
Resource group	The resource group you created for the function app in the previous article. You can find this resource group name by right-clicking the function app in the Azure Resources browser, selecting properties, and then searching for the <code>resourceGroup</code> setting in the returned JSON resource file.
Region	Ideally, the same location as the function app.
Name	A descriptive name for your Azure OpenAI Service resource, such as <i>mySampleOpenAI</i> .
Pricing Tier	The pricing tier for the resource. Currently, only the Standard tier is available for the Azure OpenAI Service. For more info on pricing visit the Azure OpenAI pricing page ↗

Content review policy

To detect and mitigate harmful use of the Azure OpenAI Service, Microsoft logs the content you send to the Completions and image generations APIs as well as the content it sends back. If content is flagged by the service's filters, it may be reviewed by a Microsoft full-time employee.

[Learn more about how Microsoft processes, uses, and stores your data](#)

[Apply for modified content filters and abuse monitoring](#)

[Review the Azure OpenAI code of conduct](#)

[Previous](#)

[Next](#)

4. Select **Next** twice to accept the default values for both the **Network** and **Tags** tabs.

The service you create doesn't have any network restrictions, including from the internet.

5. Select **Next** a final time to move to the final stage in the process: **Review + submit**.

6. Confirm your configuration settings, and select **Create**.

The Azure portal displays a notification when the new resource is available. Select **Go to resource** in the notification or search for your new Azure OpenAI resource by name.

7. In the Azure OpenAI resource page for your new resource, select **Click here to view endpoints** under **Essentials > Endpoints**. Copy the **endpoint URL** and the **keys**. Save these values, you need them later.

Now that you have the credentials to connect to your model in Azure OpenAI, you need to set these access credentials in application settings.

3. Deploy a model

Now you can deploy a model. You can select from one of several available models in Azure OpenAI Studio.

To deploy a model, follow these steps:

1. Sign in to [Azure OpenAI Studio](#).
2. Choose the subscription and the Azure OpenAI resource you created, and select **Use resource**.
3. Under **Management** select **Deployments**.
4. Select **Create new deployment** and configure the following fields:

[] [Expand table](#)

Field	Description
Deployment name	Choose a name carefully. The deployment name is used in your code to call the model by using the client libraries and the REST APIs, so you must save for use later on.
Select a model	Model availability varies by region. For a list of available models per region, see Model summary table and region availability .

i Important

When you access the model via the API, you need to refer to the deployment name rather than the underlying model name in API calls, which is one of the key differences between OpenAI and Azure OpenAI. OpenAI only requires the model name. Azure OpenAI always requires deployment name, even when using the model parameter. In our docs, we often have examples where deployment names are represented as identical to model names to help indicate which model works with a particular API endpoint. Ultimately your

deployment names can follow whatever naming convention is best for your use case.

- Accept the default values for the rest of the setting and select **Create**.

The deployments table shows a new entry that corresponds to your newly created model.

You now have everything you need to add Azure OpenAI-based text completion to your function app.

4. Update application settings

- In Visual Studio Code, open the local code project you created when you completed the [previous article](#).
- In the `local.settings.json` file in the project root folder, update the `AzureWebJobsStorage` setting to `UseDevelopmentStorage=true`. You can skip this step if the `AzureWebJobsStorage` setting in `local.settings.json` is set to the connection string for an existing Azure Storage account instead of `UseDevelopmentStorage=true`.
- In the `local.settings.json` file, add these settings values:
 - `AZURE_OPENAI_ENDPOINT`: required by the binding extension. Set this value to the endpoint of the Azure OpenAI resource you created earlier.
 - `AZURE_OPENAI_KEY`: required by the binding extension. Set this value to the key for the Azure OpenAI resource.
 - `CHAT_MODEL_DEPLOYMENT_NAME`: used to define the input binding. Set this value to the name you chose for your model deployment.
- Save the file. When you deploy to Azure, you must also add these settings to your function app.

5. Update the extension bundle

To access the preview Azure OpenAI bindings, you must use a preview version of the extension bundle that contains this extension.

Replace the `extensionBundle` setting in your current `host.json` file with this JSON:

JSON

```
"extensionBundle": {  
  "id": "Microsoft.Azure.Functions.ExtensionBundle.Preview",  
  "version": "[4.*, 5.0.0)"  
}
```

Now, you can use the Azure OpenAI output binding in your project.

6. Return text completion from the model

The code you add creates a `whois` HTTP function endpoint in your existing project. In this function, data passed in a URL `name` parameter of a GET request is used to dynamically create a completion prompt. This dynamic prompt is bound to a text completion input binding, which returns a response from the model based on the prompt. The completion from the model is returned in the HTTP response.

1. In Visual Studio Code, Press F1 and in the command palette type `Azure Functions: Create Function...`, select **HTTP trigger**, type the function name `whois`, select **Anonymous**, and press Enter.
2. Open the new `whois/function.json` code file and replace its contents with this code, which adds a definition for the `TextCompletionResponse` input binding:

```
JSON  
  
{  
  "bindings": [  
    {  
      "authLevel": "function",  
      "type": "httpTrigger",  
      "direction": "in",  
      "name": "Request",  
      "route": "whois/{name}",  
      "methods": [  
        "get"  
      ]  
    },  
    {  
      "type": "http",  
      "direction": "out",  
      "name": "Response"  
    },  
    {  
      "type": "textCompletion",  
      "direction": "in",  
      "name": "TextCompletionResponse",  
      "prompt": "Who is {name}?",  
      "maxTokens": "100",  
      "model": "text-davinci-003"  
    }  
  ]  
}
```

```
        "model": "%CHAT_MODEL_DEPLOYMENT_NAME%"  
    }  
}  
}
```

3. Replace the content of the `whois/run.ps1` code file with this code, which returns the input binding response:

PowerShell

```
using namespace System.Net  
  
param($Request, $TriggerMetadata, $TextCompletionResponse)  
  
Push-OutputBinding -Name Response -Value ([HttpResponseContext]@{  
    StatusCode = [HttpStatusCode]::OK  
    Body      = $TextCompletionResponse.Content  
})
```

7. Run the function

1. In Visual Studio Code, Press F1 and in the command palette type `Azurite: Start` and press Enter to start the Azurite storage emulator.
2. Press `F5` to start the function app project and Core Tools in debug mode.
3. With the Core Tools running, send a GET request to the `whois` endpoint function, with a name in the path, like this URL:

`http://localhost:7071/api/whois/<NAME>`

Replace the `<NAME>` string with the value you want passed to the `"Who is {name}?"` prompt. The `<NAME>` must be the URL-encoded name of a public figure, like `Abraham%20Lincoln`.

The response you see is the text completion response from your Azure OpenAI model.

4. After a response is returned, press `Ctrl + C` to stop Core Tools.

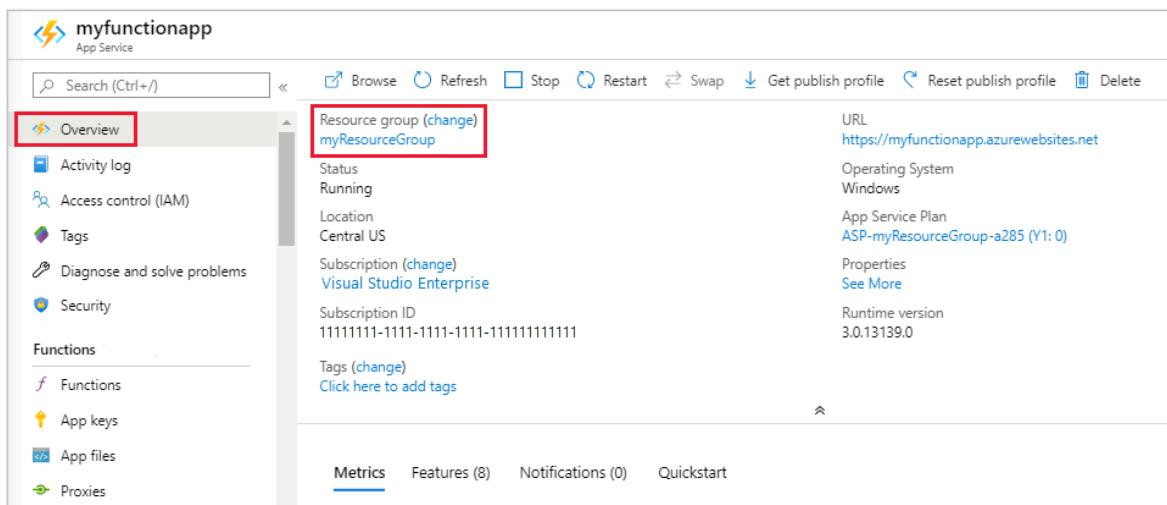

8. Clean up resources

In Azure, *resources* refer to function apps, functions, storage accounts, and so forth. They're grouped into *resource groups*, and you can delete everything in a group by

deleting the group.

You created resources to complete these quickstarts. You could be billed for these resources, depending on your [account status](#) and [service pricing](#). If you don't need the resources anymore, here's how to delete them:

1. In Visual Studio Code, press `F1` to open the command palette. In the command palette, search for and select `Azure: Open in portal`.
2. Choose your function app and press `Enter`. The function app page opens in the Azure portal.
3. In the **Overview** tab, select the named link next to **Resource group**.

4. On the **Resource group** page, review the list of included resources, and verify that they're the ones you want to delete.
5. Select **Delete resource group**, and follow the instructions.

Deletion may take a couple of minutes. When it's done, a notification appears for a few seconds. You can also select the bell icon at the top of the page to view the notification.

Tutorial: Add Azure OpenAI text completion hints to your functions in Visual Studio Code

Article • 07/12/2024

This article shows you how to use Visual Studio Code to add an HTTP endpoint to the function app you created in the previous quickstart article. When triggered, this new HTTP endpoint uses an [Azure OpenAI text completion input binding](#) to get text completion hints from your data model.

During this tutorial, you learn how to accomplish these tasks:

- ✓ Create resources in Azure OpenAI.
- ✓ Deploy a model in OpenAI the resource.
- ✓ Set access permissions to the model resource.
- ✓ Enable your function app to connect to OpenAI.
- ✓ Add OpenAI bindings to your HTTP triggered function.

1. Check prerequisites

- Complete the steps in [part 1 of the Visual Studio Code quickstart](#).
- Obtain access to Azure OpenAI in your Azure subscription. If you haven't already been granted access, complete [this form](#) to request access.
- The [Azurite storage emulator](#). While you can also use an actual Azure Storage account, the article assumes you're using this emulator.

2. Create your Azure OpenAI resources

The following steps show how to create an Azure OpenAI data model in the Azure portal.

1. Sign in with your Azure subscription in the [Azure portal](#).
2. Select **Create a resource** and search for the **Azure OpenAI**. When you locate the service, select **Create**.
3. On the **Create Azure OpenAI** page, provide the following information for the fields on the **Basics** tab:

[+] [Expand table](#)

Field	Description
Subscription	Your subscription, which has been onboarded to use Azure OpenAI.
Resource group	The resource group you created for the function app in the previous article. You can find this resource group name by right-clicking the function app in the Azure Resources browser, selecting properties, and then searching for the <code>resourceGroup</code> setting in the returned JSON resource file.
Region	Ideally, the same location as the function app.
Name	A descriptive name for your Azure OpenAI Service resource, such as <i>mySampleOpenAI</i> .
Pricing Tier	The pricing tier for the resource. Currently, only the Standard tier is available for the Azure OpenAI Service. For more info on pricing visit the Azure OpenAI pricing page ↗

Now that you have the credentials to connect to your model in Azure OpenAI, you need to set these access credentials in application settings.

3. Deploy a model

Now you can deploy a model. You can select from one of several available models in Azure OpenAI Studio.

To deploy a model, follow these steps:

1. Sign in to [Azure OpenAI Studio](#).
2. Choose the subscription and the Azure OpenAI resource you created, and select **Use resource**.
3. Under **Management** select **Deployments**.
4. Select **Create new deployment** and configure the following fields:

[] [Expand table](#)

Field	Description
Deployment name	Choose a name carefully. The deployment name is used in your code to call the model by using the client libraries and the REST APIs, so you must save for use later on.
Select a model	Model availability varies by region. For a list of available models per region, see Model summary table and region availability .

i Important

When you access the model via the API, you need to refer to the deployment name rather than the underlying model name in API calls, which is one of the key differences between OpenAI and Azure OpenAI. OpenAI only requires the model name. Azure OpenAI always requires deployment name, even when using the model parameter. In our docs, we often have examples where deployment names are represented as identical to model names to help indicate which model works with a particular API endpoint. Ultimately your

deployment names can follow whatever naming convention is best for your use case.

- Accept the default values for the rest of the setting and select **Create**.

The deployments table shows a new entry that corresponds to your newly created model.

You now have everything you need to add Azure OpenAI-based text completion to your function app.

4. Update application settings

- In Visual Studio Code, open the local code project you created when you completed the [previous article](#).
- In the `local.settings.json` file in the project root folder, update the `AzureWebJobsStorage` setting to `UseDevelopmentStorage=true`. You can skip this step if the `AzureWebJobsStorage` setting in `local.settings.json` is set to the connection string for an existing Azure Storage account instead of `UseDevelopmentStorage=true`.
- In the `local.settings.json` file, add these settings values:
 - `AZURE_OPENAI_ENDPOINT`: required by the binding extension. Set this value to the endpoint of the Azure OpenAI resource you created earlier.
 - `AZURE_OPENAI_KEY`: required by the binding extension. Set this value to the key for the Azure OpenAI resource.
 - `CHAT_MODEL_DEPLOYMENT_NAME`: used to define the input binding. Set this value to the name you chose for your model deployment.
- Save the file. When you deploy to Azure, you must also add these settings to your function app.

5. Update the extension bundle

To access the preview Azure OpenAI bindings, you must use a preview version of the extension bundle that contains this extension.

Replace the `extensionBundle` setting in your current `host.json` file with this JSON:

JSON

```
"extensionBundle": {  
    "id": "Microsoft.Azure.Functions.ExtensionBundle.Preview",  
    "version": "[4.*, 5.0.0)"  
}
```

Now, you can use the Azure OpenAI output binding in your project.

6. Return text completion from the model

The code you add creates a `whois` HTTP function endpoint in your existing project. In this function, data passed in a URL `name` parameter of a GET request is used to dynamically create a completion prompt. This dynamic prompt is bound to a text completion input binding, which returns a response from the model based on the prompt. The completion from the model is returned in the HTTP response.

1. In the existing `function_app.py` project file, add this `import` statement:

Python

```
import json
```

2. In the same file, add this code that defines a new HTTP trigger endpoint named

`whois`:

Python

```
@app.route(route="whois/{name}", methods=["GET"])  
@app.text_completion_input(arg_name="response", prompt="Who is  
{name}?", max_tokens="100", model = "%CHAT_MODEL_DEPLOYMENT_NAME%")  
def whois(req: func.HttpRequest, response: str) -> func.HttpResponse:  
    response_json = json.loads(response)  
    return func.HttpResponse(response_json["content"], status_code=200)  
  
@app.route(route="genericcompletion", methods=["POST"])  
@app.text_completion_input(arg_name="response", prompt="{Prompt}",  
model = "%CHAT_MODEL_DEPLOYMENT_NAME%")  
def genericcompletion(req: func.HttpRequest, response: str) ->  
func.HttpResponse:  
    response_json = json.loads(response)  
    return func.HttpResponse(response_json["content"], status_code=200)
```

7. Run the function

1. In Visual Studio Code, Press F1 and in the command palette type `Azurite: Start` and press Enter to start the Azurite storage emulator.
2. Press `F5` to start the function app project and Core Tools in debug mode.
3. With the Core Tools running, send a GET request to the `whois` endpoint function, with a name in the path, like this URL:

```
http://localhost:7071/api/whois/<NAME>
```

Replace the `<NAME>` string with the value you want passed to the `"Who is {name}?"` prompt. The `<NAME>` must be the URL-encoded name of a public figure, like `Abraham%20Lincoln`.

The response you see is the text completion response from your Azure OpenAI model.

4. After a response is returned, press `Ctrl + C` to stop Core Tools.

8. Clean up resources

In Azure, *resources* refer to function apps, functions, storage accounts, and so forth. They're grouped into *resource groups*, and you can delete everything in a group by deleting the group.

You created resources to complete these quickstarts. You could be billed for these resources, depending on your [account status](#) and [service pricing](#). If you don't need the resources anymore, here's how to delete them:

1. In Visual Studio Code, press `F1` to open the command palette. In the command palette, search for and select `Azure: Open in portal`.
2. Choose your function app and press `Enter`. The function app page opens in the Azure portal.
3. In the **Overview** tab, select the named link next to **Resource group**.

The screenshot shows the Azure portal interface for an App Service named 'myfunctionapp'. The left sidebar has a 'Functions' section with 'Overview', 'Activity log', 'Access control (IAM)', 'Tags', 'Diagnose and solve problems', and 'Security'. Below that is another 'Functions' section with 'Functions', 'App keys', 'App files', and 'Proxies'. The main pane shows the 'Overview' tab for a resource group named 'myResourceGroup'. The resource group details include:

- Status: Running
- Location: Central US
- Subscription: Visual Studio Enterprise
- Subscription ID: 11111111-1111-1111-1111-111111111111
- Tags: Click here to add tags
- URL: <https://myfunctionapp.azurewebsites.net>
- Operating System: Windows
- App Service Plan: ASP-myResourceGroup-a285 (Y1: 0)
- Properties: See More
- Runtime version: 3.0.13139.0

At the bottom of the main pane are tabs for Metrics, Features (8), Notifications (0), and Quickstart.

4. On the **Resource group** page, review the list of included resources, and verify that they're the ones you want to delete.

5. Select **Delete resource group**, and follow the instructions.

Deletion may take a couple of minutes. When it's done, a notification appears for a few seconds. You can also select the bell icon at the top of the page to view the notification.

Tutorial: Add Azure OpenAI text completion hints to your functions in Visual Studio Code

Article • 07/12/2024

This article shows you how to use Visual Studio Code to add an HTTP endpoint to the function app you created in the previous quickstart article. When triggered, this new HTTP endpoint uses an [Azure OpenAI text completion input binding](#) to get text completion hints from your data model.

During this tutorial, you learn how to accomplish these tasks:

- ✓ Create resources in Azure OpenAI.
- ✓ Deploy a model in OpenAI the resource.
- ✓ Set access permissions to the model resource.
- ✓ Enable your function app to connect to OpenAI.
- ✓ Add OpenAI bindings to your HTTP triggered function.

1. Check prerequisites

- Complete the steps in [part 1 of the Visual Studio Code quickstart](#).
- Obtain access to Azure OpenAI in your Azure subscription. If you haven't already been granted access, complete [this form](#) to request access.
- The [Azurite storage emulator](#). While you can also use an actual Azure Storage account, the article assumes you're using this emulator.

2. Create your Azure OpenAI resources

The following steps show how to create an Azure OpenAI data model in the Azure portal.

1. Sign in with your Azure subscription in the [Azure portal](#).
2. Select **Create a resource** and search for the **Azure OpenAI**. When you locate the service, select **Create**.
3. On the **Create Azure OpenAI** page, provide the following information for the fields on the **Basics** tab:

[+] [Expand table](#)

Field	Description
Subscription	Your subscription, which has been onboarded to use Azure OpenAI.
Resource group	The resource group you created for the function app in the previous article. You can find this resource group name by right-clicking the function app in the Azure Resources browser, selecting properties, and then searching for the <code>resourceGroup</code> setting in the returned JSON resource file.
Region	Ideally, the same location as the function app.
Name	A descriptive name for your Azure OpenAI Service resource, such as <i>mySampleOpenAI</i> .
Pricing Tier	The pricing tier for the resource. Currently, only the Standard tier is available for the Azure OpenAI Service. For more info on pricing visit the Azure OpenAI pricing page ↗

Create Azure OpenAI

...

Content review policy

To detect and mitigate harmful use of the Azure OpenAI Service, Microsoft logs the content you send to the Completions and image generations APIs as well as the content it sends back. If content is flagged by the service's filters, it may be reviewed by a Microsoft full-time employee.

[Learn more about how Microsoft processes, uses, and stores your data](#)

[Apply for modified content filters and abuse monitoring](#)

[Review the Azure OpenAI code of conduct](#)

[Previous](#)

[Next](#)

4. Select **Next** twice to accept the default values for both the **Network** and **Tags** tabs.

The service you create doesn't have any network restrictions, including from the internet.

5. Select **Next** a final time to move to the final stage in the process: **Review + submit**.

6. Confirm your configuration settings, and select **Create**.

The Azure portal displays a notification when the new resource is available. Select **Go to resource** in the notification or search for your new Azure OpenAI resource by name.

7. In the Azure OpenAI resource page for your new resource, select **Click here to view endpoints** under **Essentials > Endpoints**. Copy the **endpoint URL** and the **keys**. Save these values, you need them later.

Now that you have the credentials to connect to your model in Azure OpenAI, you need to set these access credentials in application settings.

3. Deploy a model

Now you can deploy a model. You can select from one of several available models in Azure OpenAI Studio.

To deploy a model, follow these steps:

1. Sign in to [Azure OpenAI Studio](#).
2. Choose the subscription and the Azure OpenAI resource you created, and select **Use resource**.
3. Under **Management** select **Deployments**.
4. Select **Create new deployment** and configure the following fields:

[] [Expand table](#)

Field	Description
Deployment name	Choose a name carefully. The deployment name is used in your code to call the model by using the client libraries and the REST APIs, so you must save for use later on.
Select a model	Model availability varies by region. For a list of available models per region, see Model summary table and region availability .

i Important

When you access the model via the API, you need to refer to the deployment name rather than the underlying model name in API calls, which is one of the key differences between OpenAI and Azure OpenAI. OpenAI only requires the model name. Azure OpenAI always requires deployment name, even when using the model parameter. In our docs, we often have examples where deployment names are represented as identical to model names to help indicate which model works with a particular API endpoint. Ultimately your

deployment names can follow whatever naming convention is best for your use case.

- Accept the default values for the rest of the setting and select **Create**.

The deployments table shows a new entry that corresponds to your newly created model.

You now have everything you need to add Azure OpenAI-based text completion to your function app.

4. Update application settings

- In Visual Studio Code, open the local code project you created when you completed the [previous article](#).
- In the local.settings.json file in the project root folder, update the `AzureWebJobsStorage` setting to `UseDevelopmentStorage=true`. You can skip this step if the `AzureWebJobsStorage` setting in `local.settings.json` is set to the connection string for an existing Azure Storage account instead of `UseDevelopmentStorage=true`.
- In the local.settings.json file, add these settings values:
 - `AZURE_OPENAI_ENDPOINT`: required by the binding extension. Set this value to the endpoint of the Azure OpenAI resource you created earlier.
 - `AZURE_OPENAI_KEY`: required by the binding extension. Set this value to the key for the Azure OpenAI resource.
 - `CHAT_MODEL_DEPLOYMENT_NAME`: used to define the input binding. Set this value to the name you chose for your model deployment.
- Save the file. When you deploy to Azure, you must also add these settings to your function app.

5. Update the extension bundle

To access the preview Azure OpenAI bindings, you must use a preview version of the extension bundle that contains this extension.

Replace the `extensionBundle` setting in your current `host.json` file with this JSON:

JSON

```
"extensionBundle": {  
  "id": "Microsoft.Azure.Functions.ExtensionBundle.Preview",  
  "version": "[4.*, 5.0.0)"  
}
```

Now, you can use the Azure OpenAI output binding in your project.

6. Return text completion from the model

The code you add creates a `whois` HTTP function endpoint in your existing project. In this function, data passed in a URL `name` parameter of a GET request is used to dynamically create a completion prompt. This dynamic prompt is bound to a text completion input binding, which returns a response from the model based on the prompt. The completion from the model is returned in the HTTP response.

1. In Visual Studio Code, Press F1 and in the command palette type `Azure Functions: Create Function...`, select **HTTP trigger**, type the function name `whois`, and press Enter.
2. In the new `whois.ts` code file, replace the contents of the file with this code:

TypeScript

```
import { app, input } from "@azure/functions";  
  
// This OpenAI completion input requires a {name} binding value.  
const openAICompletionInput = input.generic({  
  prompt: 'Who is {name}?',  
  maxTokens: '100',  
  type: 'textCompletion',  
  model: '%CHAT_MODEL_DEPLOYMENT_NAME%'  
})  
  
app.http('whois', {  
  methods: ['GET'],  
  route: 'whois/{name}',  
  authLevel: 'function',  
  extraInputs: [openAICompletionInput],  
  handler: async (_request, context) => {  
    var response: any =  
    context.extraInputs.get(openAICompletionInput)  
    return { body: response.content.trim() }  
  }  
});
```

7. Run the function

1. In Visual Studio Code, Press F1 and in the command palette type `Azurite: Start` and press Enter to start the Azurite storage emulator.
2. Press `F5` to start the function app project and Core Tools in debug mode.
3. With the Core Tools running, send a GET request to the `whois` endpoint function, with a name in the path, like this URL:

```
http://localhost:7071/api/whois/<NAME>
```

Replace the `<NAME>` string with the value you want passed to the `"Who is {name}?"` prompt. The `<NAME>` must be the URL-encoded name of a public figure, like `Abraham%20Lincoln`.

The response you see is the text completion response from your Azure OpenAI model.

4. After a response is returned, press `Ctrl + C` to stop Core Tools.

8. Clean up resources

In Azure, *resources* refer to function apps, functions, storage accounts, and so forth. They're grouped into *resource groups*, and you can delete everything in a group by deleting the group.

You created resources to complete these quickstarts. You could be billed for these resources, depending on your [account status](#) and [service pricing](#). If you don't need the resources anymore, here's how to delete them:

1. In Visual Studio Code, press `F1` to open the command palette. In the command palette, search for and select `Azure: Open in portal`.
2. Choose your function app and press `Enter`. The function app page opens in the Azure portal.
3. In the **Overview** tab, select the named link next to **Resource group**.

The screenshot shows the Azure portal interface for an App Service named 'myfunctionapp'. The left sidebar has a 'Functions' section with 'Overview', 'Activity log', 'Access control (IAM)', 'Tags', 'Diagnose and solve problems', and 'Security'. Below that is another 'Functions' section with 'Functions', 'App keys', 'App files', and 'Proxies'. The main pane shows the 'Overview' tab for a resource group named 'myResourceGroup'. The details include:

- Status: Running
- Location: Central US
- Subscription: Visual Studio Enterprise
- Subscription ID: 11111111-1111-1111-1111-111111111111
- Tags: Click here to add tags
- URL: <https://myfunctionapp.azurewebsites.net>
- Operating System: Windows
- App Service Plan: ASP-myResourceGroup-a285 (Y1: 0)
- Properties: See More
- Runtime version: 3.0.13139.0

At the bottom, there are tabs for Metrics, Features (8), Notifications (0), and Quickstart.

4. On the **Resource group** page, review the list of included resources, and verify that they're the ones you want to delete.

5. Select **Delete resource group**, and follow the instructions.

Deletion may take a couple of minutes. When it's done, a notification appears for a few seconds. You can also select the bell icon at the top of the page to view the notification.

Tutorial: Create a function to integrate with Azure Logic Apps

Article • 08/09/2024

Azure Functions integrates with Azure Logic Apps in the Logic Apps Designer. This integration allows you use the computing power of Functions in orchestrations with other Azure and third-party services.

This tutorial shows you how to create a workflow to analyze X activity. As tweets are evaluated, the workflow sends notifications when positive sentiments are detected.

In this tutorial, you learn to:

- ✓ Create an Azure AI services API Resource.
- ✓ Create a function that categorizes tweet sentiment.
- ✓ Create a logic app that connects to X.
- ✓ Add sentiment detection to the logic app.
- ✓ Connect the logic app to the function.
- ✓ Send an email based on the response from the function.

Prerequisites

- An active [X](#) account.
- An [Outlook.com](#) account (for sending notifications).

ⓘ Note

If you want to use the Gmail connector, only G-Suite business accounts can use this connector without restrictions in logic apps. If you have a Gmail consumer account, you can use the Gmail connector with only specific Google-approved apps and services, or you can [create a Google client app to use for authentication in your Gmail connector](#).

For more information, see [Data security and privacy policies for Google connectors in Azure Logic Apps](#).

Create Text Analytics resource

The Azure AI services APIs are available in Azure as individual resources. Use the Text Analytics API to detect the sentiment of posted tweets.

1. Sign in to the [Azure portal](#).
2. Select **Create a resource** in the upper left-hand corner of the Azure portal.
3. Under *Categories*, select **AI + Machine Learning**
4. Under *Text Analytics*, select **Create**.
5. Enter the following values in the *Create Text Analytics* screen.

[\[+\] Expand table](#)

Setting	Value	Remarks
Subscription	Your Azure subscription name	
Resource group	Create a new resource group named tweet-sentiment-tutorial	Later, you delete this resource group to remove all the resources created during this tutorial.
Region	Select the region closest to you	
Name	TweetSentimentApp	
Pricing tier	Select Free F0	

6. Select **Review + create**.
7. Select **Create**.
8. Once the deployment is complete, select **Go to Resource**.

Get Text Analytics settings

With the Text Analytics resource created, you'll copy a few settings and set them aside for later use.

1. Select **Keys and Endpoint**.
2. Copy **Key 1** by clicking on the icon at the end of the input box.
3. Paste the value into a text editor.
4. Copy the **Endpoint** by clicking on the icon at the end of the input box.

5. Paste the value into a text editor.

Create the function app

1. From the top search box, search for and select **Function app**.

2. Select **Create**.

3. Enter the following values.

[] [Expand table](#)

Setting	Suggested Value	Remarks
Subscription	Your Azure subscription name	
Resource group	<code>tweet-sentiment-tutorial</code>	Use the same resource group name throughout this tutorial.
Function App name	<code>TweetSentimentAPI + a unique suffix</code>	Function application names are globally unique. Valid characters are <code>a-z</code> (case insensitive), <code>0-9</code> , and <code>-</code> .
Publish	Code	
Runtime stack	.NET	The function code provided for you is in C#.
Version	Select the latest version number	
Region	Select the region closest to you	

4. Select **Review + create**.

5. Select **Create**.

6. Once the deployment is complete, select **Go to Resource**.

Create an HTTP-triggered function

1. From the left menu of the *Functions* window, select **Functions**.

2. Select **Add** from the top menu and enter the following values.

Setting	Value	Remarks
Development environment	Develop in portal	
Template	HTTP Trigger	
New Function	TweetSentimentFunction	This is the name of your function.
Authorization level	Function	

3. Select the **Add** button.

4. Select the **Code + Test** button.

5. Paste the following code in the code editor window.

```
C#  
  
#r "Newtonsoft.Json"  
  
using System;  
using System.Net;  
using Microsoft.AspNetCore.Mvc;  
using Microsoft.Extensions.Logging;  
using Microsoft.Extensions.Primitives;  
using Newtonsoft.Json;  
  
public static async Task<IActionResult> Run(HttpContext req, ILogger log)  
{  
  
    string requestBody = String.Empty;  
    using (StreamReader streamReader = new StreamReader(req.Body))  
    {  
        requestBody = await streamReader.ReadToEndAsync();  
    }  
  
    dynamic score = JsonConvert.DeserializeObject(requestBody);  
    string value = "Positive";  
  
    if(score < .3)  
    {  
        value = "Negative";  
    }  
    else if (score < .6)  
    {  
        value = "Neutral";  
    }  
  
    return requestBody != null  
        ? (ActionResult)new OkObjectResult(value)
```

```
: new BadRequestObjectResult("Pass a sentiment score in the  
request body.");  
}
```

A sentiment score is passed into the function, which returns a category name for the value.

6. Select the **Save** button on the toolbar to save your changes.

ⓘ Note

To test the function, select **Test/Run** from the top menu. On the *Input* tab, enter a value of **0.9** in the *Body* input box, and then select **Run**. Verify that a value of *Positive* is returned in the *HTTP response content* box in the *Output* section.

Next, create a logic app that integrates with Azure Functions, X, and the Azure AI services API.

Create a logic app

1. From the top search box, search for and select **Logic Apps**.
2. Select **Add**.
3. Select **Consumption** and enter the following values.

[] Expand table

Setting	Suggested Value
Subscription	Your Azure subscription name
Resource group	tweet-sentiment-tutorial
Logic app name	TweetSentimentApp
Region	Select the region closest to you, preferably the same region you selected in previous steps.

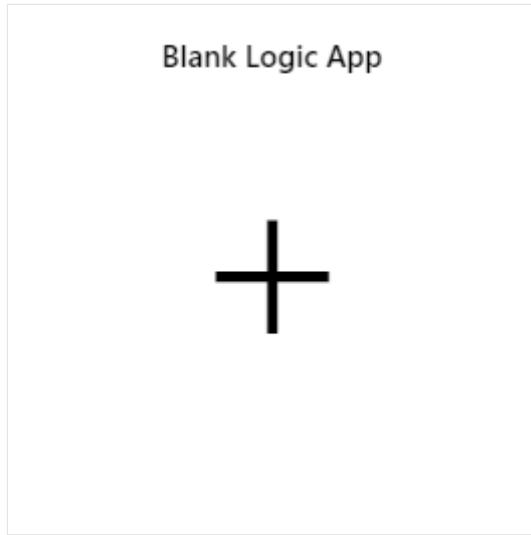

Accept default values for all other settings.

4. Select **Review + create**.

5. Select **Create**.

6. Once the deployment is complete, select **Go to Resource**.

7. Select the **Blank Logic App** button.

8. Select the **Save** button on the toolbar to save your progress.

You can now use the Logic Apps Designer to add services and triggers to your application.

Connect to X

Create a connection to X so your app can poll for new tweets.

1. Search for **X** in the top search box.

2. Select the **X** icon.

3. Select the **When a new tweet is posted** trigger.

4. Enter the following values to set up the connection.

[] Expand table

Setting	Value
Connection name	MyXConnection
Authentication Type	Use default shared application

5. Select **Sign in**.

6. Follow the prompts in the pop-up window to complete signing in to X.

7. Next, enter the following values in the *When a new tweet is posted* box.

[+] Expand table

Setting	Value
Search text	#my-x-tutorial
How often do you want to check for items?	1 in the textbox, and Hour in the dropdown. You may enter different values but be sure to review the current limitations of the X connector.

8. Select the **Save** button on the toolbar to save your progress.

Next, connect to text analytics to detect the sentiment of collected tweets.

Add Text Analytics sentiment detection

1. Select **New step**.
2. Search for **Text Analytics** in the search box.
3. Select the **Text Analytics** icon.
4. Select **Detect Sentiment** and enter the following values.

[+] Expand table

Setting	Value
Connection name	TextAnalyticsConnection
Account Key	Paste in the Text Analytics account key you set aside earlier.
Site URL	Paste in the Text Analytics endpoint you set aside earlier.

5. Select **Create**.
6. Click inside the *Add new parameter* box, and check the box next to **documents** that appears in the pop-up.
7. Click inside the *documents Id - 1* textbox to open the dynamic content pop-up.
8. In the *dynamic content* search box, search for **id**, and click on **Tweet id**.
9. Click inside the *documents Text - 1* textbox to open the dynamic content pop-up.

10. In the *dynamic content* search box, search for **text**, and click on **Tweet text**.
11. In **Choose an action**, type **Text Analytics**, and then click the **Detect sentiment** action.
12. Select the **Save** button on the toolbar to save your progress.

The *Detect Sentiment* box should look like the following screenshot.

The screenshot shows the 'Parameters' tab of the 'Sentiment (V4)' logic app step. It includes fields for 'Resource Subdomain Or Region' (set to 'westus'), 'Documents' (containing 'Id - 1' with 'Tweet id' and 'Text - 1' with 'Tweet text' inputs), 'Language - 1' (set to 'en'), and an 'Advanced parameters' section with 'Showing 1 of 5' items. A note at the bottom indicates a connection to 'Detect Sentiment'.

Connected to Detect Sentiment. [Change connection](#)

Connect sentiment output to function endpoint

1. Select **New step**.

2. Search for **Azure Functions** in the search box.
3. Select the **Azure Functions** icon.
4. Search for your function name in the search box. If you followed the guidance above, your function name begins with **TweetSentimentAPI**.
5. Select the function icon.
6. Select the **TweetSentimentFunction** item.
7. Click inside the *Request Body* box, and select the **Detect Sentiment score** item from the pop-up window.
8. Select the **Save** button on the toolbar to save your progress.

Add conditional step

1. Select the **Add an action** button.
2. Click inside the *Control* box, and search for and select **Control** in the pop-up window.
3. Select **Condition**.
4. Click inside the *Choose a value* box, and select the **TweetSentimentFunction Body** item from the pop-up window.
5. Enter **Positive** in the *Choose a value* box.
6. Select the **Save** button on the toolbar to save your progress.

Add email notifications

1. Under the *True* box, select the **Add an action** button.
2. Search for and select **Office 365 Outlook** in the text box.
3. Search for **send** and select **Send an email** in the text box.
4. Select the **Sign in** button.
5. Follow the prompts in the pop-up window to complete signing in to Office 365 Outlook.
6. Enter your email address in the *To* box.

7. Click inside the *Subject* box and click on the **Body** item under *TweetSentimentFunction*. If the *Body* item isn't shown in the list, click the **See more** link to expand the options list.
8. After the *Body* item in the *Subject*, enter the text **Tweet from:**
9. After the *Tweet from:* text, click on the box again and select **User name** from the *When a new tweet is posted* options list.
10. Click inside the *Body* box and select **Tweet text** under the *When a new tweet is posted* options list. If the *Tweet text* item isn't shown in the list, click the **See more** link to expand the options list.
11. Select the **Save** button on the toolbar to save your progress.

The email box should now look like this screenshot.

Connected Change connection

Run the workflow

1. From your X account, tweet the following text: I'm enjoying #my-x-tutorial.
2. Return to the Logic Apps Designer and select the **Run** button.
3. Check your email for a message from the workflow.

Clean up resources

To clean up all the Azure services and accounts created during this tutorial, delete the resource group.

1. Search for **Resource groups** in the top search box.

2. Select the **tweet-sentiment-tutorial**.
3. Select **Delete resource group**
4. Enter **tweet-sentiment-tutorial** in the text box.
5. Select the **Delete** button.

Optionally, you may want to return to your X account and delete any test tweets from your feed.

Quickstart: Create a function in Azure with Python using Visual Studio Code

Article • 09/10/2024

In this article, you use Visual Studio Code to create a Python function that responds to HTTP requests. After testing the code locally, you deploy it to the serverless environment of Azure Functions.

This article uses the Python v2 programming model for Azure Functions, which provides a decorator-based approach for creating functions. To learn more about the Python v2 programming model, see the [Developer Reference Guide](#)

Completing this quickstart incurs a small cost of a few USD cents or less in your Azure account.

There's also a [CLI-based version](#) of this article.

This video shows you how to create a Python function in Azure using Visual Studio Code.

[https://learn-video.azurefd.net/vod/player?id=a1e10f96-2940-489c-bc53-da2b915c8fc2&locale=en-us&embedUrl=%2Fazure%2Fazure-functions%2Fcreate-first-function-vs-code-python ↗](https://learn-video.azurefd.net/vod/player?id=a1e10f96-2940-489c-bc53-da2b915c8fc2&locale=en-us&embedUrl=%2Fazure%2Fazure-functions%2Fcreate-first-function-vs-code-python)

The steps in the video are also described in the following sections.

Configure your environment

Before you begin, make sure that you have the following requirements in place:

- An Azure account with an active subscription. [Create an account for free ↗](#).
- A Python version that is [supported by Azure Functions](#). For more information, see [How to install Python ↗](#).
- [Visual Studio Code ↗](#) on one of the [supported platforms ↗](#).
- The [Python extension ↗](#) for Visual Studio Code.
- The [Azure Functions extension ↗](#) for Visual Studio Code, version 1.8.1 or later.
- The [Azurite V3 extension ↗](#) local storage emulator. While you can also use an actual Azure storage account, this article assumes you're using the Azurite emulator.

Install or update Core Tools

The Azure Functions extension for Visual Studio Code integrates with Azure Functions Core Tools so that you can run and debug your functions locally in Visual Studio Code using the Azure Functions runtime. Before getting started, it's a good idea to install Core Tools locally or update an existing installation to use the latest version.

In Visual Studio Code, select F1 to open the command palette, and then search for and run the command **Azure Functions: Install or Update Core Tools**.

This command tries to either start a package-based installation of the latest version of Core Tools or update an existing package-based installation. If you don't have npm or Homebrew installed on your local computer, you must instead [manually install or update Core Tools](#).

Create your local project

In this section, you use Visual Studio Code to create a local Azure Functions project in Python. Later in this article, you publish your function code to Azure.

1. In Visual Studio Code, press `F1` to open the command palette and search for and run the command `Azure Functions: Create New Project...`.
2. Choose the directory location for your project workspace and choose **Select**. You should either create a new folder or choose an empty folder for the project workspace. Don't choose a project folder that is already part of a workspace.
3. Provide the following information at the prompts:

[] [Expand table](#)

Prompt	Selection
Select a language	Choose <code>Python (Programming Model V2)</code> .
Select a Python interpreter to create a virtual environment	Choose your preferred Python interpreter. If an option isn't shown, type in the full path to your Python binary.
Select a template for your project's first function	Choose <code>HTTP trigger</code> .
Name of the function you want to create	Enter <code>HttpExample</code> .

Prompt	Selection
Authorization level	Choose <code>ANONYMOUS</code> , which lets anyone call your function endpoint. For more information, see Authorization level .
Select how you would like to open your project	Choose <code>Open in current window</code> .

- Visual Studio Code uses the provided information and generates an Azure Functions project with an HTTP trigger. You can view the local project files in the Explorer. The generated `function_app.py` project file contains your functions.
- In the `local.settings.json` file, update the `AzureWebJobsStorage` setting as in the following example:

JSON

```
"AzureWebJobsStorage": "UseDevelopmentStorage=true",
```

This tells the local Functions host to use the storage emulator for the storage connection required by the Python v2 model. When you publish your project to Azure, this setting uses the default storage account instead. If you're using an Azure Storage account during local development, set your storage account connection string here.

Start the emulator

- In Visual Studio Code, press `F1` to open the command palette. In the command palette, search for and select `Azurite: Start`.
- Check the bottom bar and verify that Azurite emulation services are running. If so, you can now run your function locally.

Run the function locally

Visual Studio Code integrates with [Azure Functions Core tools](#) to let you run this project on your local development computer before you publish to Azure.

- To start the function locally, press `F5` or the Run and Debug icon in the left-hand side Activity bar. The Terminal panel displays the Output from Core Tools. Your app starts in the Terminal panel. You can see the URL endpoint of your HTTP-triggered function running locally.

The screenshot shows the Visual Studio Code interface with the Terminal tab selected. The output in the terminal window is as follows:

```
PROBLEMS OUTPUT DEBUG CONSOLE TERMINAL AZURE: ACTIVITY LOG host start - Task ✓ + × ↻ ↺ ↺ ×

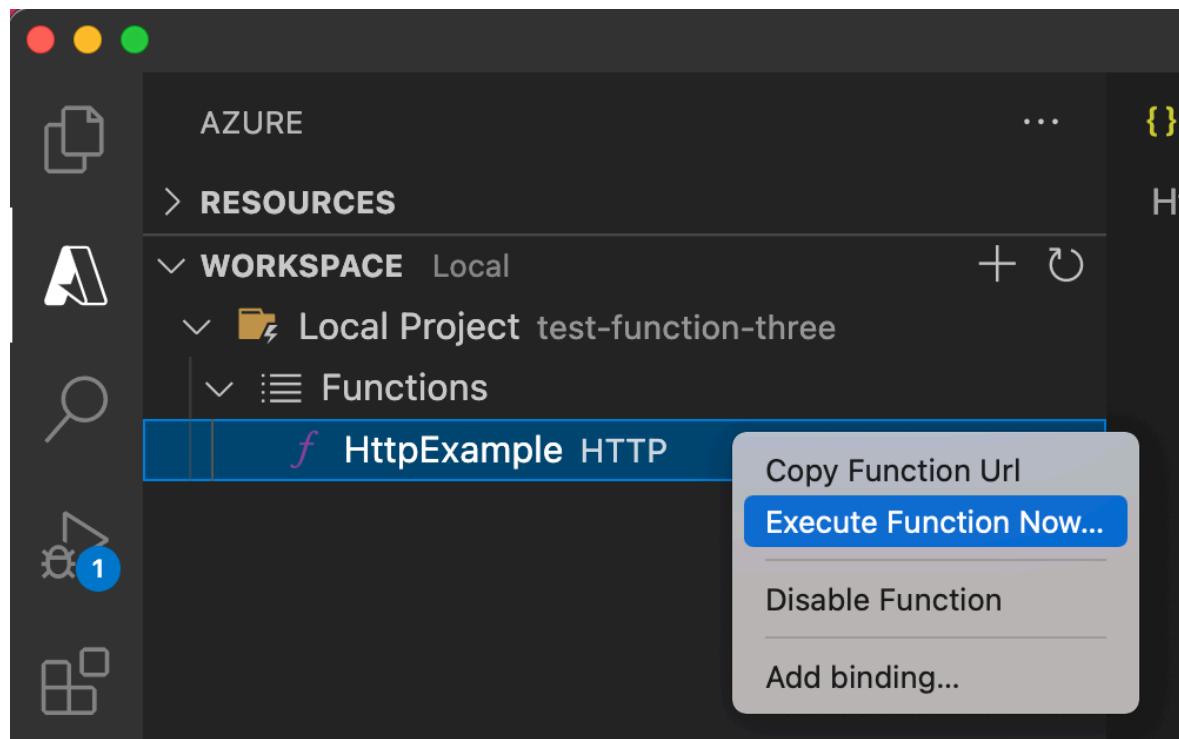

Functions:

HttpExample: [GET,POST] http://localhost:7071/api/HttpExample

For detailed output, run func with --verbose flag.
[2022-05-25T18:45:53.470Z] Worker process started and initialized.
[2022-05-25T18:45:54.960Z] Host lock lease acquired by instance ID '000000000000000000000000E24CCCAC'.
```

If you have trouble running on Windows, make sure that the default terminal for Visual Studio Code isn't set to **WSL Bash**.

- With Core Tools still running in **Terminal**, choose the Azure icon in the activity bar. In the **Workspace** area, expand **Local Project > Functions**. Right-click (Windows) or **Ctrl** click (macOS) the new function and choose **Execute Function Now....**

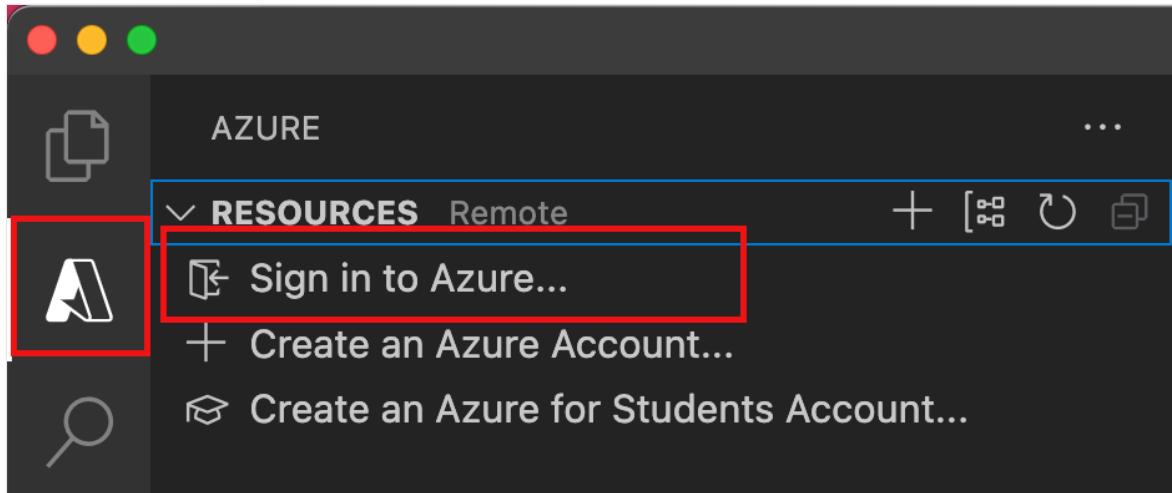

- In **Enter request body** you see the request message body value of `{ "name": "Azure" }`. Press Enter to send this request message to your function.
- When the function executes locally and returns a response, a notification is raised in Visual Studio Code. Information about the function execution is shown in **Terminal** panel.
- With the **Terminal** panel focused, press **Ctrl + C** to stop Core Tools and disconnect the debugger.

After you verify that the function runs correctly on your local computer, it's time to use Visual Studio Code to publish the project directly to Azure.

Sign in to Azure

Before you can create Azure resources or publish your app, you must sign in to Azure.

1. If you aren't already signed in, in the **Activity bar**, select the Azure icon. Then under **Resources**, select **Sign in to Azure**.

If you're already signed in and can see your existing subscriptions, go to the next section. If you don't yet have an Azure account, select **Create an Azure Account**. Students can select **Create an Azure for Students Account**.

2. When you are prompted in the browser, select your Azure account and sign in by using your Azure account credentials. If you create a new account, you can sign in after your account is created.
3. After you successfully sign in, you can close the new browser window. The subscriptions that belong to your Azure account are displayed in the side bar.

Create the function app in Azure

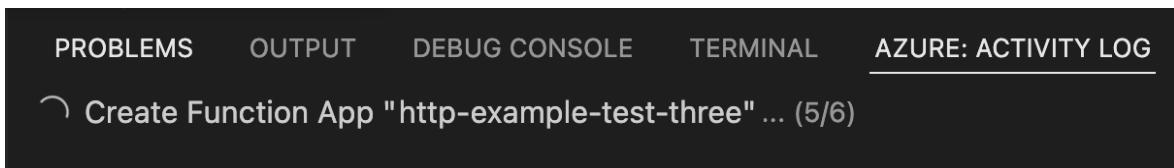

In this section, you create a function app and related resources in your Azure subscription. Many of the resource creation decisions are made for you based on default behaviors. For more control over the created resources, you must instead [create your function app with advanced options](#).

1. In Visual Studio Code, select F1 to open the command palette. At the prompt (>), enter and then select **Azure Functions: Create Function App in Azure**.
2. At the prompts, provide the following information:

[] [Expand table](#)

Prompt	Action
Select subscription	Select the Azure subscription to use. The prompt doesn't appear when you have only one subscription visible under Resources .
Enter a globally unique name for the function app	Enter a name that is valid in a URL path. The name you enter is validated to make sure that it's unique in Azure Functions.
Select a runtime stack	Select the language version you currently run locally.
Select a location for new resources	Select an Azure region. For better performance, select a region near you.

In the **Azure: Activity Log** panel, the Azure extension shows the status of individual resources as they're created in Azure.

- When the function app is created, the following related resources are created in your Azure subscription. The resources are named based on the name you entered for your function app.

- A [resource group](#), which is a logical container for related resources.
- A standard [Azure Storage account](#), which maintains state and other information about your projects.
- A function app, which provides the environment for executing your function code. A function app lets you group functions as a logical unit for easier management, deployment, and sharing of resources within the same hosting plan.
- An Azure App Service plan, which defines the underlying host for your function app.
- An Application Insights instance that's connected to the function app, and which tracks the use of your functions in the app.

A notification is displayed after your function app is created and the deployment package is applied.

💡 Tip

By default, the Azure resources required by your function app are created based on the name you enter for your function app. By default, the resources

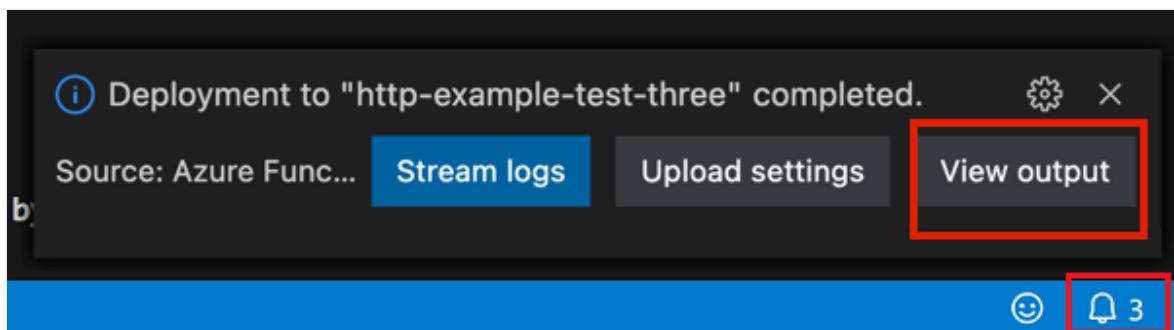

are created with the function app in the same, new resource group. If you want to customize the names of the associated resources or reuse existing resources, [publish the project with advanced create options](#).

Deploy the project to Azure

ⓘ Important

Deploying to an existing function app always overwrites the contents of that app in Azure.

1. In the command palette, enter and then select **Azure Functions: Deploy to Function App**.
2. Select the function app you just created. When prompted about overwriting previous deployments, select **Deploy** to deploy your function code to the new function app resource.
3. When deployment is completed, select **View Output** to view the creation and deployment results, including the Azure resources that you created. If you miss the notification, select the bell icon in the lower-right corner to see it again.

Run the function in Azure

1. Press **F1** to display the command palette, then search for and run the command **Azure Functions:Execute Function Now....**. If prompted, select your subscription.
2. Select your new function app resource and **HttpExample** as your function.
3. In **Enter request body** type `{ "name": "Azure" }`, then press Enter to send this request message to your function.

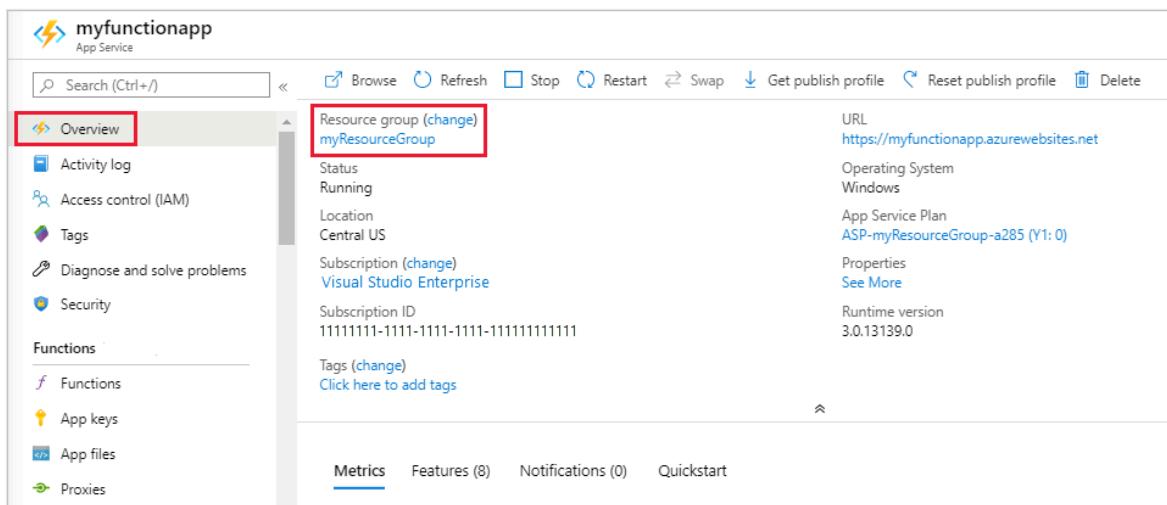

4. When the function executes in Azure, the response is displayed in the notification area. Expand the notification to review the full response.

Clean up resources

When you continue to the [next step](#) and add an Azure Storage queue binding to your function, you'll need to keep all your resources in place to build on what you've already done.

Otherwise, you can use the following steps to delete the function app and its related resources to avoid incurring any further costs.

1. In Visual Studio Code, press `F1` to open the command palette. In the command palette, search for and select `Azure: Open in portal`.
2. Choose your function app and press `Enter`. The function app page opens in the Azure portal.
3. In the **Overview** tab, select the named link next to **Resource group**.

4. On the **Resource group** page, review the list of included resources, and verify that they're the ones you want to delete.
5. Select **Delete resource group**, and follow the instructions.

Deletion may take a couple of minutes. When it's done, a notification appears for a few seconds. You can also select the bell icon at the top of the page to view the notification.

For more information about Functions costs, see [Estimating Consumption plan costs](#).

Next steps

You created and deployed a function app with a simple HTTP-triggered function. In the next articles, you expand that function by connecting to a storage service in Azure. To learn more about connecting to other Azure services, see [Add bindings to an existing function in Azure Functions](#).

[Connect to Azure Cosmos DB](#)

[Connect to an Azure Storage queue](#)

Create serverless APIs in Visual Studio using Azure Functions and API Management integration

Article • 08/07/2024

REST APIs are often described using an OpenAPI definition (formerly known as Swagger) file. This file contains information about operations in an API and how the request and response data for the API should be structured.

In this tutorial, you learn how to:

- ✓ Create the code project in Visual Studio
- ✓ Install the OpenAPI extension
- ✓ Add an HTTP trigger endpoint, which includes OpenAPI definitions
- ✓ Test function APIs locally using built-in OpenAPI functionality
- ✓ Publish project to a function app in Azure
- ✓ Enable API Management integration
- ✓ Download the OpenAPI definition file

The serverless function you create provides an API that lets you determine whether an emergency repair on a wind turbine is cost-effective. Since you create both the function app and API Management instance in a consumption tier, your cost for completing this tutorial is minimal.

Prerequisites

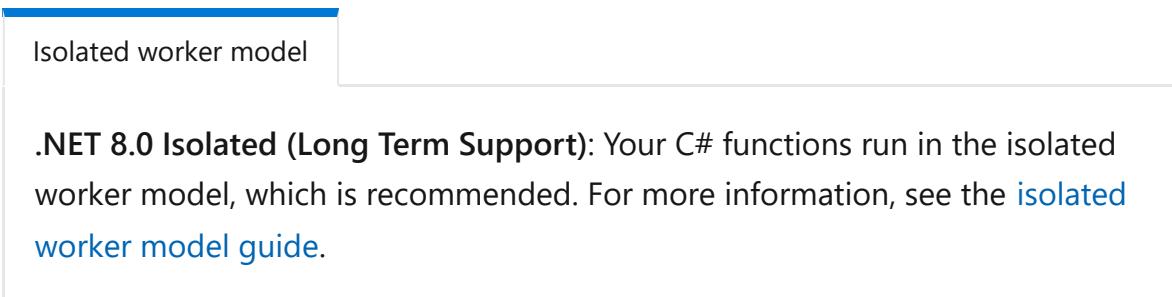

- [Visual Studio 2022](#). Make sure you select the **Azure development** workload during installation.
- An active [Azure subscription](#), [create a free account](#) before you begin.

Create the code project

The Azure Functions project template in Visual Studio creates a project that you can publish to a function app in Azure. You'll also create an HTTP triggered function from a template that supports OpenAPI definition file (formerly Swagger file) generation.

1. From the Visual Studio menu, select **File > New > Project**.

2. In **Create a new project**, enter *functions* in the search box, choose the **Azure Functions** template, and then select **Next**.
3. In **Configure your new project**, enter a **Project name** for your project like `TurbineRepair`, and then select **Create**.
4. For the **Create a new Azure Functions application** settings, select one of these options for **Functions worker**, where the option you choose depends on your chosen process model:

5. For the rest of the options, use the values in the following table:

[] [Expand table](#)

Setting	Value	Description
Function template	Empty	This creates a project without a trigger, which gives you more control over the name of the HTTP triggered function when you add it later.
Use Azurite for runtime storage account (AzureWebJobsStorage)	Selected	You can use the emulator for local development of HTTP trigger functions. Because a function app in Azure requires a storage account, one is assigned or created when you publish your project to Azure.
Authorization level	Function	When running in Azure, clients must provide a key when accessing the endpoint. For more information, see Authorization level .

6. Select **Create** to create the function project.

Next, you update the project by installing the OpenAPI extension for Azure Functions, which enables the discoverability of API endpoints in your app.

Install the OpenAPI extension

To install the OpenAPI extension:

1. From the **Tools** menu, select **NuGet Package Manager > Package Manager Console**.
2. In the console, run the following [Install-Package](#) command to install the OpenAPI extension:

The screenshot shows a command-line interface for the Azure Functions Package Manager. At the top, it says "Isolated worker model". Below that, under the heading "command", is the command: "NuGet\Install-Package Microsoft.Azure.Functions.Worker.Extensions.OpenApi -Version 1.5.1". A note below the command says: "You might need to update the [specific version](#), based on your version of .NET."

Now, you can add your HTTP endpoint function.

Add an HTTP endpoint function

In a C# class library, the bindings used by the function are defined by applying attributes in the code. To create a function with an HTTP trigger:

1. In **Solution Explorer**, right-click your project node and select **Add > New Azure Function**.
2. Enter **Turbine.cs** for the class, and then select **Add**.
3. Choose the **Http trigger** template, set **Authorization level** to **Function**, and then select **Add**. A Turbine.cs code file is added to your project that defines a new function endpoint with an HTTP trigger.

Now you can replace the HTTP trigger template code with code that implements the Turbine function endpoint, along with attributes that use OpenAPI to define endpoint.

Update the function code

The function uses an HTTP trigger that takes two parameters:

[\[+\] Expand table](#)

Parameter name	Description
<i>hours</i>	The estimated time to make a turbine repair, up to the nearest whole hour.
<i>capacity</i>	The capacity of the turbine, in kilowatts.

The function then calculates how much a repair costs, and how much revenue the turbine could make in a 24-hour period. Parameters are supplied either in the query string or in the payload of a POST request.

In the `Turbine.cs` project file, replace the contents of the class generated from the HTTP trigger template with the following code, which depends on your process model:

Isolated worker model

```
C#
using Microsoft.AspNetCore.Http;
using Microsoft.AspNetCore.Mvc;
using Microsoft.Azure.Functions.Worker;
using Microsoft.Azure.WebJobs.Extensions.OpenApi.Core.Attributes;
using Microsoft.Azure.WebJobs.Extensions.OpenApi.Core.Enums;
using Microsoft.Extensions.Logging;
using Microsoft.OpenApi.Models;
using Newtonsoft.Json;
using System.Net;

namespace TurbineRepair
{
    public class Turbine
    {
        const double revenuePerkW = 0.12;
        const double technicianCost = 250;
        const double turbineCost = 100;

        private readonly ILogger<Turbine> _logger;

        public Turbine(ILogger<Turbine> logger)
        {
            _logger = logger;
        }

        [Function("TurbineRepair")]
        [OpenApiOperation(operationId: "Run")]
        [OpenApiSecurity("function_key", SecuritySchemeType.ApiKey, Name = "code", In = OpenApiSecurityLocationType.Query)]
        [OpenApiRequestBody("application/json", typeof(RequestBodyModel),
            Description = "JSON request body containing { hours, capacity}")]
        [OpenApiResponseWithBody(statusCode: HttpStatusCode.OK,
```

```

    contentType: "application/json", bodyType: typeof(string),
        Description = "The OK response message containing a JSON
result.")]
    public static async Task<IActionResult> Run(
        [HttpTrigger(AuthorizationLevel.Function, "post", Route =
null)] HttpRequest req,
        ILogger log)
    {
        // Get request body data.
        string requestBody = await new
StreamReader(req.Body).ReadToEndAsync();
        dynamic? data = JsonConvert.DeserializeObject(requestBody);
        int? capacity = data?.capacity;
        int? hours = data?.hours;

        // Return bad request if capacity or hours are not passed in
        if (capacity == null || hours == null)
        {
            return new BadRequestObjectResult("Please pass capacity
and hours in the request body");
        }
        // Formulas to calculate revenue and cost
        double? revenueOpportunity = capacity * revenuePerkW * 24;
        double? costToFix = hours * technicianCost + turbineCost;
        string repairTurbine;

        if (revenueOpportunity > costToFix)
        {
            repairTurbine = "Yes";
        }
        else
        {
            repairTurbine = "No";
        };

        return new OkObjectResult(new
        {
            message = repairTurbine,
            revenueOpportunity = "$" + revenueOpportunity,
            costToFix = "$" + costToFix
        });
    }
    public class RequestBodyModel
    {
        public int Hours { get; set; }
        public int Capacity { get; set; }
    }
}
}

```

This function code returns a message of `Yes` or `No` to indicate whether an emergency repair is cost-effective. It also returns the revenue opportunity that the turbine

represents and the cost to fix the turbine.

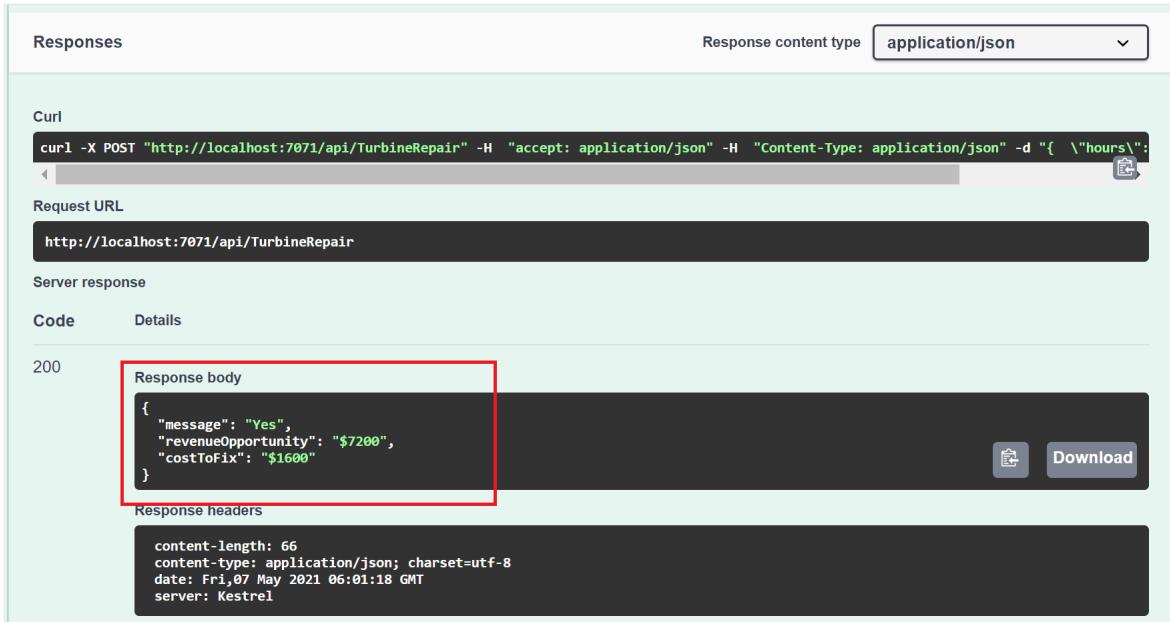

Run and verify the API locally

When you run the function, the OpenAPI endpoints make it easy to try out the function locally using a generated page. You don't need to provide function access keys when running locally.

1. Press F5 to start the project. When Functions runtime starts locally, a set of OpenAPI and Swagger endpoints are shown in the output, along with the function endpoint.
2. In your browser, open the RenderSwaggerUI endpoint, which should look like `http://localhost:7071/api/swagger/ui`. A page is rendered, based on your OpenAPI definitions.
3. Select **POST > Try it out**, enter values for `hours` and `capacity` either as query parameters or in the JSON request body, and select **Execute**.

The screenshot shows the 'Try it out' dialog for a POST request to the '/TurbineRepair' endpoint. The dialog has a green header bar with 'POST' and the endpoint path. Below the header is a 'Parameters' section with a 'Cancel' button. The main body shows a table with 'Name' and 'Description' columns. A row for 'body object (body)' has an 'Edit Value | Model' link and a JSON input field containing '{ "hours": 6, "capacity": 2500 }'. A red box highlights this JSON input field. At the bottom, there's another 'Cancel' button, a 'Parameter content type' dropdown set to 'application/json', and a large blue 'Execute' button highlighted with a red box.

4. When you enter integer values like 6 for `hours` and 2500 for `capacity`, you get a JSON response that looks like the following example:

```
curl -X POST "http://localhost:7071/api/TurbineRepair" -H "accept: application/json" -H "Content-Type: application/json" -d "{\"hours\":6, \"capacity\":2500}"
```

Request URL
`http://localhost:7071/api/TurbineRepair`

Server response

Code Details

200 Response body

```
{  
  "message": "Yes",  
  "revenueOpportunity": "$7200",  
  "costToFix": "$1600"  
}
```

Response headers

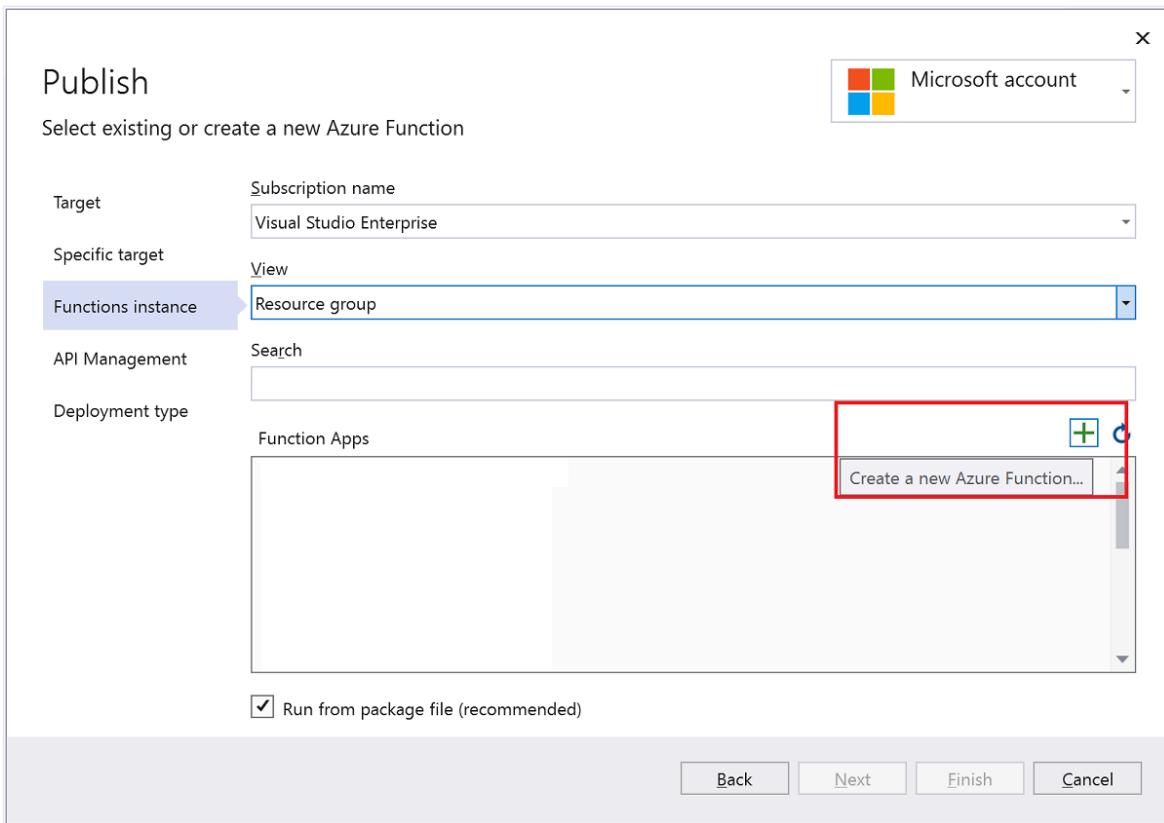

```
content-length: 66  
content-type: application/json; charset=utf-8  
date: Fri, 07 May 2021 06:01:18 GMT  
server: Kestrel
```

Now you have a function that determines the cost-effectiveness of emergency repairs. Next, you publish your project and API definitions to Azure.

Publish the project to Azure

Before you can publish your project, you must have a function app in your Azure subscription. Visual Studio publishing creates a function app the first time you publish your project. It can also create an API Management instance that integrates with your function app to expose the TurbineRepair API.

1. In **Solution Explorer**, right-click the project and select **Publish** and in **Target**, select **Azure** then **Next**.
2. For the **Specific target**, choose **Azure Function App (Windows)** to create a function app that runs on Windows, then select **Next**.
3. In **Function Instance**, choose **+ Create a new Azure Function....**

4. Create a new instance using the values specified in the following table:

[\[...\] Expand table](#)

Setting	Value	Description
Name	Globally unique name	Name that uniquely identifies your new function app. Accept this name or enter a new name. Valid characters are: a-z, 0-9, and -.
Subscription	Your subscription	The Azure subscription to use. Accept this subscription or select a new one from the drop-down list.
Resource group	Name of your resource group	The resource group in which to create your function app. Select an existing resource group from the drop-down list or choose New to create a new resource group.
Plan Type	Consumption	When you publish your project to a function app that runs in a Consumption plan , you pay only for executions of your functions app. Other hosting plans incur higher costs.
Location	Location of the service	Choose a Location in a region near you or other services your functions access.
Azure Storage	General-purpose storage account	An Azure Storage account is required by the Functions runtime. Select New to configure a general-purpose

Setting	Value	Description
		storage account. You can also choose an existing account that meets the storage account requirements .

Name: TurbineRepair20210506232328

Subscription name: Visual Studio Enterprise

Resource group: TurbineRepairGroup* [New...](#)

Plan Type: Consumption

Location: South Central US

Azure Storage: turbinerepair20210506232* (East US) [New...](#)

Buttons: Export..., Create, Cancel

5. Select **Create** to create a function app and its related resources in Azure. Status of resource creation is shown in the lower left of the window.
6. Back in **Functions instance**, make sure that **Run from package file** is checked. Your function app is deployed using [Zip Deploy](#) with [Run-From-Package](#) mode enabled. This deployment method is recommended for your functions project, since it results in better performance.
7. Select **Next**, and in **API Management** page, also choose **+ Create an API Management API**.
8. Create an **API in API Management** by using values in the following table:

[Expand table](#)

Setting	Value	Description
API name	TurbineRepair	Name for the API.
Subscription name	Your subscription	The Azure subscription to use. Accept this subscription or select a new one from the drop-down list.
Resource group	Name of your resource group	Select the same resource group as your function app from the drop-down list.
API Management service	New instance	Select New to create a new API Management instance in the same location in the serverless tier. Select OK to create the instance.

API in API Management

Create new

Microsoft account

X

API name

TurbineRepair

Subscription name

Visual Studio Enterprise

Resource group

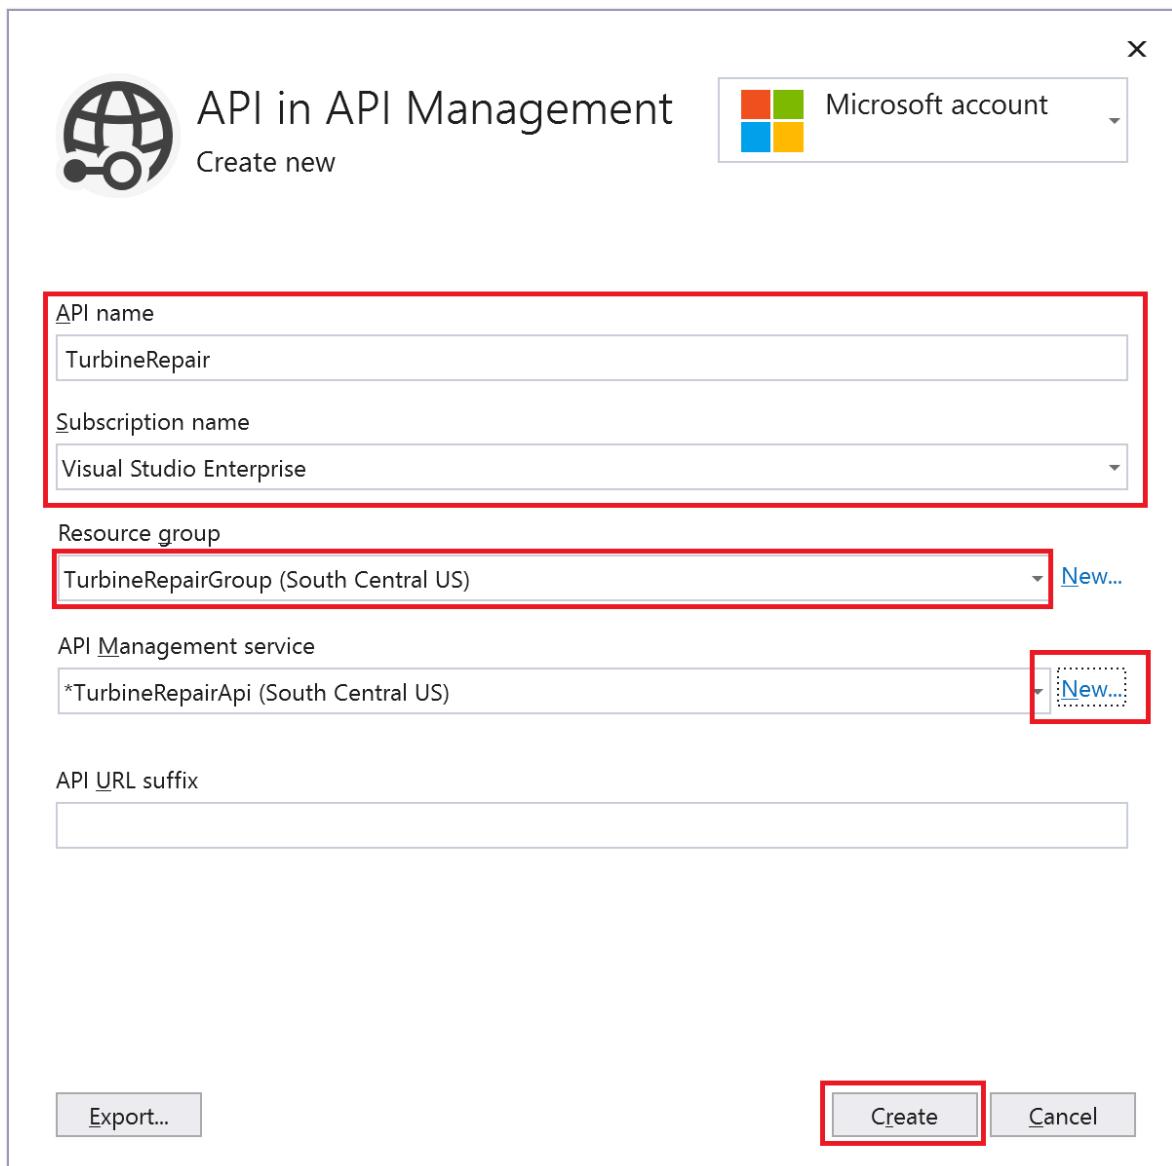

TurbineRepairGroup (South Central US)

API Management service

*TurbineRepairApi (South Central US)

API URL suffix

Export... Create Cancel

9. Select **Create** to create the API Management instance with the TurbineRepair API from the function integration.

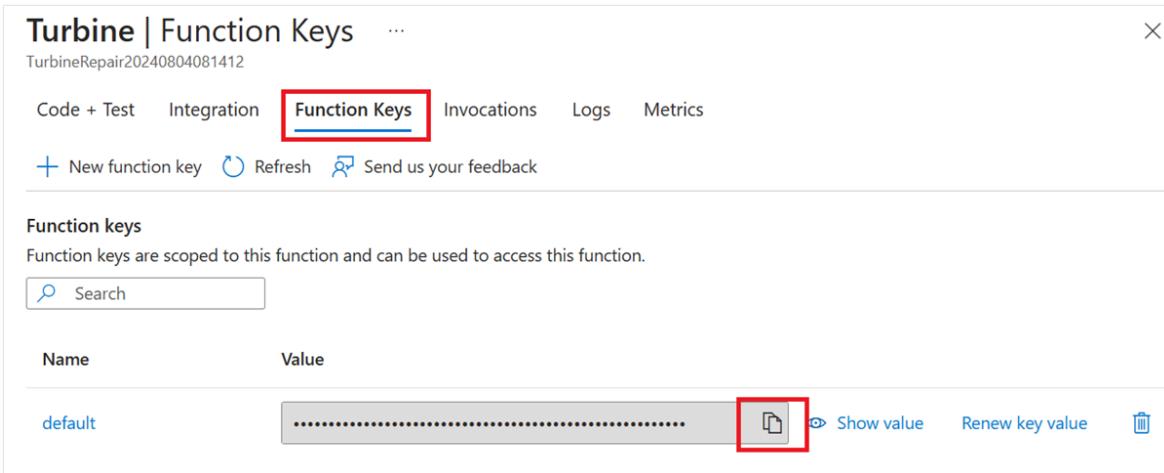

10. Select **Finish** and after the publish profile creation process completes, select **Close**.

11. Verify the Publish page now says **Ready to publish**, and then select **Publish** to deploy the package containing your project files to your new function app in Azure.

After the deployment completes, the root URL of the function app in Azure is shown in the **Publish** tab.

Get the function access key

1. In the **Publish** tab, select the ellipses (...) next to **Hosting** and select **Open in Azure portal**. The function app you created is opened in the Azure portal in your default browser.
2. Under **Functions** on the **Overview page**, select > **Turbine** then select **Function keys**.

The screenshot shows the 'Turbine | Function Keys' blade in the Azure portal. At the top, there's a navigation bar with tabs: 'Code + Test', 'Integration', 'Function Keys' (which is highlighted with a red box), 'Invocations', 'Logs', and 'Metrics'. Below the tabs, there are buttons for '+ New function key', 'Refresh', and 'Send us your feedback'. The main area is titled 'Function keys' and contains the sub-instruction: 'Function keys are scoped to this function and can be used to access this function.' Below this, there's a search bar labeled 'Search'. A table lists function keys, with one row shown: 'Name' (default) and 'Value' (redacted). To the right of the value column are icons: a copy-to-clipboard icon (highlighted with a red box), 'Show value', 'Renew key value', and a delete icon.

3. Under **Function keys**, select the *copy to clipboard* icon next to the **default** key. You can now set this key you copied in API Management so that it can access the function endpoint.

Configure API Management

1. In the function app page, expand **API** and select **API Management**.
2. If the function app isn't already connected to the new API Management instance, select it under **API Management**, select **API > OpenAPI Document on Azure Functions**, make sure **Import functions** is checked, and select **Link API**. Make sure that only **TurbineRepair** is selected for import and then **Select**.

3. Select **Go to API Management** at the top of the page, and in the API Management instance, expand **APIs**.

4. Under **APIs > All APIs**, select **OpenAPI Document on Azure Functions > POST Run**, then under **Inbound processing** select **Add policy > Set query parameters**.

5. Below **Inbound processing**, in **Set query parameters**, type `code` for **Name**, select **+Value**, paste in the copied function key, and select **Save**. API Management includes the function key when it passes calls through to the function endpoint.

The screenshot shows the 'Inbound processing' section of the API Management configuration. On the left, there's a sidebar with 'Design', 'Settings', 'Test', 'Revisions', and 'Change log'. The main area shows the path 'OpenAPI Document on Azure Fu... > Run > Policies'. The 'Inbound processing' section has a sub-section titled 'Set query parameters' with the instruction 'Modify the request before it is sent to the backend service.' It contains a table:

NAME	VALUE	ACTION	DELETE
code	(redacted)	override	

At the bottom of the table, there's a '+ Add parameter' link. At the very bottom of the page, there are 'Operations' and 'Definitions' tabs, and a 'Save' button which is highlighted with a red box, and a 'Discard' button.

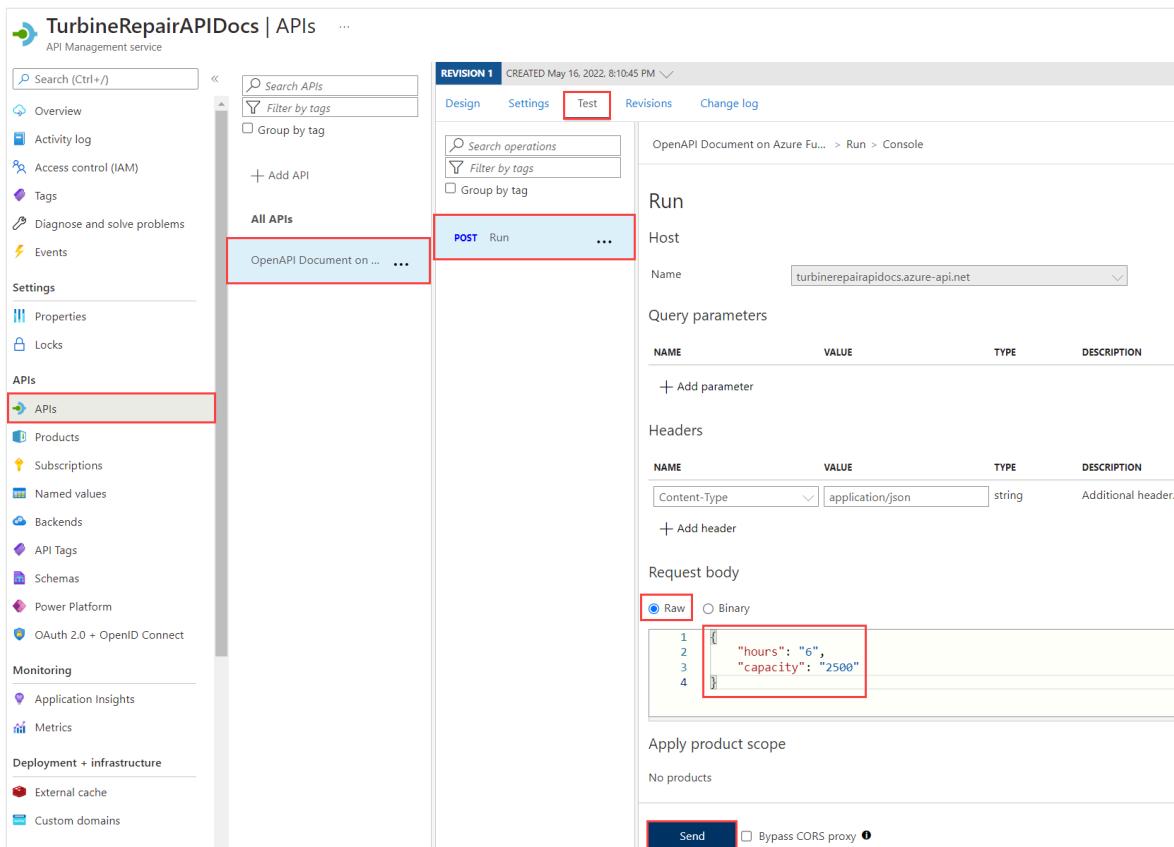

Now that the function key is set, you can call the `turbine` API endpoint to verify that it works when hosted in Azure.

Verify the API in Azure

1. In the API, select the **Test** tab and then **POST Run**, enter the following code in the **Request body > Raw**, and select **Send**:

The screenshot shows the 'Test' tab of the API configuration. The 'Request body > Raw' section contains the following JSON:

```
{  
  "hours": "6",  
  "capacity": "2500"  
}
```

As before, you can also provide the same values as query parameters.

2. Select **Send**, and then view the **HTTP response** to verify the same results are returned from the API.

Download the OpenAPI definition

If your API works as expected, you can download the OpenAPI definition for the new hosted APIs from API Management.

1. a. Under **APIs**, select **OpenAPI Document on Azure Functions**, select the ellipses (...), and select **Export**.

The screenshot shows the Azure API Management service interface. On the left, there's a sidebar with various navigation links: Overview, Activity log, Access control (IAM), Tags, Diagnose and solve problems, Events, Settings (Properties and Locks), APIs (Products, Subscriptions, Named values, Backends, API Tags), and a main APIs section. The 'APIs' link under 'APIs' is highlighted with a red box. In the main content area, there's a search bar for APIs, a 'Filter by tags' button, and a 'Group by tag' checkbox. Below that is a '+ Add API' button and a 'All APIs' section. An API entry is selected, with its details shown: 'OpenAPI Document on ...' and a three-dot ellipsis button. To the right of the API entry is a context menu with several options: Clone (with a copy icon), Add revision (with a pencil icon), Add version (with a list icon), Import (with an upward arrow icon), Export (highlighted with a red box and a downward arrow icon), Create Power Connector (with a diamond icon), and Delete (with a trash bin icon).

2. Choose the means of API export, including OpenAPI files in various formats. You can also [export APIs from Azure API Management to the Power Platform](#).

Clean up resources

In the preceding steps, you created Azure resources in a resource group. If you don't expect to need these resources in the future, you can delete them by deleting the resource group.

From the Azure portal menu or **Home** page, select **Resource groups**. Then, on the **Resource groups** page, select the group you created.

On the **myResourceGroup** page, make sure that the listed resources are the ones you want to delete.

Select **Delete resource group**, type the name of your group in the text box to confirm, and then select **Delete**.

Next steps

You've used Visual Studio 2022 to create a function that's self-documenting because of the [OpenAPI Extension](#) and integrated with API Management. You can now refine the definition in API Management in the portal. You can also [learn more about API Management](#).

[Edit the OpenAPI definition in API Management](#)

Tutorial: Integrate Azure Functions with an Azure virtual network by using private endpoints

Article • 03/30/2023

This tutorial shows you how to use Azure Functions to connect to resources in an Azure virtual network by using private endpoints. You create a new function app using a new storage account that's locked behind a virtual network via the Azure portal. The virtual network uses a Service Bus queue trigger.

In this tutorial, you'll:

- ✓ Create a function app in the Elastic Premium plan with virtual network integration and private endpoints.
- ✓ Create Azure resources, such as the Service Bus
- ✓ Lock down your Service Bus behind a private endpoint.
- ✓ Deploy a function app that uses both the Service Bus and HTTP triggers.
- ✓ Test to see that your function app is secure inside the virtual network.
- ✓ Clean up resources.

Create a function app in a Premium plan

You create a C# function app in an [Elastic Premium plan](#), which supports networking capabilities such as virtual network integration on create along with serverless scale. This tutorial uses C# and Windows. Other languages and Linux are also supported.

1. On the Azure portal menu or the [Home](#) page, select [Create a resource](#).
2. On the [New](#) page, select [Compute > Function App](#).
3. On the [Basics](#) page, use the following table to configure the function app settings.

Setting	Suggested value	Description
Subscription	Your subscription	Subscription under which this new function app is created.
Resource Group	myResourceGroup	Name for the new resource group where you create your function app.
Function App name	Globally unique name	Name that identifies your new function app. Valid characters are a-z (case insensitive), 0-9, and -.

Setting	Suggested value	Description
Publish	Code	Choose to publish code files or a Docker container.
Runtime stack	.NET	This tutorial uses .NET.
Version	6 (LTS)	This tutorial uses .NET 6.0 running in the same process as the Functions host .
Region	Preferred region	Choose a region near you or near other services that your functions access.
Operating system	Windows	This tutorial uses Windows but also works for Linux.
Plan	Functions Premium	<p>Hosting plan that defines how resources are allocated to your function app. By default, when you select Premium, a new App Service plan is created. The default Sku and size is EP1, where <i>EP</i> stands for <i>elastic premium</i>. For more information, see the list of Premium SKUs.</p> <p>When you run JavaScript functions on a Premium plan, choose an instance that has fewer vCPUs. For more information, see Choose single-core Premium plans.</p>

4. Select **Next: Storage**. On the **Storage** page, enter the following settings.

Setting	Suggested value	Description
Storage account	Globally unique name	Create a storage account used by your function app. Storage account names must be between 3 and 24 characters long. They may contain numbers and lowercase letters only. You can also use an existing account that isn't restricted by firewall rules and meets the storage account requirements . When using Functions with a locked down storage account, a v2 storage account is needed. This is the default storage version created when creating a function app with networking capabilities through the create blade.

5. Select **Next: Networking**. On the **Networking** page, enter the following settings.

! **Note**

Some of these settings aren't visible until other options are selected.

Setting	Suggested value	Description
Enable public access	Off	Deny public network access will block all incoming traffic except that comes from private endpoints.
Enable network injection	On	The ability to configure your application with VNet integration at creation appears in the portal window after this option is switched to On .
Virtual Network	Create New	Select the Create New field. In the pop-out screen, provide a name for your virtual network and select Ok . Options to restrict inbound and outbound access to your function app on create are displayed. You must explicitly enable VNet integration in the Outbound access portion of the window to restrict outbound access.

Enter the following settings for the **Inbound access** section. This step creates a private endpoint on your function app.

💡 Tip

To continue interacting with your function app from portal, you'll need to add your local computer to the virtual network. If you don't wish to restrict inbound access, skip this step.

Setting	Suggested value	Description
Enable private endpoints	On	The ability to configure your application with VNet integration at creation appears in the portal after this option is enabled.
Private endpoint name	myInboundPrivateEndpointName	Name that identifies your new function app private endpoint.
Inbound subnet	Create New	This option creates a new subnet for your inbound private endpoint. Multiple private endpoints may be added to a singular subnet. Provide a Subnet Name . The Subnet Address Block may be left at the default value. Select Ok . To learn more about subnet sizing, see Subnets .

Setting	Suggested value	Description
DNS	Azure Private DNS Zone	This value indicates which DNS server your private endpoint uses. In most cases if you're working within Azure, Azure Private DNS Zone is the DNS zone you should use as using Manual for custom DNS zones have increased complexity.

Enter the following settings for the **Outbound access** section. This step integrates your function app with a virtual network on creation. It also exposes options to create private endpoints on your storage account and restrict your storage account from network access on create. When function app is vnet integrated, all outbound traffic by default goes [through the vnet..](#)

Setting	Suggested value	Description
Enable VNet Integration	On	This integrates your function app with a VNet on create and direct all outbound traffic through the VNet.
Outbound subnet	Create new	This creates a new subnet for your function app's VNet integration. A function app can only be VNet integrated with an empty subnet. Provide a Subnet Name . The Subnet Address Block may be left at the default value. If you wish to configure it, please learn more about Subnet sizing here. Select Ok . The option to create Storage private endpoints is displayed. To use your function app with virtual networks, you need to join it to a subnet.

Enter the following settings for the **Storage private endpoint** section. This step creates private endpoints for the blob, queue, file, and table endpoints on your storage account on create. This effectively integrates your storage account with the VNet.

Setting	Suggested value	Description
Add storage private endpoint	On	The ability to configure your application with VNet integration at creation is displayed in the portal after this option is enabled.
Private endpoint name	myInboundPrivateEndpointName	Name that identifies your storage account private endpoint.

Setting	Suggested value	Description
Private endpoint subnet	Create New	This creates a new subnet for your inbound private endpoint on the storage account. Multiple private endpoints may be added to a singular subnet. Provide a Subnet Name . The Subnet Address Block may be left at the default value. If you wish to configure it, please learn more about Subnet sizing here. Select Ok .
DNS	Azure Private DNS Zone	This value indicates which DNS server your private endpoint uses. In most cases if you're working within Azure, Azure Private DNS Zone is the DNS zone you should use as using Manual for custom DNS zones will have increased complexity.

6. Select **Next: Monitoring**. On the **Monitoring** page, enter the following settings.

Setting	Suggested value	Description
Application Insights	Default	Create an Application Insights resource of the same app name in the nearest supported region. Expand this setting if you need to change the New resource name or store your data in a different Location in an Azure geography .

7. Select **Review + create** to review the app configuration selections.

8. On the **Review + create** page, review your settings. Then select **Create** to create and deploy the function app.

9. In the upper-right corner of the portal, select the **Notifications** icon and watch for the **Deployment succeeded** message.

10. Select **Go to resource** to view your new function app. You can also select **Pin to dashboard**. Pinning makes it easier to return to this function app resource from your dashboard.

Congratulations! You've successfully created your premium function app.

Note

Some deployments may occasionally fail to create the private endpoints in the storage account with the error 'StorageAccountOperationInProgress'. This failure occurs even though the function app itself gets created successfully. When you

encounter such an error, delete the function app and retry the operation. You can instead create the private endpoints on the storage account manually.

Create a Service Bus

Next, you create a Service Bus instance that is used to test the functionality of your function app's network capabilities in this tutorial.

1. On the Azure portal menu or the **Home** page, select **Create a resource**.
2. On the **New** page, search for *Service Bus*. Then select **Create**.
3. On the **Basics** tab, use the following table to configure the Service Bus settings. All other settings can use the default values.

Setting	Suggested value	Description
Subscription	Your subscription	The subscription in which your resources are created.
Resource group	myResourceGroup	The resource group you created with your function app.
Namespace name	myServiceBus	The name of the Service Bus instance for which the private endpoint is enabled.
Location	myFunctionRegion	The region where you created your function app.
Pricing tier	Premium	Choose this tier to use private endpoints with Azure Service Bus.

4. Select **Review + create**. After validation finishes, select **Create**.

Lock down your Service Bus

Create the private endpoint to lock down your Service Bus:

1. In your new Service Bus, in the menu on the left, select **Networking**.
2. On the **Private endpoint connections** tab, select **Private endpoint**.

The screenshot shows the Azure portal interface for a Service Bus Namespace named 'myServiceBus-tutorial'. The left sidebar has a 'Networking' section with several options: Overview, Activity log, Access control (IAM), Tags, Diagnose and solve problems, Events, Settings (Shared access policies, Scale, Geo-Recovery), Networking (which is highlighted with a red box), and Encryption.

The main content area is titled 'Firewalls and virtual networks' and shows a table for 'Private endpoint connections'. The table includes columns for Connection name, Connection state, and actions (Approve, Reject, Remove, Refresh). A red box highlights the 'Private endpoint' button in the top-left of the table header.

3. On the **Basics** tab, use the private endpoint settings shown in the following table.

Setting	Suggested value	Description
Subscription	Your subscription	The subscription in which your resources are created.
Resource group	myResourceGroup	The resource group you created with your function app.
Name	sb-endpoint	The name of the private endpoint for the service bus.
Region	myFunctionRegion	The region where you created your storage account.

4. On the **Resource** tab, use the private endpoint settings shown in the following table.

Setting	Suggested value	Description
Subscription	Your subscription	The subscription under which your resources are created.
Resource type	Microsoft.ServiceBus/namespaces	The resource type for the Service Bus.
Resource	myServiceBus	The Service Bus you created earlier in the tutorial.

Setting	Suggested value	Description
Target subresource	namespace	The private endpoint that is used for the namespace from the Service Bus.

5. On the **Virtual Network** tab, for the **Subnet** setting, choose **default**.
6. Select **Review + create**. After validation finishes, select **Create**.
7. After the private endpoint is created, return to the **Networking** section of your Service Bus namespace and check the **Public Access** tab.
8. Ensure **Selected networks** is selected.
9. Select **+ Add existing virtual network** to add the recently created virtual network.
10. On the **Add networks** tab, use the network settings from the following table:

Setting	Suggested value	Description
Subscription	Your subscription	The subscription under which your resources are created.
Virtual networks	myVirtualNet	The name of the virtual network to which your function app connects.
Subnets	functions	The name of the subnet to which your function app connects.

11. Select **Add your client IP address** to give your current client IP access to the namespace.

 **Note**

Allowing your client IP address is necessary to enable the Azure portal to publish messages to the queue later in this tutorial.

12. Select **Enable** to enable the service endpoint.
13. Select **Add** to add the selected virtual network and subnet to the firewall rules for the Service Bus.
14. Select **Save** to save the updated firewall rules.

Resources in the virtual network can now communicate with the Service Bus using the private endpoint.

Create a queue

Create the queue where your Azure Functions Service Bus trigger gets events:

1. In your Service Bus, in the menu on the left, select **Queues**.
2. Select **Queue**. For the purposes of this tutorial, provide the name *queue* as the name of the new queue.

The screenshot shows the Azure portal interface for creating a new queue. On the left, the navigation menu is open, with the 'Queues' option under the 'Entities' section highlighted by a red box. In the center, there is a list of queues with the message 'No results.' Below this is a search bar. To the right, a 'Create queue' dialog box is open. The 'Name' field contains 'queue', which is also highlighted by a red box. Other settings in the dialog include 'Max queue size: 1 GB', 'Max delivery count: 10', 'Message time to live: 14 Days, 0 Hours, 0 Minutes, 0 Seconds', and 'Lock duration: 0 Days, 0 Hours, 0 Minutes, 30 Seconds'. There are several optional checkboxes at the bottom, none of which are checked. A large blue 'Create' button is at the bottom right of the dialog.

3. Select **Create**.

Get a Service Bus connection string

1. In your Service Bus, in the menu on the left, select **Shared access policies**.
2. Select **RootManageSharedAccessKey**. Copy and save the **Primary Connection String**. You need this connection string when you configure the app settings.

Configure your function app settings

1. In your function app, in the menu on the left, select **Configuration**.
2. To use your function app with virtual networks and service bus, update the app settings shown in the following table. To add or edit a setting, select **+ New application setting** or the **Edit** icon in the rightmost column of the app settings table. When you finish, select **Save**.

Setting	Suggested value	Description
SERVICEBUS_CONNECTION	myServiceBusConnectionString	Create this app setting for the connection string of your Service Bus. This storage connection string is from the Get a Service Bus connection string section.
WEBSITE_CONTENTOVERVNET	1	Create this app setting. A value of 1 enables your function app to scale when your storage account is restricted to a virtual network.

3. Since you're using an Elastic Premium hosting plan, In the **Configuration** view, select the **Function runtime settings** tab. Set **Runtime Scale Monitoring** to **On**. Then select **Save**. Runtime-driven scaling allows you to connect non-HTTP trigger functions to services that run inside your virtual network.

The screenshot shows the Azure Function App Configuration page for a 'scaling-sample' function app. The left sidebar lists various settings like Overview, Activity log, Access control (IAM), Tags, Diagnose and solve problems, Microsoft Defender for Cloud, and Events (preview). The main area has tabs for Application settings, Function runtime settings (which is selected and highlighted in blue), and General settings. Under Function runtime settings, there's a 'Runtime version' dropdown set to '~4'. Below it is a section titled 'Runtime Scale Monitor...' with a radio button set to 'On'. A note below says: 'Enable this setting to allow your app to be scaled based on runtime metrics.'

① Note

Runtime scaling isn't needed for function apps hosted in a Dedicated App Service plan.

Deploy a Service Bus trigger and HTTP trigger

① Note

Enabling private endpoints on a function app also makes the Source Control Manager (SCM) site publicly inaccessible. The following instructions give deployment directions using the Deployment Center within the function app. Alternatively, use **zip deploy** or **self-hosted agents** that are deployed into a subnet on the virtual network.

1. In GitHub, go to the following sample repository. It contains a function app and two functions, an HTTP trigger, and a Service Bus queue trigger.
<https://github.com/Azure-Samples/functions-vnet-tutorial>
2. At the top of the page, select **Fork** to create a fork of this repository in your own GitHub account or organization.
3. In your function app, in the menu on the left, select **Deployment Center**. Then select **Settings**.
4. On the **Settings** tab, use the deployment settings shown in the following table.

Setting	Suggested value	Description
---------	-----------------	-------------

Setting	Suggested value	Description
Source	GitHub	You should have created a GitHub repository for the sample code in step 2.
Organization	myOrganization	The organization your repo is checked into. It's usually your account.
Repository	functions-vnet-tutorial	The repository forked from https://github.com/Azure-Samples/functions-vnet-tutorial .
Branch	main	The main branch of the repository you created.
Runtime stack	.NET	The sample code is in C#.
Version	.NET Core 3.1	The runtime version.

5. Select Save.

6. Your initial deployment might take a few minutes. When your app is successfully deployed, on the Logs tab, you see a Success (Active) status message. If necessary, refresh the page.

Congratulations! You've successfully deployed your sample function app.

Test your locked-down function app

1. In your function app, in the menu on the left, select **Functions**.

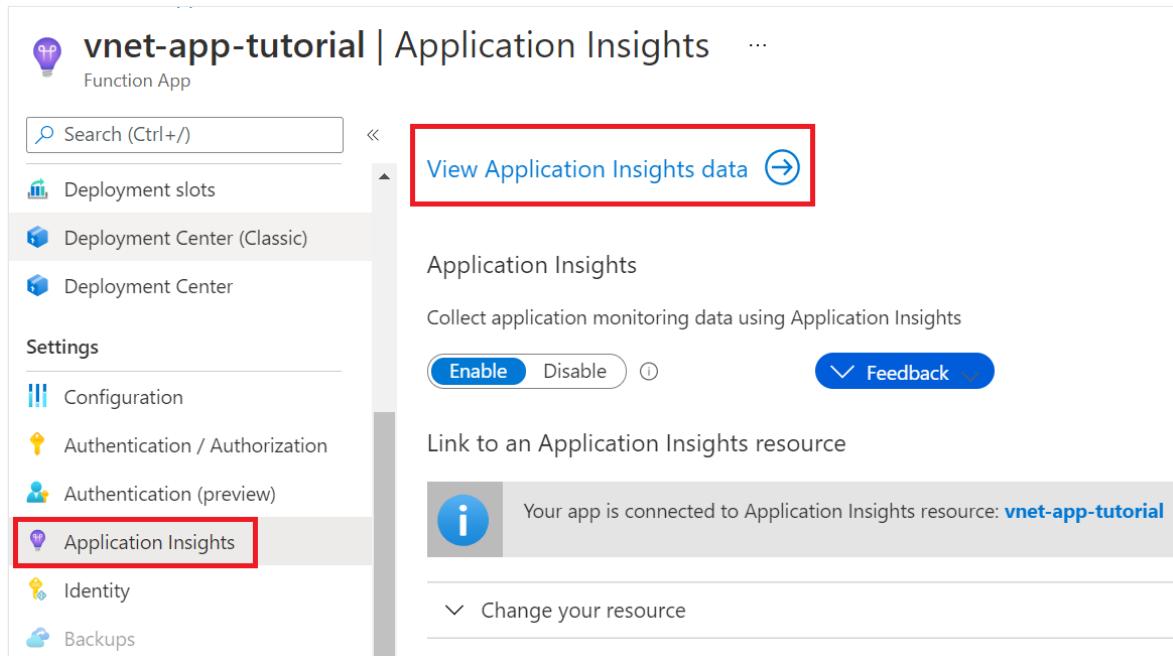

2. Select **ServiceBusQueueTrigger**.

3. In the menu on the left, select **Monitor**.

You see that you can't monitor your app. Your browser doesn't have access to the virtual network, so it can't directly access resources within the virtual network.

Here's an alternative way to monitor your function by using Application Insights:

1. In your function app, in the menu on the left, select **Application Insights**. Then select **View Application Insights data**.

2. In the menu on the left, select **Live metrics**.

3. Open a new tab. In your Service Bus, in the menu on the left, select **Queues**.

4. Select your queue.

5. In the menu on the left, select **Service Bus Explorer**. Under **Send**, for **Content Type**, choose **Text/Plain**. Then enter a message.

6. Select **Send** to send the message.

The screenshot shows the Service Bus Explorer interface for a queue named 'queue' under the namespace 'myServiceBus-tutorial'. The left sidebar contains navigation links for Overview, Access control (IAM), Diagnose and solve problems, Settings (with Shared access policies and Service Bus Explorer (preview) selected), Properties, Locks, Automation (Tasks (preview) and Export template), and Support + troubleshooting (New support request). The main area has tabs for Send, Receive, and Peek, with 'Send' selected. A form titled 'Send Message to Queue **queue**' is displayed, with 'Content Type *' set to 'Text/Plain' and the message body containing 'Hello World'. A red box highlights the message body input field. Below the message body is a checkbox for 'Expand Advanced Properties' and a section for 'Custom Properties' with two empty text fields for Name and Value. At the bottom is a large red-bordered 'Send' button.

- On the Live metrics tab, you should see that your Service Bus queue trigger has fired. If it hasn't, resend the message from Service Bus Explorer.

The screenshot shows the Application Insights Live metrics page for the 'vnet-app-tutorial' application. The left sidebar includes Overview, Activity log, Access control (IAM), Tags, Diagnose and solve problems, Investigate (Application map, Smart Detection, and Live metrics selected), Transaction search, and Availability. The main area displays 'Incoming Requests' and 'Outgoing Requests' metrics. On the right, the 'Sample telemetry' section shows a list of trace logs. One log entry is highlighted with a red box: '45502 AM | Trace @c221a34ce7ffe37...1462144ac5e60b2 C# ServiceBus queue trigger function processed message: Hello World'. This indicates the function was triggered by a message from the Service Bus queue.

Congratulations! You've successfully tested your function app setup with private endpoints.

Understand private DNS zones

You've used a private endpoint to connect to Azure resources. You're connecting to a private IP address instead of the public endpoint. Existing Azure services are configured to use an existing DNS to connect to the public endpoint. You must override the DNS configuration to connect to the private endpoint.

A private DNS zone is created for each Azure resource that was configured with a private endpoint. A DNS record is created for each private IP address associated with the

private endpoint.

The following DNS zones were created in this tutorial:

- privatelink.file.core.windows.net
- privatelink.blob.core.windows.net
- privatelink.servicebus.windows.net
- privatelink.azurewebsites.net

Clean up resources

In the preceding steps, you created Azure resources in a resource group. If you don't expect to need these resources in the future, you can delete them by deleting the resource group.

From the Azure portal menu or **Home** page, select **Resource groups**. Then, on the **Resource groups** page, select **myResourceGroup**.

On the **myResourceGroup** page, make sure that the listed resources are the ones you want to delete.

Select **Delete resource group**, type **myResourceGroup** in the text box to confirm, and then select **Delete**.

Next steps

In this tutorial, you created a Premium function app, storage account, and Service Bus. You secured all of these resources behind private endpoints.

Use the following links to learn more Azure Functions networking options and private endpoints:

Tutorial: Establish Azure Functions private site access

Article • 06/28/2022

This tutorial shows you how to enable [private site access](#) with Azure Functions. By using private site access, you can require that your function code is only triggered from a specific virtual network.

Private site access is useful in scenarios when access to the function app needs to be limited to a specific virtual network. For example, the function app may be applicable to only employees of a specific organization, or services which are within the specified virtual network (such as another Azure Function, Azure Virtual Machine, or an AKS cluster).

If a Functions app needs to access Azure resources within the virtual network, or connected via [service endpoints](#), then [virtual network integration](#) is needed.

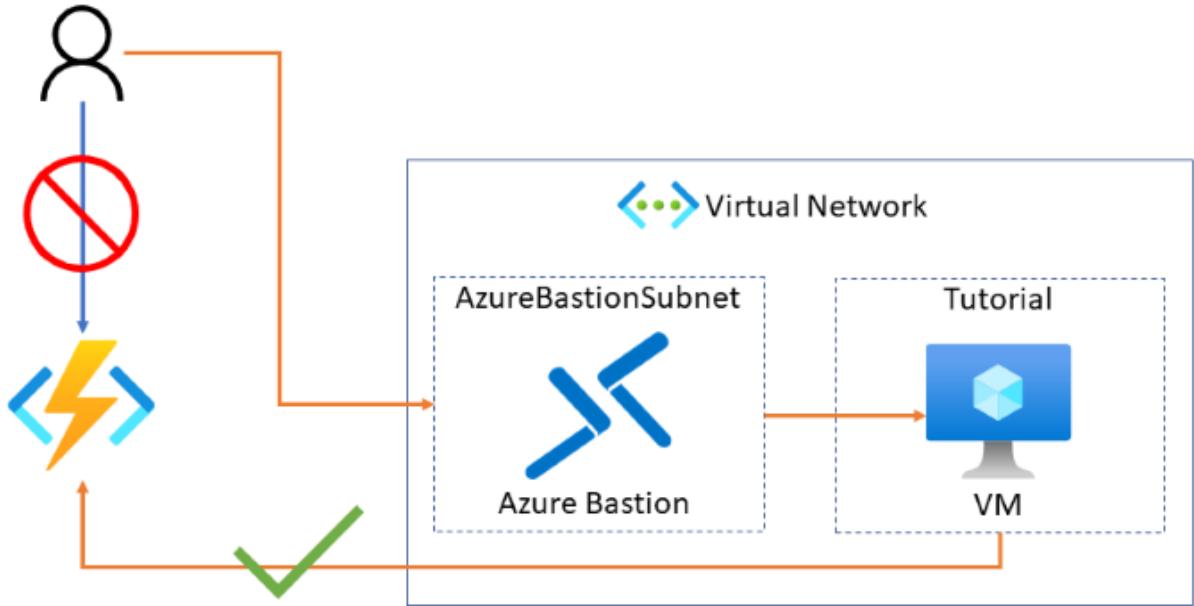

In this tutorial, you learn how to configure private site access for your function app:

- ✓ Create a virtual machine
- ✓ Create an Azure Bastion service
- ✓ Create an Azure Functions app
- ✓ Configure a virtual network service endpoint
- ✓ Create and deploy an Azure Function
- ✓ Invoke the function from outside and within the virtual network

If you don't have an Azure subscription, create a [free account](#) before you begin.

Topology

The following diagram shows the architecture of the solution to be created:

Prerequisites

For this tutorial, it's important that you understand IP addressing and subnetting. You can start with [this article that covers the basics of addressing and subnetting ↗](#). Many more articles and videos are available online.

Sign in to Azure portal

Sign in to the [Azure portal ↗](#).

Create a virtual machine

The first step in this tutorial is to create a new virtual machine inside a virtual network. The virtual machine will be used to access your function once you've restricted its access to only be available from within the virtual network.

1. Select the **Create a resource** button.
2. In the search field, type **Windows Server**, and select **Windows Server** in the search results.
3. Select **Windows Server 2019 Datacenter** from the list of Windows Server options, and press the **Create** button.
4. In the *Basics* tab, use the VM settings as specified in the table below the image:

Create a virtual machine

[Basics](#) [Disks](#) [Networking](#) [Management](#) [Advanced](#) [Tags](#) [Review + create](#)

Create a virtual machine that runs Linux or Windows. Select an image from Azure marketplace or use your own customized image.

Complete the Basics tab then Review + create to provision a virtual machine with default parameters or review each tab for full customization.

6. In *Create virtual network*, use the settings in the table below the image:

Create virtual network

The Microsoft Azure Virtual Network service enables Azure resources to securely communicate with each other in a virtual network which is a logical isolation of the Azure cloud dedicated to your subscription. You can connect virtual networks to other virtual networks, or your on-premises network. [Learn more](#)

Name * myResourceGroup-vnet

Address space
The virtual network's address space, specified as one or more address prefixes in CIDR notation (e.g. 192.168.1.0/24).

<input type="checkbox"/> Address range	Addresses	Overlap
<input type="checkbox"/> 10.10.0.0/16	10.10.0.0 - 10.10.255.255 (65536 addresses)	None
	(0 Addresses)	

Subnets
The subnet's address range in CIDR notation. It must be contained by the address space of the virtual network.

<input type="checkbox"/> Subnet name	Address range	Addresses
<input type="checkbox"/> Tutorial	10.10.1.0/24	10.10.1.0 - 10.10.1.255 (256 addresses)
		(0 Addresses)

OK **Discard**

Setting	Suggested value	Description
Name	myResourceGroup-vnet	You can use the default name generated for your virtual network.
Address range	10.10.0.0/16	Use a single address range for the virtual network.
Subnet name	Tutorial	Name of the subnet.
Address range (subnet)	10.10.1.0/24	The subnet size defines how many interfaces can be added to the subnet. This subnet is used by the VM. A /24 subnet provides 254 host addresses.

7. Select **OK** to create the virtual network.
8. Back in the *Networking* tab, ensure **None** is selected for *Public IP*.
9. Choose the *Management* tab, then in *Diagnostic storage account*, choose **Create new** to create a new Storage account.
10. Leave the default values for the *Identity*, *Auto-shutdown*, and *Backup* sections.
11. Select *Review + create*. After validation completes, select **Create**. The VM create process takes a few minutes.

Configure Azure Bastion

Azure Bastion [↗](#) is a fully managed Azure service which provides secure RDP and SSH access to virtual machines directly from the Azure portal. Using the Azure Bastion service removes the need to configure network settings related to RDP access.

1. In the portal, choose **Add** at the top of the resource group view.
2. In the search field, type **Bastion**.
3. Select **Bastion** in the search results.
4. Select **Create** to begin the process of creating a new Azure Bastion resource. You will notice an error message in the *Virtual network* section as there is not yet an AzureBastionSubnet subnet. The subnet is created in the following steps. Use the settings in the table below the image:

8. Select **Review & Create**. Once validation completes, select **Create**. It will take a few minutes for the Azure Bastion resource to be created.

Create an Azure Functions app

The next step is to create a function app in Azure using the [Consumption plan](#). You deploy your function code to this resource later in the tutorial.

1. In the portal, choose **Add** at the top of the resource group view.
2. Select **Compute > Function App**
3. On the *Basics* section, use the function app settings as specified in the table below.

Setting	Suggested value	Description
---------	-----------------	-------------

Setting	Suggested value	Description
<i>Resource Group</i>	myResourceGroup	Choose the resource group to contain all the resources for this tutorial. Using the same resource group for the function app and VM makes it easier to clean up resources when you're done with this tutorial.
<i>Function App name</i>	Globally unique name	Name that identifies your new function app. Valid characters are a-z (case insensitive), 0-9, and -.
<i>Publish</i>	Code	Option to publish code files or a Docker container.
<i>Runtime stack</i>	Preferred language	Choose a runtime that supports your favorite function programming language.
<i>Region</i>	North Central US	Choose a region near you or near other services your functions access.

Select the **Next: Hosting >** button.

4. For the *Hosting* section, select the proper *Storage account*, *Operating system*, and *Plan* as described in the following table.

Setting	Suggested value	Description
<i>Storage account</i>	Globally unique name	Create a storage account used by your function app. Storage account names must be between 3 and 24 characters in length and may contain numbers and lowercase letters only. You can also use an existing account, which must meet the storage account requirements .
<i>Operating system</i>	Preferred operating system	An operating system is pre-selected for you based on your runtime stack selection, but you can change the setting if necessary.
<i>Plan</i>	Consumption	The hosting plan dictates how the function app is scaled and resources available to each instance.

5. Select **Review + Create** to review the app configuration selections.

6. Select **Create** to provision and deploy the function app.

Configure access restrictions

The next step is to configure [access restrictions](#) to ensure only resources on the virtual network can invoke the function.

Private site access is enabled by creating an Azure Virtual Network service endpoint between the function app and the specified virtual network. Access restrictions are implemented via service endpoints. Service endpoints ensure only traffic originating from within the specified virtual network can access the designated resource. In this case, the designated resource is the Azure Function.

1. Within the function app, select the **Networking** link under the *Settings* section header.
2. The *Networking* page is the starting point to configure Azure Front Door, the Azure CDN, and also Access Restrictions.
3. Select **Configure Access Restrictions** to configure private site access.
4. On the *Access Restrictions* page, you see only the default restriction in place. The default doesn't place any restrictions on access to the function app. Select **Add rule** to create a private site access restriction configuration.
5. In the *Add Access Restriction* pane, provide a *Name*, *Priority*, and *Description* for the new rule.
6. Select **Virtual Network** from the *Type* drop-down box, then select the previously created virtual network, and then select the **Tutorial** subnet.

ⓘ Note

It may take several minutes to enable the service endpoint.

7. The *Access Restrictions* page now shows that there is a new restriction. It may take a few seconds for the *Endpoint status* to change from Disabled through Provisioning to Enabled.

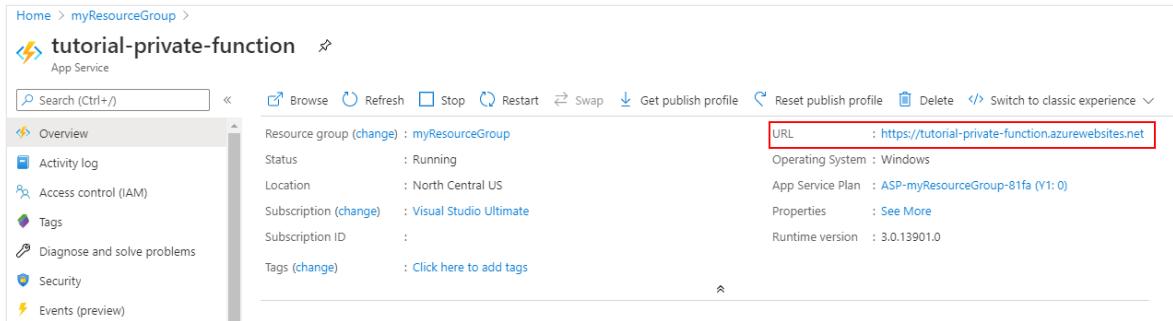

ⓘ Important

Each function app has an **Advanced Tool (Kudu) site** that is used to manage function app deployments. This site is accessed from a URL like:

`<FUNCTION_APP_NAME>.scm.azurewebsites.net`. Enabling access restrictions on the Kudu site prevents the deployment of the project code from a local developer workstation, and then an agent is needed within the virtual network to perform the deployment.

Access the functions app

1. Return to the previously created function app. In the *Overview* section, copy the URL.

The screenshot shows the Azure portal's overview page for an app service named 'tutorial-private-function'. The URL is highlighted with a red box: `https://tutorial-private-function.azurewebsites.net`. Other details shown include the resource group 'myResourceGroup', status 'Running', location 'North Central US', subscription 'Visual Studio Ultimate', and runtime version '3.0.13901.0'.

If you try to access the function app now from your computer outside of your virtual network, you'll receive an HTTP 403 page indicating that access is forbidden.

2. Return to the resource group and select the previously created virtual machine. In order to access the site from the VM, you need to connect to the VM via the Azure Bastion service.
3. Select **Connect** and then choose **Bastion**.
4. Provide the required username and password to log into the virtual machine.
5. Select **Connect**. A new browser window will pop up to allow you to interact with the virtual machine. It's possible to access the site from the web browser on the VM because the VM is accessing the site through the virtual network. While the site is only accessible from within the designated virtual network, a public DNS entry remains.

Create a function

The next step in this tutorial is to create an HTTP-triggered Azure Function. Invoking the function via an HTTP GET or POST should result in a response of "Hello, {name}".

1. Follow one of the following quickstarts to create and deploy your Azure Functions app.
 - [Visual Studio Code](#)
 - [Visual Studio](#)
 - [Command line](#)
 - [Maven \(Java\)](#)

- When publishing your Azure Functions project, choose the function app resource that you created earlier in this tutorial.
- Verify the function is deployed.

The screenshot shows the Azure portal's Functions blade. On the left, there's a sidebar with links: Overview, Activity log, Access control (IAM), Tags, Diagnose and solve problems, Security, Events (preview), Functions (which is selected and highlighted with a red box), App keys, App files, and Proxies. The main area lists functions: 'HttpTriggerCSharp1' (highlighted with a red box). It shows the trigger as 'HTTP' and the status as 'Enabled'. There are buttons for '+ Add', 'Develop Locally', 'Refresh', 'Enable', 'Disable', and 'Delete'.

Invoke the function directly

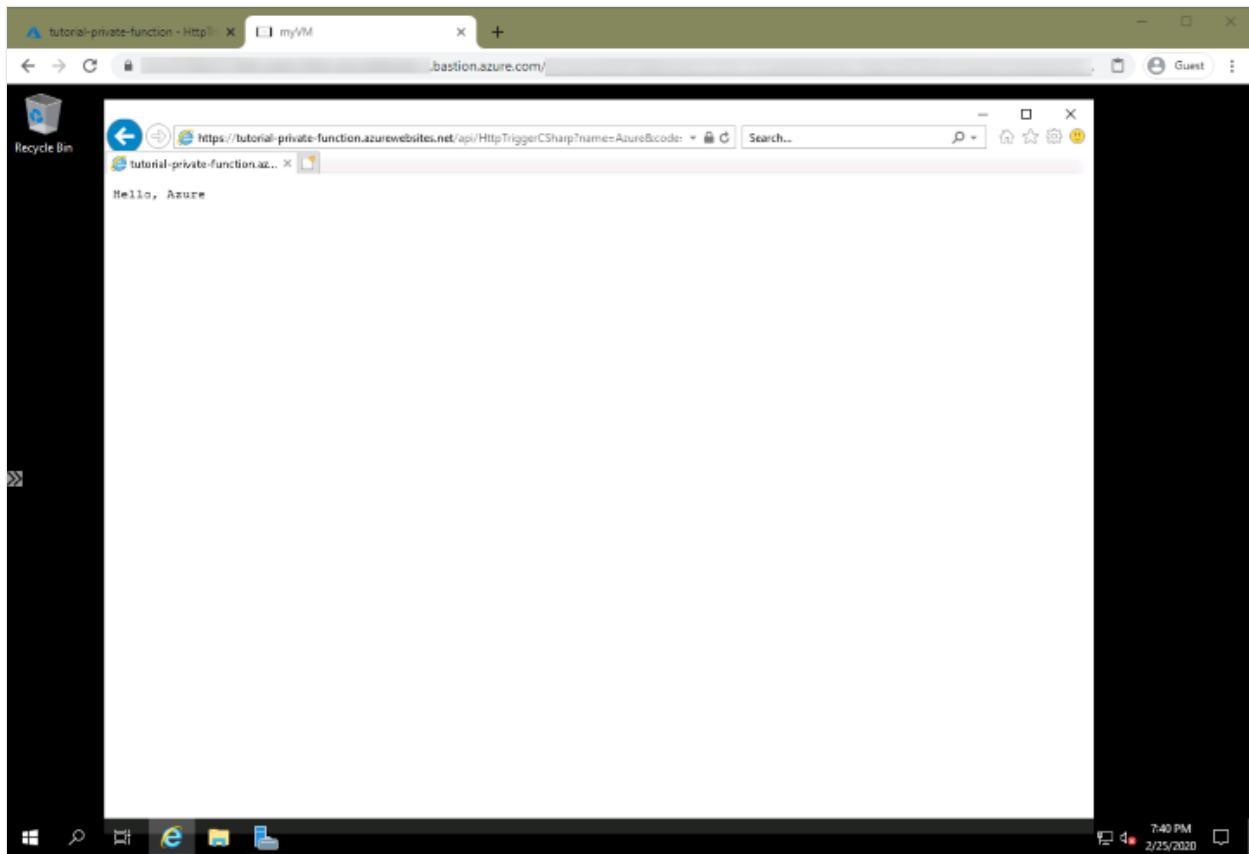

- In order to test access to the function, you need to copy the function URL. Select the deployed function, and then select **Get Function Url**. Then click the **Copy** button to copy the URL to your clipboard.

The screenshot shows the 'HttpTriggerCSharp1' function details page. In the top right, there's a 'Get Function Url' button (highlighted with a red box). Below it, a 'Get Function Url' dialog box is open, showing a dropdown menu set to 'default (function key)' and a long URL in the text input field. A red box highlights the URL in the input field. At the bottom of the dialog is an 'OK' button.

- Paste the URL into a web browser. When you now try to access the function app from a computer outside of your virtual network, you receive an HTTP 403 response indicating access to the app is forbidden.

Invoke the function from the virtual network

Accessing the function via a web browser (by using the Azure Bastion service) on the configured VM on the virtual network results in success!

Clean up resources

In the preceding steps, you created Azure resources in a resource group. If you don't expect to need these resources in the future, you can delete them by deleting the resource group.

From the Azure portal menu or **Home** page, select **Resource groups**. Then, on the **Resource groups** page, select **myResourceGroup**.

On the **myResourceGroup** page, make sure that the listed resources are the ones you want to delete.

Select **Delete resource group**, type **myResourceGroup** in the text box to confirm, and then select **Delete**.

Tutorial: Control Azure Functions outbound IP with an Azure virtual network NAT gateway

Article • 01/27/2023

Virtual network address translation (NAT) simplifies outbound-only internet connectivity for virtual networks. When configured on a subnet, all outbound connectivity uses your specified static public IP addresses. An NAT can be useful for apps that need to consume a third-party service that uses an allowlist of IP address as a security measure. To learn more, see [What is Azure NAT Gateway?](#).

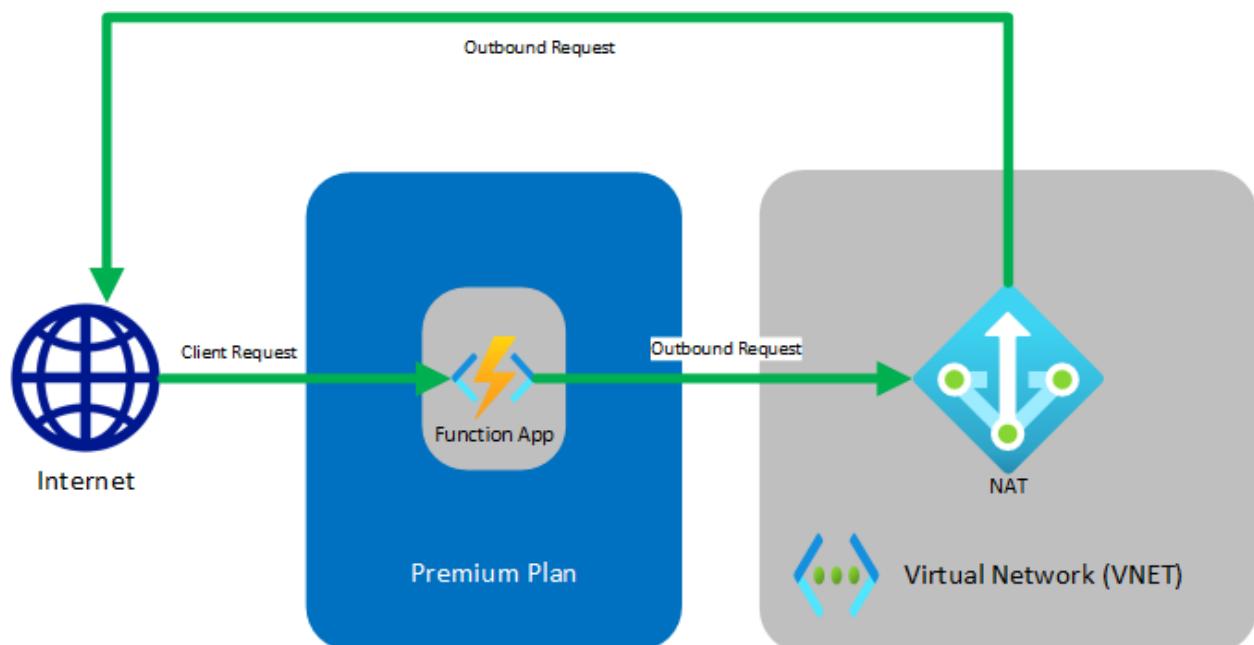

This tutorial shows you how to use NAT gateways to route outbound traffic from an HTTP triggered function. This function lets you check its own outbound IP address.

During this tutorial, you'll:

- ✓ Create a virtual network
- ✓ Create a Premium plan function app
- ✓ Create a public IP address
- ✓ Create a NAT gateway
- ✓ Configure function app to route outbound traffic through the NAT gateway

Topology

The following diagram shows the architecture of the solution that you create:

Functions running in the Premium plan have the same hosting capabilities as web apps in Azure App Service, which includes the VNet Integration feature. To learn more about VNet Integration, including troubleshooting and advanced configuration, see [Integrate your app with an Azure virtual network](#).

Prerequisites

For this tutorial, it's important that you understand IP addressing and subnetting. You can start with [this article that covers the basics of addressing and subnetting](#). Many more articles and videos are available online.

If you don't have an Azure subscription, create a [free account](#) before you begin.

If you've already completed the [integrate Functions with an Azure virtual network](#) tutorial, you can skip to [Create an HTTP trigger function](#).

Create a virtual network

1. From the Azure portal menu, select **Create a resource**. From the Azure Marketplace, select **Networking > Virtual network**.
2. In **Create virtual network**, enter or select the settings specified as shown in the following table:

Setting	Value
Subscription	Select your subscription.
Resource group	Select Create new , enter <i>myResourceGroup</i> , then select OK .
Name	Enter <i>myResourceGroup-vnet</i> .
Location	Select East US .

3. Select **Next: IP Addresses**, and for **IPv4 address space**, enter **10.10.0.0/16**.
4. Select **Add subnet**, then enter *Tutorial-Net* for **Subnet name** and **10.10.1.0/24** for **Subnet address range**.

Home > New > Virtual Network >

Create virtual network

Basics IP Addresses Security Tags Review + create

The virtual network's address space, specified as one or more address prefixes in CIDR notation (e.g. 192.168.1.0/24).

IPv4 address space

✓ Delete

Add IPv6 address space ⓘ

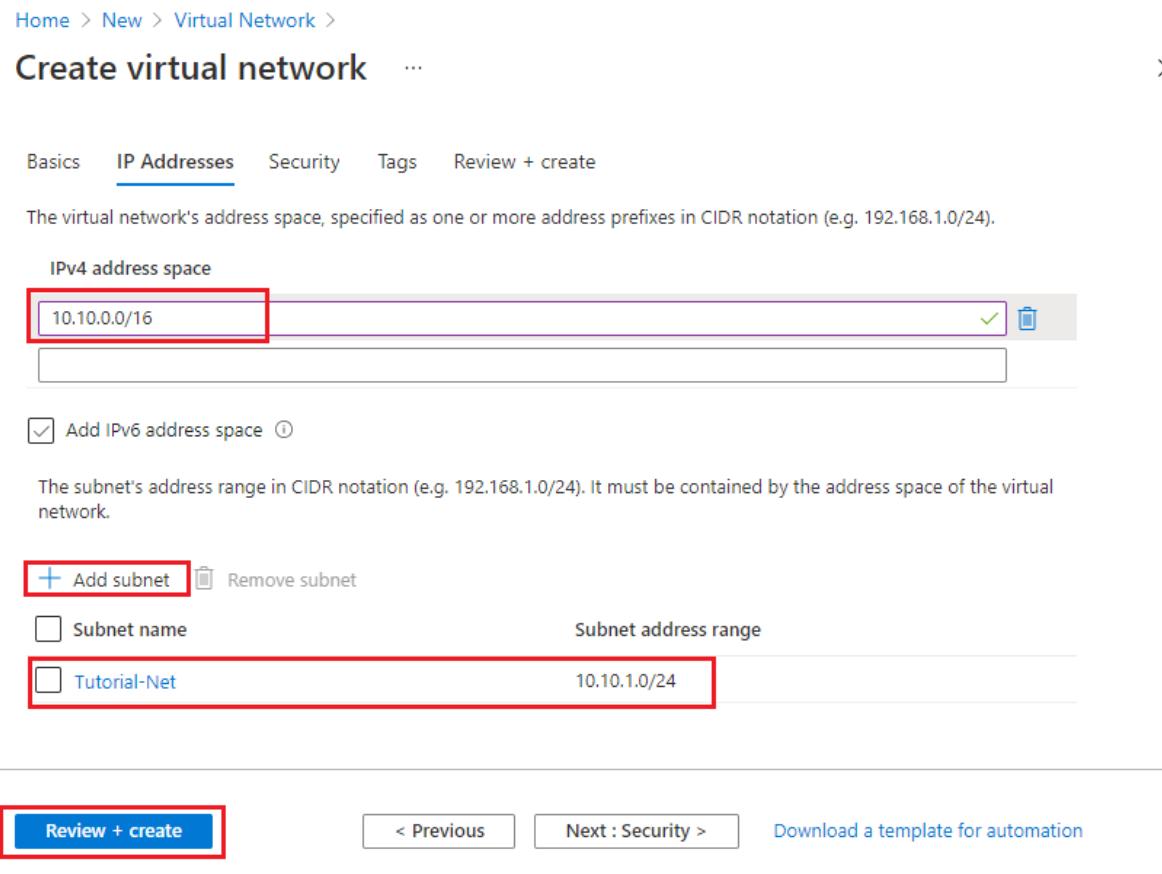

The subnet's address range in CIDR notation (e.g. 192.168.1.0/24). It must be contained by the address space of the virtual network.

+ Add subnet Remove subnet

Subnet name Subnet address range

10.10.1.0/24

Review + create < Previous Next : Security > Download a template for automation

5. Select **Add**, then select **Review + create**. Leave the rest as default and select **Create**.

6. In **Create virtual network**, select **Create**.

Next, you create a function app in the [Premium plan](#). This plan provides serverless scale while supporting virtual network integration.

Create a function app in a Premium plan

This tutorial shows you how to create your function app in a [Premium plan](#). The same functionality is also available when using a [Dedicated \(App Service\) plan](#).

Note

For the best experience in this tutorial, choose .NET for runtime stack and choose Windows for operating system. Also, create your function app in the same region as your virtual network.

1. From the Azure portal menu or the **Home** page, select **Create a resource**.
2. In the **New** page, select **Compute > Function App**.

3. On the **Basics** page, use the function app settings as specified in the following table:

Setting	Suggested value	Description
Subscription	Your subscription	The subscription under which this new function app is created.
Resource Group	<i>myResourceGroup</i>	Name for the new resource group in which to create your function app.
Function App name	Globally unique name	Name that identifies your new function app. Valid characters are <code>a-z</code> (case insensitive), <code>0-9</code> , and <code>-</code> .
Publish	Code	Option to publish code files or a Docker container.
Runtime stack	Preferred language	Choose a runtime that supports your favorite function programming language. In-portal editing isn't currently supported for Python development .
Region	Preferred region	Choose a region near you or near other services your functions access.

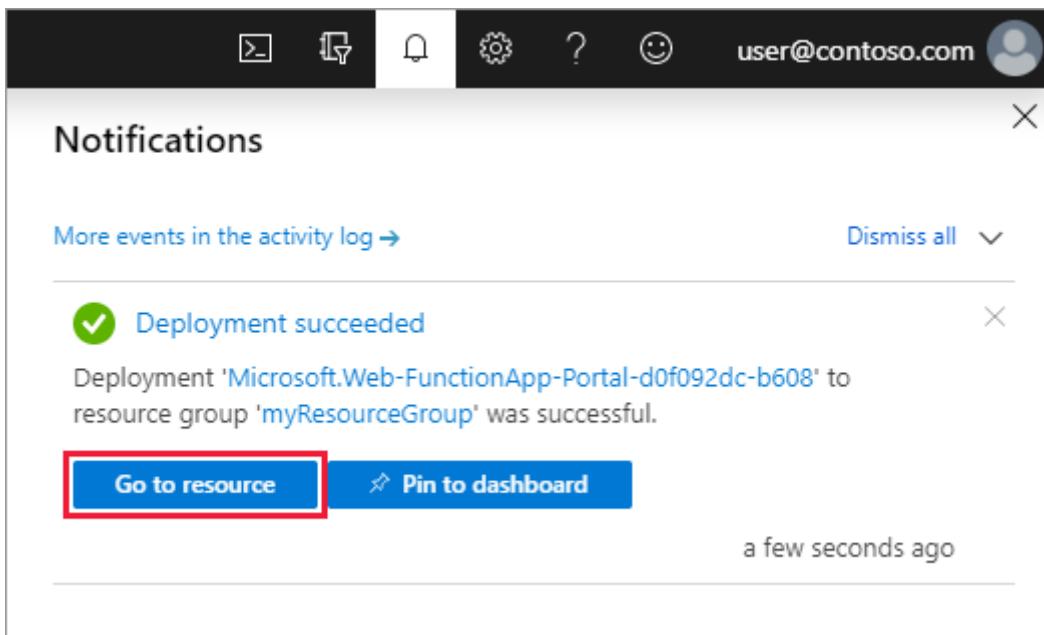

4. Select **Next: Hosting**. On the **Hosting** page, enter the following settings:

Setting	Suggested value	Description
Storage account	Globally unique name	Create a storage account used by your function app. Storage account names must be between 3 and 24 characters in length and may contain numbers and lowercase letters only. You can also use an existing account, which must meet the storage account requirements .
Operating system	Preferred operating system	An operating system is pre-selected for you based on your runtime stack selection, but you can change the setting if necessary. Python is only supported on Linux. In-portal editing is only supported on Windows.
Plan	Premium	Hosting plan that defines how resources are allocated to your function app. Select Premium . By default, a new App Service plan is created. The default Sku and size is EP1 , where EP stands for <i>elastic premium</i> . To learn more, see the list of Premium SKUs . When running JavaScript functions on a Premium plan, you should choose an instance that has fewer vCPUs. For more information, see Choose single-core Premium plans .

5. Select **Next: Monitoring**. On the **Monitoring** page, enter the following settings:

Setting	Suggested value	Description
Application Insights	Default	Creates an Application Insights resource of the same <i>App name</i> in the nearest supported region. By expanding this setting, you can change the New resource name or choose a different Location in an Azure geography to store your data.

6. Select **Review + create** to review the app configuration selections.
7. On the **Review + create** page, review your settings, and then select **Create** to provision and deploy the function app.
8. Select the **Notifications** icon in the upper-right corner of the portal and watch for the **Deployment succeeded** message.
9. Select **Go to resource** to view your new function app. You can also select **Pin to dashboard**. Pinning makes it easier to return to this function app resource from your dashboard.

Connect your function app to the virtual network

You can now connect your function app to the virtual network.

1. In your function app, select **Networking** in the left menu, then under **VNet Integration**, select **Click here to configure**.

function-vnet | Networking

Function App

Search (Ctrl+ /)

Settings

- Configuration
- Authentication / Authorization
- Authentication (preview)

10.10.2.0/24

SUBNET NAME

ADDRESS RANGE

Tutorial-Net

10.10.1.0 - 10.10.1.255

OK

Setting	Suggested value	Description
Virtual Network	MyResourceGroup-vnet	This virtual network is the one you created earlier.
Subnet	Create New Subnet	Create a subnet in the virtual network for your function app to use. VNet Integration must be configured to use an empty subnet.
Subnet name	Function-Net	Name of the new subnet.
Virtual network address block	10.10.0.0/16	You should only have one address block defined.
Subnet Address Block	10.10.2.0/24	The subnet size restricts the total number of instances that your Premium plan function app can scale out to. This example uses a /24 subnet with 254 available host addresses. This subnet is over-provisioned, but easy to calculate.

4. Select **OK** to add the subnet. Close the **VNet Integration** and **Network Feature Status** pages to return to your function app page.

The function app can now access the virtual network. When connectivity is enabled, the `vnetrouteallenabled` site setting is set to `1`. You must have either this site setting or the legacy `WEBSITE_VNET_ROUTE_ALL` application setting set to `1`.

Next, you'll add an HTTP-triggered function to the function app.

Create an HTTP trigger function

1. From the left menu of the **Functions** window, select **Functions**, then select **Add** from the top menu.
2. From the **New Function** window, select **Http trigger** and accept the default name for **New Function**, or enter a new name.
3. In **Code + Test**, replace the template-generated C# script (.csx) code with the following code:

```
C#  
  
#r "Newtonsoft.Json"  
  
using System.Net;  
using Microsoft.AspNetCore.Mvc;  
using Microsoft.Extensions.Primitives;  
using Newtonsoft.Json;  
  
public static async Task<IActionResult> Run(HttpContext req, ILogger log)  
{  
    log.LogInformation("C# HTTP trigger function processed a  
request.");  
  
    var client = new HttpClient();  
    var response = await client.GetAsync("https://ifconfig.me");  
    var responseMessage = await response.Content.ReadAsStringAsync();  
  
    return new OkObjectResult(responseMessage);  
}
```

This code calls an external website that returns the IP address of the caller, which in this case is this function. This method lets you easily determine the outbound IP address being used by your function app.

Now you're ready to run the function and check the current outbound IPs.

Verify current outbound IPs

Now, you can run the function. But first, check in the portal and see what outbound IPs are being used by the function app.

1. In your function app, select **Properties** and review the **Outbound IP Addresses** field.

The screenshot shows the 'natdemo' Function App Properties page. The 'Properties' section is highlighted with a red box. Under 'Outbound IP addresses', a list of IP addresses is shown: 52.191.224.90, 52.191.224.96, 52.191.224.105, 52.191.224.124, 52.191.224.131, and 52.191.224.176.

2. Now, return to your HTTP trigger function, select **Code + Test** and then **Test/Run**.

The screenshot shows the 'IpCheck' function's 'Code + Test' page. The 'Code + Test' section is highlighted with a red box. The 'Test/Run' button is also highlighted with a red box. The code editor shows a C# file named 'run.csx'.

```
1 #r "Newtonsoft.Json"
2
3 using System.Net;
4 using Microsoft.AspNetCore.Mvc;
5 using Microsoft.Extensions.Primitives;
6 using Newtonsoft.Json;
7
8 public static async Task<IActionResult> Run(
```

3. Select **Run** to execute the function, then switch to the **Output**.

Input	Output
HTTP response code	200 OK
HTTP response content	52.191.224.124

4. Verify that IP address in the HTTP response body is one of the values from the outbound IP addresses you viewed earlier.

Now, you can create a public IP and use a NAT gateway to modify this outbound IP address.

Create public IP

1. From your resource group, select **Add**, search the Azure Marketplace for **Public IP address**, and select **Create**. Use the settings in the table below the image:

Create public IP address

IPv4 IPv6 Both

SKU * ⓘ

Standard Basic

Tier

Setting	Suggested value
Name	Outbound-IP
Subscription	ensure your subscription is displayed
Resource group	myResourceGroup (or name you assigned to your resource group)
Location	East US (or location you assigned to your other resources)
Availability Zone	No Zone

2. Select **Create** to submit the deployment.
3. Once the deployment completes, navigate to your newly created Public IP Address resource and view the IP Address in the **Overview**.

The screenshot shows the Azure portal interface for a Public IP address named "Outbound-IP". The "Overview" tab is selected, indicated by a red box. The "Essentials" section displays the following details:

- Resource group (change) : myResourceGroup
- Location : East US
- Subscription (change) : kbmicrosoft vs ent dev
- Subscription ID : [redacted]
- SKU : Standard
- Tier : Regional
- IP address : 52.170.234.218 (highlighted with a red box)
- DNS name : -
- Associated to : -

On the left sidebar, other tabs like "Activity log", "Access control (IAM)", and "Tags" are visible, but "Overview" is the active tab.

Create NAT gateway

Now, let's create the NAT gateway. When you start with the [previous virtual networking tutorial](#), `Function-Net` was the suggested subnet name and `MyResourceGroup-vnet` was the suggested virtual network name in that tutorial.

1. From your resource group, select **Add**, search the Azure Marketplace for **NAT gateway**, and select **Create**. Use the settings in the table below the image to populate the **Basics** tab:

Create network address translation (NAT) gateway

[Basics](#) [Outbound IP](#) [Subnet](#) [Tags](#) [Review + create](#)

Azure NAT gateway can be used to translate outbound flows from a virtual network to the public internet.
[Learn more about NAT gateways.](#)

Project details

Select a subscription to manage deployed resources and costs. Use resource groups like folders to organize and manage all your resources.

Setting	Suggested value
Subscription	Your subscription
Resource group	myResourceGroup (or name you assigned to your resource group)
NAT gateway name	myNatGateway
Region	East US (or location you assigned to your other resources)
Availability Zone	None

2. Select Next: Outbound IP. In the Public IP addresses field, select the previously created public IP address. Leave Public IP Prefixes unselected.
3. Select Next: Subnet. Select the *myResourceGroup-vnet* resource in the Virtual network field and *Function-Net* subnet.

Create network address translation (NAT) gateway ...

Basics Outbound IP **Subnet** Tags Review + create

Configure which subnets of a virtual network should use this NAT gateway. Subnets with Basic load balancers or virtual machines that are using a Basic public IP are not compatible and cannot be used.

Note: While you do not have to complete this step to create a NAT gateway, the NAT gateway will not be functional until you have added at least one subnet. You can also add and reconfigure which subnets are included after creating the NAT gateway.

Virtual network ⓘ

myResourceGroup-vnet

Create new

Subnets having IPv6 address spaces or associated to other NAT gateways are not included.

Subnet name	Subnet address range
Tutorial-Net	10.10.1.0/24
<input checked="" type="checkbox"/> Function-Net	10.10.2.0/24

Manage subnets >

4. Select **Review + Create** then **Create** to submit the deployment.

Once the deployment completes, the NAT gateway is ready to route traffic from your function app subnet to the Internet.

Verify new outbound IPs

Repeat [the steps earlier](#) to run the function again. You should now see the outbound IP address that you configured in the NAT shown in the function output.

Clean up resources

You created resources to complete this tutorial. You'll be billed for these resources, depending on your [account status](#) and [service pricing](#). To avoid incurring extra costs, delete the resources when you no longer need them.

1. In the Azure portal, go to the **Resource group** page.

To get to that page from the function app page, select the **Overview** tab, and then select the link under **Resource group**.

The screenshot shows the Azure portal interface for an App Service application named "myfunctionapp". The left sidebar has a "Functions" section with options like "Functions", "App keys", "App files", and "Proxies". The main content area is titled "Overview" and shows details about the resource group "myResourceGroup". The "Resource group (change)" section is highlighted with a red box. Key details shown include:

- Status: Running
- Location: Central US
- Subscription: Visual Studio Enterprise
- Subscription ID: 11111111-1111-1111-1111-111111111111
- Tags: Click here to add tags
- Metrics (selected)
- Features (8)
- Notifications (0)
- Quickstart

The URL listed is <https://myfunctionapp.azurewebsites.net>.

To get to that page from the dashboard, select **Resource groups**, and then select the resource group that you used for this article.

2. In the **Resource group** page, review the list of included resources, and verify that they're the ones you want to delete.
3. Select **Delete resource group** and follow the instructions.

Deletion might take a couple of minutes. When it's done, a notification appears for a few seconds. You can also select the bell icon at the top of the page to view the notification.

Next steps

[Azure Functions networking options](#)

Tutorial: Create a function app that connects to Azure services using identities instead of secrets

Article • 06/27/2024

This tutorial shows you how to configure a function app using Microsoft Entra identities instead of secrets or connection strings, where possible. Using identities helps you avoid accidentally leaking sensitive secrets and can provide better visibility into how data is accessed. To learn more about identity-based connections, see [configure an identity-based connection](#).

While the procedures shown work generally for all languages, this tutorial currently supports C# class library functions on Windows specifically.

In this tutorial, you learn how to:

- ✓ Create a function app in Azure using an ARM template
- ✓ Enable both system-assigned and user-assigned managed identities on the function app
- ✓ Create role assignments that give permissions to other resources
- ✓ Move secrets that can't be replaced with identities into Azure Key Vault
- ✓ Configure an app to connect to the default host storage using its managed identity

After you complete this tutorial, you should complete the follow-on tutorial that shows how to [use identity-based connections instead of secrets with triggers and bindings].

Prerequisites

- An Azure account with an active subscription. [Create an account for free](#).
- The [.NET 6.0 SDK](#)
- The [Azure Functions Core Tools](#) version 4.x.

Why use identity?

Managing secrets and credentials is a common challenge for teams of all sizes. Secrets need to be secured against theft or accidental disclosure, and they might need to be periodically rotated. Many Azure services allow you to instead use an identity in [Microsoft Entra ID](#) to authenticate clients and check against permissions, which can be

modified and revoked quickly. Doing so allows for greater control over application security with less operational overhead. An identity could be a human user, such as the developer of an application, or a running application in Azure with a [managed identity](#).

Because some services don't support Microsoft Entra authentication, your applications might still require secrets in certain cases. However, these secrets can be stored in [Azure Key Vault](#), which helps simplify the management lifecycle for your secrets. Access to a key vault is also controlled with identities.

By understanding how to use identities instead of secrets when you can, and to use Key Vault when you can't, you reduce risk, decrease operational overhead, and generally improve the security posture for your applications.

Create a function app that uses Key Vault for necessary secrets

Azure Files is an example of a service that doesn't yet support Microsoft Entra authentication for Server Message Block (SMB) file shares. Azure Files is the default file system for Windows deployments on Premium and Consumption plans. While we could [remove Azure Files entirely](#), doing so introduces limitations you might not want. Instead, you move the Azure Files connection string into Azure Key Vault. That way it's centrally managed, with access controlled by the identity.

Create an Azure Key Vault

First you need a key vault to store secrets in. You configure it to use [Azure role-based access control \(RBAC\)](#) for determining who can read secrets from the vault.

1. In the [Azure portal](#), choose **Create a resource (+)**.
2. On the **Create a resource** page, select **Security > Key Vault**.
3. On the **Basics** page, use the following table to configure the key vault.

[] [Expand table](#)

Option	Suggested value	Description
Subscription	Your subscription	Subscription under which this new function app is created.
Resource Group	myResourceGroup	Name for the new resource group where you create your function app.

Option	Suggested value	Description
Key vault name	Globally unique name	Name that identifies your new key vault. The vault name must only contain alphanumeric characters and dashes and can't start with a number.
Pricing Tier	Standard	Options for billing. Standard is sufficient for this tutorial.
Region	Preferred region	Choose a region near you or near other services that your functions access.

Use the default selections for the "Recovery options" sections.

4. Make a note of the name you used, for use later.
5. Select **Next: Access Policy** to navigate to the **Access Policy** tab.
6. Under **Permission model**, choose **Azure role-based access control**
7. Select **Review + create**. Review the configuration, and then select **Create**.

Set up an identity and permissions for the app

In order to use Azure Key Vault, your app needs to have an identity that can be granted permission to read secrets. This app uses a user-assigned identity so that the permissions can be set up before the app is even created. For more information about managed identities for Azure Functions, see [How to use managed identities in Azure Functions](#).

1. In the [Azure portal](#), choose **Create a resource (+)**.
2. On the **Create a resource** page, select **Identity > User Assigned Managed Identity**.
3. On the **Basics** page, use the following table to configure the identity.

[] Expand table

Option	Suggested value	Description
Subscription	Your subscription	Subscription under which this new function app is created.
Resource Group	myResourceGroup	Name for the new resource group where you create your function app.

Option	Suggested value	Description
Region	Preferred region	Choose a region near you or near other services that your functions access.
Name	Globally unique name	Name that identifies your new user-assigned identity.

4. Select **Review + create**. Review the configuration, and then select **Create**.
5. When the identity is created, navigate to it in the portal. Select **Properties**, and make note of the **Resource ID** for use later.
6. Select **Azure Role Assignments**, and select **Add role assignment (Preview)**.
7. In the **Add role assignment (Preview)** page, use options as shown in the following table.

[\[+\] Expand table](#)

Option	Suggested value	Description
Scope	Key Vault	Scope is a set of resources that the role assignment applies to. Scope has levels that are inherited at lower levels. For example, if you select a subscription scope, the role assignment applies to all resource groups and resources in the subscription.
Subscription	Your subscription	Subscription under which this new function app is created.
Resource	Your key vault	The key vault you created earlier.
Role	Key Vault Secrets User	A role is a collection of permissions that are being granted. Key Vault Secrets User gives permission for the identity to read secret values from the vault.

8. Select **Save**. It might take a minute or two for the role to show up when you refresh the role assignments list for the identity.

The identity is now able to read secrets stored in the key vault. Later in the tutorial, you add additional role assignments for different purposes.

Generate a template for creating a function app

Because the portal experience for creating a function app doesn't interact with Azure Key Vault, you need to generate and edit an Azure Resource Manager template. You can then use this template to create your function app referencing the Azure Files connection string from your key vault.

ⓘ Important

Don't create the function app until after you edit the ARM template. The Azure Files configuration needs to be set up at app creation time.

1. In the [Azure portal](#), choose **Create a resource (+)**.
2. On the **Create a resource** page, select **Compute > Function App**.
3. On the **Basics** page, use the following table to configure the function app.

[\[+\] Expand table](#)

Option	Suggested value	Description
Subscription	Your subscription	Subscription under which this new function app is created.
Resource Group	myResourceGroup	Name for the new resource group where you create your function app.
Function App name	Globally unique name	Name that identifies your new function app. Valid characters are <code>a-z</code> (case insensitive), <code>0-9</code> , and <code>-</code> .
Publish	Code	Choose to publish code files or a Docker container.
Runtime stack	.NET	This tutorial uses .NET.
Region	Preferred region	Choose a region near you or near other services that your functions access.

4. Select **Review + create**. Your app uses the default values on the **Hosting** and **Monitoring** page. Review the default options, which are included in the ARM template that you generate.
5. Instead of creating your function app here, choose **Download a template for automation**, which is to the right of the **Next** button.
6. In the template page, select **Deploy**, then in the Custom deployment page, select **Edit template**.

The screenshot shows the Azure Resource Manager template editor interface. At the top, there are buttons for 'Download', 'Add to library (preview)', 'Deploy' (which is highlighted with a red box), and 'Visualize template'. Below this, a note says 'Automate deploying resources with Azure Resource Manager templates in a single, coordinated operation. Define resources and configurable input parameters and deploy with script or code. Learn more about template deployment.' There is a checked checkbox for 'Include parameters'. The main area shows a JSON template with sections for 'Template', 'Parameters', and 'Scripts'. The 'Template' section contains code starting with '1 {', '2 "schema": "http://schema.management.azure.com/schemas/2015-01-01/deploymentTemplate.json#"', '3 "contentVersion": "1.0.0.0"', '4 "parameters": {', '5 "subscriptionId": {', '6 "type": "string"'.

Edit the template

You now edit the template to store the Azure Files connection string in Key Vault and allow your function app to reference it. Make sure that you have the following values from the earlier sections before proceeding:

- The resource ID of the user-assigned identity
- The name of your key vault

ⓘ Note

If you were to create a full template for automation, you would want to include definitions for the identity and role assignment resources, with the appropriate `dependsOn` clauses. This would replace the earlier steps which used the portal.

Consult the [Azure Resource Manager guidance](#) and the documentation for each service.

1. In the editor, find where the `resources` array begins. Before the function app definition, add the following section, which puts the Azure Files connection string into Key Vault. Substitute "VAULT_NAME" with the name of your key vault.

JSON

```
{  
  "type": "Microsoft.KeyVault/vaults/secrets",  
  "apiVersion": "2016-10-01",  
  "name": "VAULT_NAME/azurefilesconnectionstring",  
  "properties": {  
    "value": "  
[concat('DefaultEndpointsProtocol=https;AccountName=',parameters('storageAccountName'),';AccountKey=',listKeys(resourceId('Microsoft.Storage/storageAccounts', parameters('storageAccountName')),'2019-06-01').keys[0].value,';EndpointSuffix=','core.windows.net')]"  
  },  
  "dependsOn": [  
    "[concat('Microsoft.Storage/storageAccounts/',  
    parameters('storageAccountName'))]"
```

```
    ],  
},
```

2. In the definition for the function app resource (which has `type` set to `Microsoft.Web/sites`), add `Microsoft.KeyVault/vaults/VAULT_NAME/secrets/azurefilesconnectionstring` to the `dependsOn` array. Again, substitute "VAULT_NAME" with the name of your key vault. Doing so prevents your app from being created before the secret is defined. The `dependsOn` array should look like the following example:

JSON

```
{  
  "type": "Microsoft.Web/sites",  
  "apiVersion": "2018-11-01",  
  "name": "[parameters('name')]",  
  "location": "[parameters('location')]",  
  "tags": null,  
  "dependsOn": [  
    "microsoft.insights/components/idxxntut",  
  
    "Microsoft.KeyVault/vaults/VAULT_NAME/secrets/azurefilesconnectionstring",  
    "[concat('Microsoft.Web/serverfarms/',  
    parameters('hostingPlanName'))]",  
    "[concat('Microsoft.Storage/storageAccounts/',  
    parameters('storageAccountName'))]"  
  ],  
  // ...  
}
```

3. Add the `identity` block from the following example into the definition for your function app resource. Substitute "IDENTITY_RESOURCE_ID" for the resource ID of your user-assigned identity.

JSON

```
{  
  "apiVersion": "2018-11-01",  
  "name": "[parameters('name')]",  
  "type": "Microsoft.Web/sites",  
  "kind": "functionapp",  
  "location": "[parameters('location')]",  
  "identity": {  
    "type": "SystemAssigned,UserAssigned",  
    "userAssignedIdentities": {  
      "IDENTITY_RESOURCE_ID": {}  
    }  
  },  
},
```

```
    "tags": null,  
    // ...  
}
```

This `identity` block also sets up a system-assigned identity, which you use later in this tutorial.

4. Add the `keyVaultReferenceIdentity` property to the `properties` object for the function app, as in the following example. Substitute "IDENTITY_RESOURCE_ID" for the resource ID of your user-assigned identity.

JSON

```
{  
    // ...  
    "properties": {  
        "name": "[parameters('name')]",  
        "keyVaultReferenceIdentity": "IDENTITY_RESOURCE_ID",  
        // ...  
    }  
}
```

You need this configuration because an app could have multiple user-assigned identities configured. Whenever you want to use a user-assigned identity, you must specify it with an ID. System-assigned identities don't need to be specified this way, because an app can only ever have one. Many features that use managed identity assume they should use the system-assigned one by default.

5. Find the JSON objects that define the `WEBSITE_CONTENTAZUREFILECONNECTIONSTRING` application setting, which should look like the following example:

JSON

```
{  
    "name": "WEBSITE_CONTENTAZUREFILECONNECTIONSTRING",  
    "value": "  
[concat('DefaultEndpointsProtocol=https;AccountName=',parameters('storageAccountName'),';AccountKey=',listKeys(resourceId('Microsoft.Storage/storageAccounts', parameters('storageAccountName'))), '2019-06-01').keys[0].value,';EndpointSuffix=' , 'core.windows.net')]"  
},
```

6. Replace the `value` field with a reference to the secret as shown in the following example. Substitute "VAULT_NAME" with the name of your key vault.

JSON

```
{  
    "name": "WEBSITE_CONTENTAZUREFILECONNECTIONSTRING",  
    "value": "[concat('@Microsoft.KeyVault(SecretUri=',  
reference(resourceId('Microsoft.KeyVault/vaults/secrets', 'VAULT_NAME',  
'azurefilesconnectionstring')).secretUri, ')')]"  
},
```

7. Select **Save** to save the updated ARM template.

Deploy the modified template

1. Make sure that your create options, including **Resource Group**, are still correct and select **Review + create**.
2. After your template validates, make a note of your **Storage Account Name**, since you'll use this account later. Finally, select **Create** to create your Azure resources and deploy your code to the function app.
3. After deployment completes, select **Go to resource group** and then select the new function app.

Congratulations! You've successfully created your function app to reference the Azure Files connection string from Azure Key Vault.

Whenever your app would need to add a reference to a secret, you would just need to define a new application setting pointing to the value stored in Key Vault. For more information, see [Key Vault references for Azure Functions](#).

💡 Tip

The [Application Insights connection string](#) and its included instrumentation key are not considered secrets and can be retrieved from App Insights using [Reader](#) permissions. You do not need to move them into Key Vault, although you certainly can.

Use managed identity for AzureWebJobsStorage

Next, you use the system-assigned identity you configured in the previous steps for the `AzureWebJobsStorage` connection. `AzureWebJobsStorage` is used by the Functions runtime and by several triggers and bindings to coordinate between multiple running instances.

It's required for your function app to operate, and like Azure Files, is configured with a connection string by default when you create a new function app.

Grant the system-assigned identity access to the storage account

Similar to the steps you previously followed with the user-assigned identity and your key vault, you now create a role assignment granting the system-assigned identity access to your storage account.

1. In the [Azure portal](#), navigate to the storage account that was created with your function app earlier.
2. Select **Access Control (IAM)**. This page is where you can view and configure who has access to the resource.
3. Select **Add** and select **add role assignment**.
4. Search for **Storage Blob Data Owner**, select it, and select **Next**
5. On the **Members** tab, under **Assign access to**, choose **Managed Identity**
6. Select **Select members** to open the **Select managed identities** panel.
7. Confirm that the **Subscription** is the one in which you created the resources earlier.
8. In the **Managed identity** selector, choose **Function App** from the **System-assigned managed identity** category. The **Function App** label might have a number in parentheses next to it, indicating the number of apps in the subscription with system-assigned identities.
9. Your app should appear in a list below the input fields. If you don't see it, you can use the **Select** box to filter the results with your app's name.
10. Select your application. It should move down into the **Selected members** section. Choose **Select**.
11. On the **Add role assignment** screen, select **Review + assign**. Review the configuration, and then select **Review + assign**.

Tip

If you intend to use the function app for a blob-triggered function, you will need to repeat these steps for the **Storage Account Contributor** and **Storage Queue Data**

Contributor roles over the account used by AzureWebJobsStorage. To learn more, see [Blob trigger identity-based connections](#).

Edit the AzureWebJobsStorage configuration

Next you update your function app to use its system-assigned identity when it uses the blob service for host storage.

Important

The `AzureWebJobsStorage` configuration is used by some triggers and bindings, and those extensions must be able to use identity-based connections, too. Apps that use blob triggers or event hub triggers may need to update those extensions. Because no functions have been defined for this app, there isn't a concern yet. To learn more about this requirement, see [Connecting to host storage with an identity](#).

Similarly, `AzureWebJobsStorage` is used for deployment artifacts when using server-side build in Linux Consumption. When you enable identity-based connections for `AzureWebJobsStorage` in Linux Consumption, you will need to deploy via [an external deployment package](#).

1. In the [Azure portal](#), navigate to your function app.
2. In your function app, expand **Settings**, and then select **Environment variables**.
3. In the **App settings** tab, select the **AzureWebJobsStorage** app setting, and edit it according to the following table:

 Expand table

Option	Suggested value	Description
Name	<code>AzureWebJobsStorage__accountName</code>	Change the name from <code>AzureWebJobsStorage</code> to the exact name <code>AzureWebJobsStorage__accountName</code> . This setting instructs the host to use the identity instead of searching for a stored secret. The new setting uses a double underscore (<code>__</code>), which is a special character in application settings.

Option	Suggested value	Description
Value	Your account name	Update the name from the connection string to just your StorageAccountName.

This configuration tells the system to use an identity to connect to the resource.

4. Select **Apply**, and then select **Apply** and **Confirm** to save your changes and restart the app function.

You've now removed the storage connection string requirement for AzureWebJobsStorage by configuring your app to instead connect to blobs using managed identities.

 **Note**

The `__accountName` syntax is unique to the AzureWebJobsStorage connection and cannot be used for other storage connections. To learn to define other connections, check the reference for each trigger and binding your app uses.

Next steps

This tutorial showed how to create a function app without storing secrets in its configuration.

Advance to the next tutorial to learn how to use identities in trigger and binding connections.

Tutorial: Use identity-based connections instead of secrets with triggers and bindings

Article • 07/02/2024

This tutorial shows you how to configure Azure Functions to connect to Azure Service Bus queues by using managed identities, instead of secrets stored in the function app settings. The tutorial is a continuation of the [Create a function app without default storage secrets in its definition](#) tutorial. To learn more about identity-based connections, see [Configure an identity-based connection..](#)

While the procedures shown work generally for all languages, this tutorial currently supports C# class library functions on Windows specifically.

In this tutorial, you learn how to:

- ✓ Create a Service Bus namespace and queue.
- ✓ Configure your function app with a managed identity.
- ✓ Create a role assignment granting that identity permission to read from the Service Bus queue.
- ✓ Create and deploy a function app with a Service Bus trigger.
- ✓ Verify your identity-based connection to the Service Bus.

Prerequisite

Complete the previous tutorial: [Create a function app with identity-based connections](#).

Create a Service Bus namespace and queue

1. In the [Azure portal](#), choose **Create a resource (+)**.
2. On the **Create a resource** page, search for and select **Service Bus**, and then select **Create**.
3. On the **Basics** page, use the following table to configure the Service Bus namespace settings. Use the default values for the remaining options.

 Expand table

Option	Suggested value	Description
Subscription	Your subscription	The subscription under which your resources are created.
Resource group	myResourceGroup	The resource group you created with your function app.
Namespace name	Globally unique name	The namespace of your instance from which to trigger your function. Because the namespace is publicly accessible, you must use a name that is globally unique across Azure. The name must also be between 6 and 50 characters in length, contain only alphanumeric characters and dashes, and can't start with a number.
Location	myFunctionRegion	The region where you created your function app.
Pricing tier	Basic	The basic Service Bus tier.

4. Select **Review + create**. After validation finishes, select **Create**.
5. After deployment completes, select **Go to resource**.
6. In your new Service Bus namespace, select **+ Queue** to add a queue.
7. Enter **myinputqueue** as the new queue's name and select **Create**.

Now that you have a queue, you can add a role assignment to the managed identity of your function app.

Configure your Service Bus trigger with a managed identity

To use Service Bus triggers with identity-based connections, you need to add the **Azure Service Bus Data Receiver** role assignment to the managed identity in your function app. This role is required when using managed identities to trigger off of your Service Bus namespace. You can also add your own account to this role, which makes it possible to connect to the Service Bus namespace during local testing.

① Note

Role requirements for using identity-based connections vary depending on the service and how you are connecting to it. Needs vary across triggers, input bindings, and output bindings. For more information about specific role requirements, see the trigger and binding documentation for the service.

1. In your Service Bus namespace that you created, select **Access control (IAM)**. This page is where you can view and configure who has access to the resource.
2. Select **+ Add** and select **Add role assignment**.
3. Search for **Azure Service Bus Data Receiver**, select it, and then select **Next**.
4. On the **Members** tab, under **Assign access to**, choose **Managed Identity**
5. Select **Select members** to open the **Select managed identities** panel.
6. Confirm that the **Subscription** is the one in which you created the resources earlier.
7. In the **Managed identity** selector, choose **Function App** from the **System-assigned managed identity** category. The **Function App** label might have a number in parentheses next to it, indicating the number of apps in the subscription with system-assigned identities.
8. Your app should appear in a list below the input fields. If you don't see it, you can use the **Select** box to filter the results with your app's name.
9. Select your application. It should move down into the **Selected members** section. Select **Select**.
10. Back on the **Add role assignment** screen, select **Review + assign**. Review the configuration, and then select **Review + assign**.

You've granted your function app access to the Service Bus namespace using managed identities.

Connect to the Service Bus in your function app

1. In the portal, search for the function app you created in the [previous tutorial](#), or browse to it in the [Function App](#) page.
2. In your function app, expand **Settings**, and then select **Environment variables**.
3. In the **App settings** tab, select **+ Add** to create a setting. Use the information in the following table to enter the **Name** and **Value** for the new setting:

 Expand table

Name	Value	Description
ServiceBusConnection__fullyQualifiedNamespace	<SERVICE_BUS_NAMESPACE>.servicebus.windows.net	This setting connects your function app to the Service Bus using an identity-based connection instead of secrets.

4. Select **Apply**, and then select **Apply** and **Confirm** to save your changes and restart the app function.

Note

When you use [Azure App Configuration](#) or [Key Vault](#) to provide settings for Managed Identity connections, setting names should use a valid key separator, such as `:` or `/`, in place of the `_` to ensure names are resolved correctly.

For example, `ServiceBusConnection:fullyQualifiedNamespace`.

Now that you've prepared the function app to connect to the Service Bus namespace using a managed identity, you can add a new function that uses a Service Bus trigger to your local project.

Add a Service Bus triggered function

1. Run the `func init` command, as follows, to create a functions project in a folder named `LocalFunctionProj` with the specified runtime:

```
C#  
func init LocalFunctionProj --dotnet
```

2. Navigate to the project folder:

```
Console
```

```
cd LocalFunctionProj
```

3. In the root project folder, run the following command:

```
command
```

```
dotnet add package Microsoft.Azure.WebJobs.Extensions.ServiceBus --version 5.2.0
```

This command replaces the default version of the Service Bus extension package with a version that supports managed identities.

4. Run the following command to add a Service Bus triggered function to the project:

```
C#
```

```
func new --name ServiceBusTrigger --template ServiceBusQueueTrigger
```

This command adds the code for a new Service Bus trigger and a reference to the extension package. You need to add a Service Bus namespace connection setting for this trigger.

5. Open the new *ServiceBusTrigger.cs* project file and replace the `ServiceBusTrigger` class with the following code:

```
C#
```

```
public static class ServiceBusTrigger
{
    [FunctionName("ServiceBusTrigger")]
    public static void Run([ServiceBusTrigger("myinputqueue",
        Connection = "ServiceBusConnection")]string myQueueItem, ILogger log)
    {
        log.LogInformation($"C# ServiceBus queue trigger function processed message:
{myQueueItem}");
    }
}
```

This code sample updates the queue name to `myinputqueue`, which is the same name as you queue you created earlier. It also sets the name of the Service Bus connection to `ServiceBusConnection`. This name is the Service Bus namespace used by the identity-based connection `ServiceBusConnection_fullyQualifiedNamespace` you configured in the portal.

① Note

If you try to run your functions now using `func start`, you'll receive an error. This is because you don't have an identity-based connection defined locally. If you want to run your function locally, set the app setting `ServiceBusConnection_fullyQualifiedNamespace` in `local.settings.json` as you did in [the previous section](#connect-to-the-service-bus-in-your-function-app). In addition, you need to assign the role to your developer identity. For more information, see [local development with identity-based connections](#).

Note

When using [Azure App Configuration](#) or [Key Vault](#) to provide settings for Managed Identity connections, setting names should use a valid key separator such as `:` or `/` in place of the `_` to ensure names are resolved correctly.

For example, `ServiceBusConnection:fullyQualifiedNamespace`.

Publish the updated project

1. Run the following command to locally generate the files needed for the deployment package:

Console

```
dotnet publish --configuration Release
```

2. Browse to the `\bin\Release\netcoreapp3.1\publish` subfolder and create a .zip file from its contents.

3. Publish the .zip file by running the following command, replacing the `FUNCTION_APP_NAME`, `RESOURCE_GROUP_NAME`, and `PATH_TO_ZIP` parameters as appropriate:

Azure CLI

```
az functionapp deploy -n FUNCTION_APP_NAME -g RESOURCE_GROUP_NAME --src-path PATH_TO_ZIP
```

Now that you've updated the function app with the new trigger, you can verify that it works using the identity.

Validate your changes

1. In the portal, search for [Application Insights](#) and select **Application Insights** under Services.
2. In **Application Insights**, browse or search for your named instance.
3. In your instance, select **Live Metrics** under **Investigate**.
4. Keep the previous tab open, and open the Azure portal in a new tab. In your new tab, navigate to your Service Bus namespace, select **Queues** from the left menu.
5. Select your queue named `myinputqueue`.
6. Select **Service Bus Explorer** from the left menu.
7. Send a test message.
8. Select your open **Live Metrics** tab and see the Service Bus queue execution.

Congratulations! You have successfully set up your Service Bus queue trigger with a managed identity.

Clean up resources

In the preceding steps, you created Azure resources in a resource group. If you don't expect to need these resources in the future, you can delete them by deleting the resource group.

From the Azure portal menu or **Home** page, select **Resource groups**. Then, on the **Resource groups** page, select **myResourceGroup**.

On the **myResourceGroup** page, make sure that the listed resources are the ones you want to delete.

Select **Delete resource group**, type **myResourceGroup** in the text box to confirm, and then select **Delete**.

Next steps

In this tutorial, you created a function app with identity-based connections.

Advance to the next article to learn how to manage identity.

Tutorial: Connect a function app to Azure SQL with managed identity and SQL bindings

Article • 10/12/2023

Azure Functions provides a [managed identity](#), which is a turn-key solution for securing access to [Azure SQL Database](#) and other Azure services. Managed identities make your app more secure by eliminating secrets from your app, such as credentials in the connection strings. In this tutorial, you'll add managed identity to an Azure Function that utilizes [Azure SQL bindings](#). A sample Azure Function project with SQL bindings is available in the [ToDo backend example](#).

When you're finished with this tutorial, your Azure Function will connect to Azure SQL database without the need of username and password.

An overview of the steps you'll take:

- ✓ Enable Microsoft Entra authentication to the SQL database
- ✓ Enable Azure Function managed identity
- ✓ Grant SQL Database access to the managed identity
- ✓ Configure Azure Function SQL connection string

Grant database access to Microsoft Entra user

First enable Microsoft Entra authentication to SQL database by assigning a Microsoft Entra user as the Active Directory admin of the server. This user is different from the Microsoft account you used to sign up for your Azure subscription. It must be a user that you created, imported, synced, or invited into Microsoft Entra ID. For more information on allowed Microsoft Entra users, see [Microsoft Entra features and limitations in SQL database](#).

Enabling Microsoft Entra authentication can be completed via the Azure portal, PowerShell, or Azure CLI. Directions for Azure CLI are below and information completing this via Azure portal and PowerShell is available in the [Azure SQL documentation on Microsoft Entra authentication](#).

1. If your Microsoft Entra tenant doesn't have a user yet, create one by following the steps at [Add or delete users using Microsoft Entra ID](#).

2. Find the object ID of the Microsoft Entra user using the `az ad user list` and replace `<user-principal-name>`. The result is saved to a variable.

For Azure CLI 2.37.0 and newer:

Azure CLI

```
azureaduser=$(az ad user list --filter "userPrincipalName eq '<user-principal-name>'" --query [].id --output tsv)
```

For older versions of Azure CLI:

Azure CLI

```
azureaduser=$(az ad user list --filter "userPrincipalName eq '<user-principal-name>'" --query [].objectId --output tsv)
```

💡 Tip

To see the list of all user principal names in Microsoft Entra ID, run `az ad user list --query [].userPrincipalName`.

3. Add this Microsoft Entra user as an Active Directory admin using `az sql server ad-admin create` command in the Cloud Shell. In the following command, replace `<server-name>` with the server name (without the `.database.windows.net` suffix).

Azure CLI

```
az sql server ad-admin create --resource-group myResourceGroup --server-name <server-name> --display-name ADMIN --object-id $azureaduser
```

For more information on adding an Active Directory admin, see [Provision a Microsoft Entra administrator for your server](#)

Enable system-assigned managed identity on Azure Function

In this step we'll add a system-assigned identity to the Azure Function. In later steps, this identity will be given access to the SQL database.

To enable system-assigned managed identity in the Azure portal:

1. Create an Azure Function in the portal as you normally would. Navigate to it in the portal.
2. Scroll down to the Settings group in the left navigation.
3. Select Identity.
4. Within the System assigned tab, switch Status to On. Click Save.

The screenshot shows the Azure Functions portal interface. On the left, there's a sidebar with options like Deployment slots, Deployment Center, Configuration, Authentication, Application Insights, and Identity. The Identity option is highlighted with a red box. The main area shows the 'sqlbindingsmanagedidentity' function app. Under the 'Identity' section, the 'System assigned' tab is selected. It displays a note about system-assigned managed identities being restricted to one per resource and authenticated with Azure AD. Below this, there's a 'Status' button with 'Off' and 'On' options, where 'On' is highlighted with a red box. At the bottom of the identity section, there are 'Object (principal) ID' and 'Permissions' sections, with 'Azure role assignments' being the current tab. At the very bottom of the identity section, there are 'Save', 'Discard', 'Refresh', and 'Got feedback?' buttons, with 'Save' also highlighted with a red box.

For information on enabling system-assigned managed identity through Azure CLI or PowerShell, check out more information on [using managed identities with Azure Functions](#).

💡 Tip

For user-assigned managed identity, switch to the User Assigned tab. Click Add and select a Managed Identity. For more information on creating user-assigned managed identity, see the [Manage user-assigned managed identities](#).

Grant SQL database access to the managed identity

In this step we'll connect to the SQL database with a Microsoft Entra user account and grant the managed identity access to the database.

1. Open your preferred SQL tool and login with a Microsoft Entra user account (such as the Microsoft Entra user we assigned as administrator). This can be accomplished in Cloud Shell with the SQLCMD command.

Bash

```
sqlcmd -S <server-name>.database.windows.net -d <db-name> -U <aad-user-name> -P "<aad-password>" -G -l 30
```

2. In the SQL prompt for the database you want, run the following commands to grant permissions to your function. For example,

SQL

```
CREATE USER [<identity-name>] FROM EXTERNAL PROVIDER;
ALTER ROLE db_datareader ADD MEMBER [<identity-name>];
ALTER ROLE db_datawriter ADD MEMBER [<identity-name>];
GO
```

<*identity-name*> is the name of the managed identity in Microsoft Entra ID. If the identity is system-assigned, the name is always the same as the name of your Function app.

Configure Azure Function SQL connection string

In the final step we'll configure the Azure Function SQL connection string to use Microsoft Entra managed identity authentication.

The connection string setting name is identified in our Functions code as the binding attribute "ConnectionStringSetting", as seen in the SQL input binding [attributes and annotations](#).

In the application settings of our Function App the SQL connection string setting should be updated to follow this format:

```
Server=demo.database.windows.net; Authentication=Active Directory Managed Identity;
Database=testdb
```

testdb is the name of the database we're connecting to and *demo.database.windows.net* is the name of the server we're connecting to.

Tip

For user-assigned managed identity, use `Server=demo.database.windows.net;`
`Authentication=Active Directory Managed Identity;` User

```
Id=ClientIdOfManagedIdentity; Database=testdb.
```

Next steps

- Read data from a database (Input binding)
- Save data to a database (Output binding)
- Review ToDo API sample with Azure SQL bindings

Tutorial: Trigger Azure Functions on blob containers using an event subscription

Article • 05/21/2024

Previous versions of the Azure Functions Blob Storage trigger poll your storage container for changes. More recent version of the Blob Storage extension (5.x+) instead use an Event Grid event subscription on the container. This event subscription reduces latency by triggering your function instantly as changes occur in the subscribed container.

This article shows how to create a function that runs based on events raised when a blob is added to a container. You use Visual Studio Code for local development and to validate your code before deploying your project to Azure.

- ✓ Create an event-based Blob Storage triggered function in a new project.
- ✓ Validate locally within Visual Studio Code using the Azurite emulator.
- ✓ Create a blob storage container in a new storage account in Azure.
- ✓ Create a function app in the Flex Consumption plan (preview).
- ✓ Create an event subscription to the new blob container.
- ✓ Deploy and validate your function code in Azure.

This article creates a C# app that runs in isolated worker mode, which supports .NET 8.0.

ⓘ Important

This tutorial has you use the [Flex Consumption plan](#), which is currently in preview. The Flex Consumption plan only supports the event-based version of the Blob Storage trigger. You can complete this tutorial using any other [hosting plan](#) for your function app.

Prerequisites

- An Azure account with an active subscription. [Create an account for free](#).
- [.NET 8.0 SDK](#).
- [Visual Studio Code](#) on one of the [supported platforms](#).

- [C# extension](#) for Visual Studio Code.
- [Azure Functions extension](#) for Visual Studio Code.
- [Azure Storage extension](#) for Visual Studio Code.

ⓘ Note

The Azure Storage extension for Visual Studio Code is currently in preview.

Create a Blob triggered function

When you create a Blob Storage trigger function using Visual Studio Code, you also create a new project. You need to edit the function to consume an event subscription as the source, rather than use the regular polled container.

1. In Visual Studio Code, open your function app.
2. Press F1 to open the command palette, enter `Azure Functions: Create Function...`, and select `Create new project`.
3. For your project workspace, select the directory location. Make sure that you either create a new folder or choose an empty folder for the project workspace.
Don't choose a project folder that's already part of a workspace.
4. At the prompts, provide the following information:

 Expand table

Prompt	Action
Select a language	Select <code>C#</code> .
Select a .NET runtime	Select <code>.NET 8.0 Isolated LTS</code> .
Select a template for your project's first function	Select <code>Azure Blob Storage trigger (using Event Grid)</code> .
Provide a function name	Enter <code>BlobTriggerEventGrid</code> .
Provide a namespace	Enter <code>My.Functions</code> .
Select setting from "local.settings.json"	Select <code>create new local app setting</code> .
Select subscription	Select your subscription.

Prompt	Action
Select a storage account	Use Azurite emulator for local storage.
This is the path within your storage account that the trigger will monitor	Accept the default value <code>samples-workitems</code> .
Select how you would like to open your project	Select <code>Open in current window</code> .

Upgrade the Storage extension

To use the Event Grid-based Blob Storage trigger, you must have at least version 5.x of the Azure Functions Storage extension.

To upgrade your project with the required extension version, in the Terminal window, run this [dotnet add package](#) command:

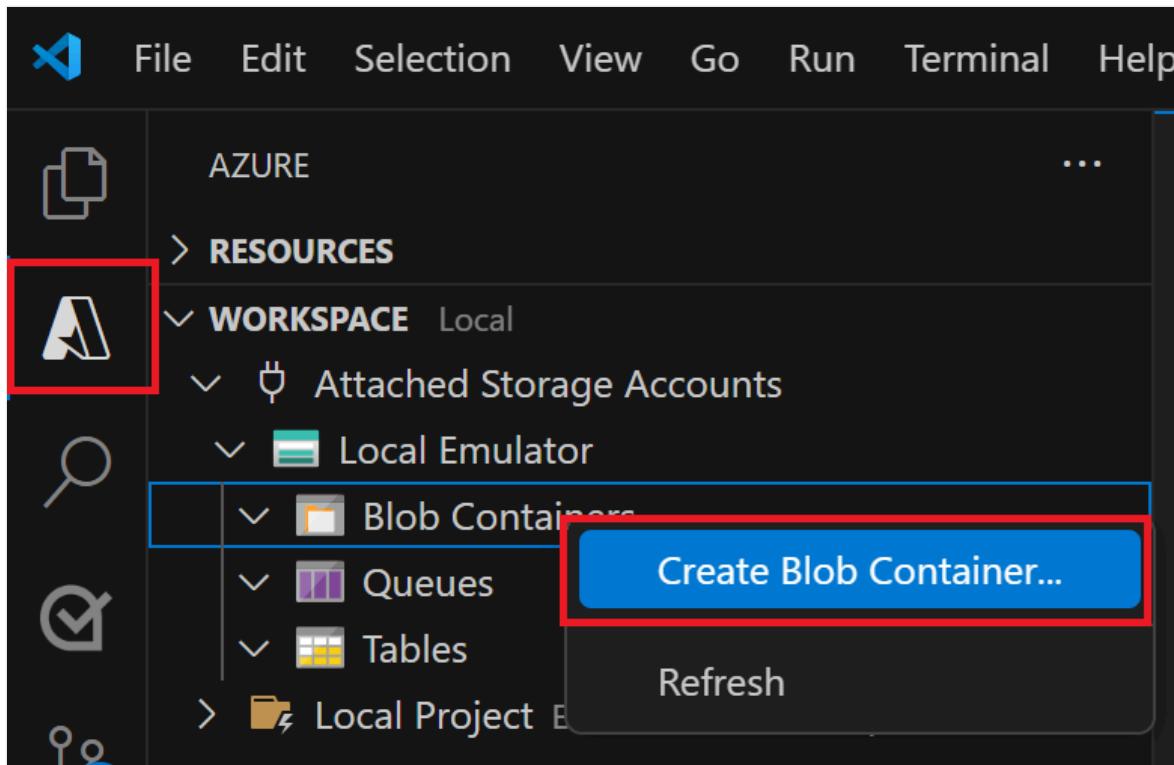

Bash

```
dotnet add package Microsoft.Azure.Functions.Worker.Extensions.Storage.Blobs
```

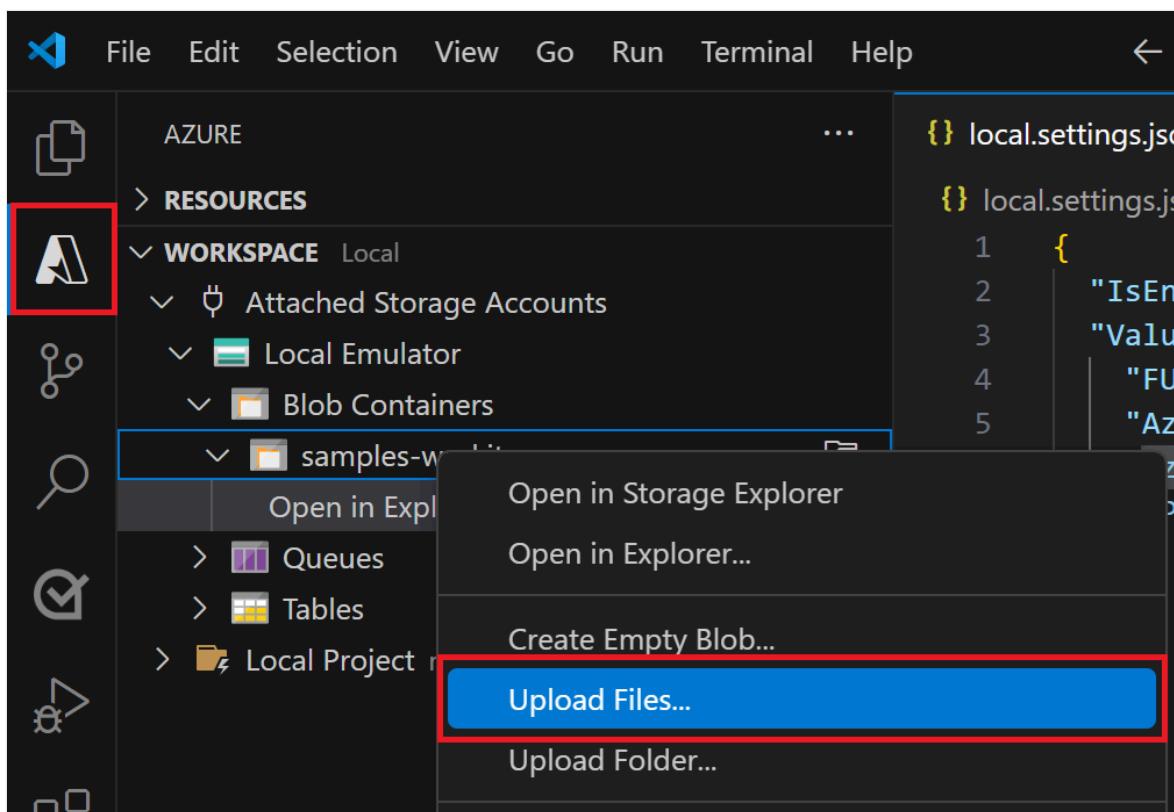

Prepare local storage emulation

Visual Studio Code uses Azurite to emulate Azure Storage services when running locally. You use Azurite to emulate the Azure Blob Storage service during local development and testing.

1. If haven't already done so, install the [Azurite v3 extension for Visual Studio Code](#).
2. Verify that the `local.settings.json` file has `"UseDevelopmentStorage=true"` set for `AzureWebJobsStorage`, which tells Core Tools to use Azurite instead of a real storage account connection when running locally.
3. Press F1 to open the command palette, type `Azurite: Start Blob Service`, and press enter, which starts the Azurite Blob Storage service emulator.
4. Select the Azure icon in the Activity bar, expand **Workspace > Attached Storage Accounts > Local Emulator**, right-click **Blob Containers**, select **Create Blob Container...**, enter the name `samples-workitems`, and press Enter.

5. Expand **Blob Containers** > **samples-workitems** and select **Upload files....**

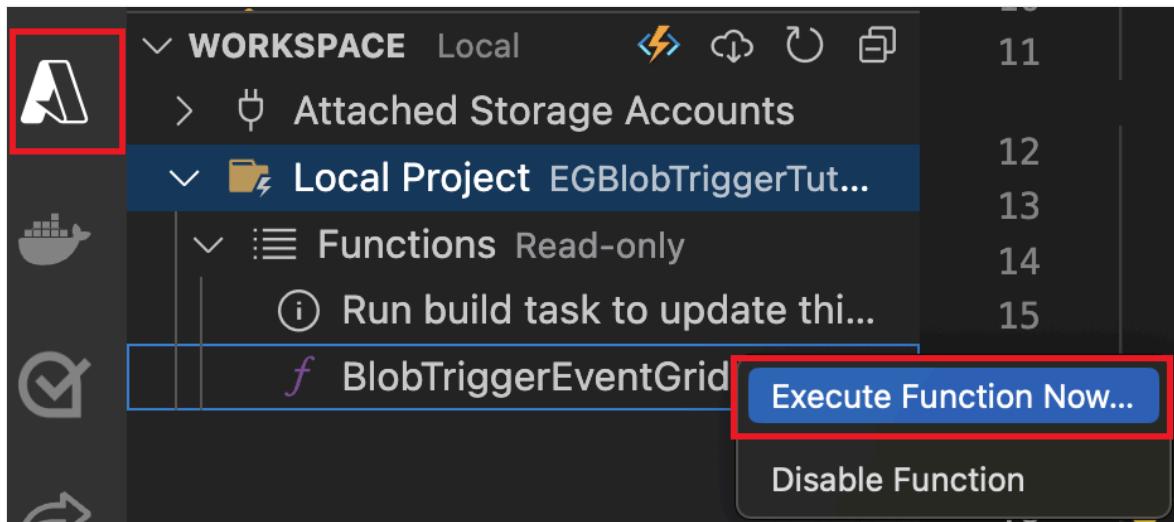

6. Choose a file to upload to the locally emulated container. This file gets processed later by your function to verify and debug your function code. A text file might work best with the Blob trigger template code.

Run the function locally

With a file in emulated storage, you can run your function to simulate an event raised by an Event Grid subscription. The event info passed to your trigger depends on the file you added to the local container.

1. Set any breakpoints and press F5 to start your project for local debugging. Azure Functions Core Tools should be running in your Terminal window.
2. Back in the Azure area, expand **Workspace > Local Project > Functions**, right-click the function, and select **Execute Function Now....**

3. In the request body dialog, type `samples-workitems/<TEST_FILE_NAME>`, replacing `<TEST_FILE_NAME>` with the name of the file you uploaded in the local storage emulator.
4. Press Enter to run the function. The value you provided is the path to your blob in the local emulator. This string gets passed to your trigger in the request payload, which simulates the payload when an event subscription calls your function to report a blob being added to the container.
5. Review the output of this function execution. You should see in the output the name of the file and its contents logged. If you set any breakpoints, you might need to continue the execution.

Now that you've successfully validated your function code locally, it's time to publish the project to a new function app in Azure.

Prepare the Azure Storage account

Event subscriptions to Azure Storage require a general-purpose v2 storage account. You can use the Azure Storage extension for Visual Studio Code to create this storage account.

1. In Visual Studio Code, press F1 again to open the command palette and enter `Azure Storage: Create Storage Account...`. Provide this information when prompted:

[+] Expand table

Prompt	Action
Enter the name of the new storage account	Provide a globally unique name. Storage account names must have 3 to 24 characters in length with only lowercase letters and numbers. For easier identification, we use the same name for the resource group and the function app name.
Select a location for new resources	For better performance, choose a region near you ↗ .

The extension creates a general-purpose v2 storage account with the name you provided. The same name is also used for the resource group that contains the storage account. The Event Grid-based Blob Storage trigger requires a general-purpose v2 storage account.

2. Press F1 again and in the command palette enter `Azure Storage: Create Blob Container...`. Provide this information when prompted:

[+] Expand table

Prompt	Action
Select a resource	Select the general-purpose v2 storage account that you created.
Enter a name for the new blob container	Enter <code>samples-workitems</code> , which is the container name referenced in your code project.

Your function app also needs a storage account to run. For simplicity, this tutorial uses the same storage account for your blob trigger and your function app. However, in production, you might want to use a separate storage account with your function app. For more information, see [Storage considerations for Azure Functions](#).

Create the function app

Use these steps to create a function app in the Flex Consumption plan. When your app is hosted in a Flex Consumption plan, Blob Storage triggers must use event subscriptions.

1. In the command pallet, enter **Azure Functions: Create function app in Azure... (Advanced)**.

2. Following the prompts, provide this information:

 Expand table

Prompt	Selection
Enter a globally unique name for the new function app.	Type a globally unique name that identifies your new function app and then select Enter. Valid characters for a function app name are <code>a-z</code> , <code>0-9</code> , and <code>-</code> .
Select a hosting plan.	Choose Flex Consumption (Preview) .
Select a runtime stack.	Choose the language stack and version on which you've been running locally.
Select a resource group for new resources.	Choose the existing resource group in which you created the storage account.
Select a location for new resources.	Select a location in a supported region near you or near other services that your functions access. Unsupported regions aren't displayed. For more information, see View currently supported regions .
Select a storage account.	Choose the name of the storage account you created.
Select an Application Insights resource for your app.	Choose Create new Application Insights resource and at the prompt provide the name for the instance used to store runtime data from your functions.

A notification appears after your function app is created. Select **View Output** in this notification to view the creation results, including the Azure resources that you created.

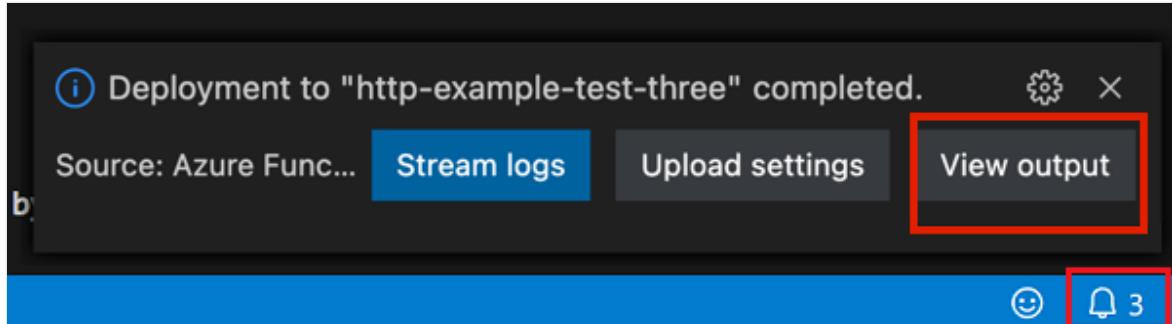

Deploy your function code

Important

Deploying to an existing function app always overwrites the contents of that app in Azure.

1. In the **Resources** area of the Azure activity, locate the function app resource you just created, right-click the resource, and select **Deploy to function app....**

- When prompted about overwriting previous deployments, select **Deploy** to deploy your function code to the new function app resource.
- After deployment completes, select **View Output** to view the creation and deployment results, including the Azure resources that you created. If you miss the notification, select the bell icon in the lower right corner to see it again.

Update application settings

Because required application settings from the `local.settings.json` file aren't automatically published, you must upload them to your function app so that your function runs correctly in Azure.

- In the command pallet, enter `Azure Functions: Download Remote Settings...`, and in the **Select a resource** prompt choose the name of your function app.
- When prompted that the `AzureWebJobsStorage` setting already exists, select **Yes** to overwrite the local emulator setting with the actual storage account connection string from Azure.
- In the `local.settings.json` file, replace the local emulator setting with same connection string used for `AzureWebJobsStorage`.
- Remove the `FUNCTIONS_WORKER_RUNTIME` entry, which isn't supported in a Flex Consumption plan.
- In the command pallet, enter `Azure Functions: Upload Local Settings...`, and in the **Select a resource** prompt choose the name of your function app.

Now both the Functions host and the trigger are sharing the same storage account.

Build the endpoint URL

To create an event subscription, you need to provide Event Grid with the URL of the specific endpoint to report Blob Storage events. This *blob extension* URL is composed of

these parts:

[+] Expand table

Part	Example
Base function app URL	<code>https://<FUNCTION_APP_NAME>.azurewebsites.net</code>
Blob-specific path	<code>/runtime/webhooks/blobs</code>
Function query string	<code>?functionName=Host.Functions.BlobTriggerEventGrid</code>
Blob extension access key	<code>&code=<BLOB_EXTENSION_KEY></code>

The blob extension access key is designed to make it more difficult for others to access your blob extension endpoint. To determine your blob extension access key:

1. In Visual Studio Code, choose the Azure icon in the Activity bar. In **Resources**, expand your subscription, expand **Function App**, right-click the function app you created, and select **Open in portal**.
2. Under **Functions** in the left menu, select **App keys**.
3. Under **System keys** select the key named **blobs_extension**, and copy the key **Value**. You include this value in the query string of new endpoint URL.
4. Create a new endpoint URL for the Blob Storage trigger based on the following example:

```
HTTP  
  
https://<FUNCTION_APP_NAME>.azurewebsites.net/runtime/webhooks/blobs?  
functionName=Host.Functions.BlobTriggerEventGrid&code=<BLOB_EXTENSION_KEY>
```

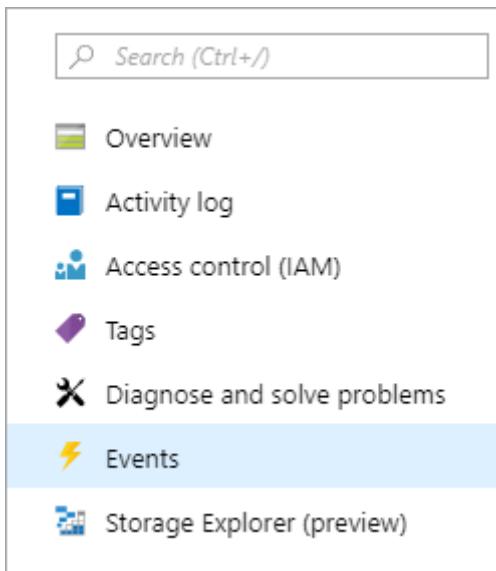

In this example, replace `<FUNCTION_APP_NAME>` with the name of your function app and replace `<BLOB_EXTENSION_KEY>` with the value you got from the portal. If you used a different name for your function, you'll also need to change the `functionName` query string value to your function name.

You can now use this endpoint URL to create an event subscription.

Create the event subscription

An event subscription, powered by Azure Event Grid, raises events based on changes in the subscribed blob container. This event is then sent to the blob extension endpoint for your function. After you create an event subscription, you can't update the endpoint URL.

1. In Visual Studio Code, choose the Azure icon in the Activity bar. In **Resources**, expand your subscription, expand **Storage accounts**, right-click the storage account you created earlier, and select **Open in portal**.
2. Sign in to the [Azure portal](#) and make a note of the **Resource group** for your storage account. You create your other resources in the same group to make it easier to clean up resources when you're done.
3. select the **Events** option from the left menu.

4. In the **Events** window, select the **+ Event Subscription** button, and provide values from the following table into the **Basic** tab:

[\[+\] Expand table](#)

Setting	Suggested value	Description
Name	<code>myBlobEventSub</code>	Name that identifies the event subscription. You can use the name to quickly find the event subscription.
Event Schema	Event Grid Schema	Use the default schema for events.
System Topic Name	<code>samples-workitems-blobs</code>	Name for the topic, which represents the container. The topic is created with the first subscription, and you'll use it for future event subscriptions.

Setting	Suggested value	Description
Filter to Event Types	Blob Created	
Endpoint Type	Web Hook	The blob storage trigger uses a web hook endpoint.
Endpoint	Your Azure-based URL endpoint	Use the URL endpoint that you built, which includes the key value.

5. Select **Confirm selection** to validate the endpoint URL.

6. Select **Create** to create the event subscription.

Upload a file to the container

You can upload a file from your computer to your blob storage container using Visual Studio Code.

1. In Visual Studio Code, press F1 to open the command palette and type `Azure Storage: Upload Files....`.
2. In the **Open** dialog box, choose a file, preferably a text file, and select **Upload**.
3. Provide the following information at the prompts:

[] Expand table

Setting	Suggested value	Description
Enter the destination directory of this upload	default	Just accept the default value of <code>/</code> , which is the container root.
Select a resource	Storage account name	Choose the name of the storage account you created in a previous step.
Select a resource type	Blob Containers	You're uploading to a blob container.
Select Blob Container	samples-workitems	This value is the name of the container you created in a previous step.

Browse your local file system to find a file to upload and then select the **Upload** button to upload the file.

Verify the function in Azure

Now that you uploaded a file to the `samples-workitems` container, the function should be triggered. You can verify by checking the following on the Azure portal:

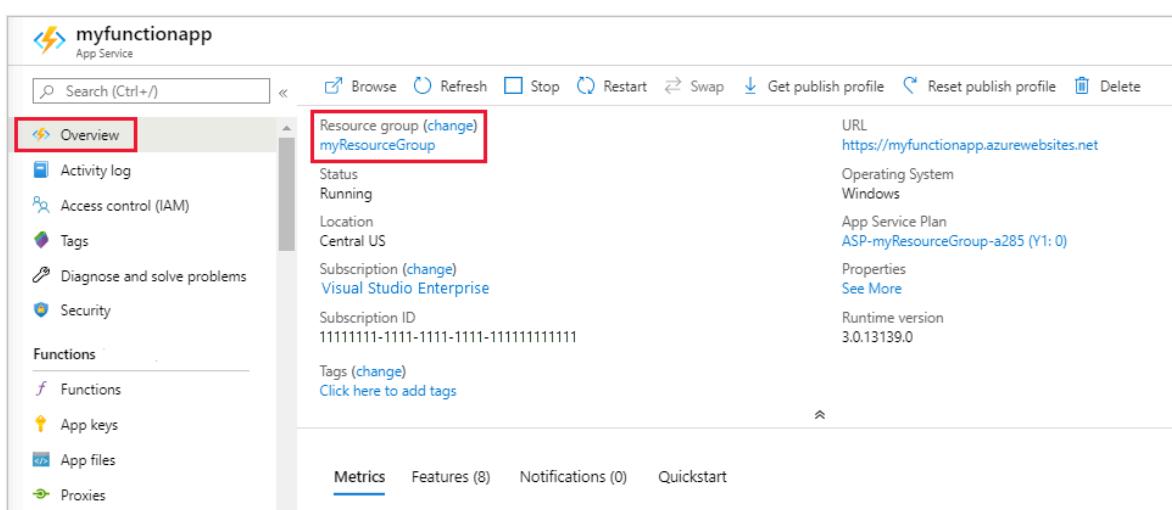

1. In your storage account, go to the **Events** page, select **Event Subscriptions**, and you should see that an event was delivered. There might be up a five-minute delay for the event to show up on the chart.
2. Back in your function app page in the portal, under **Functions** find your function and select **Invocations and more**. You should see traces written from your successful function execution.

Clean up resources

When you continue to the [next step](#) and add an Azure Storage queue binding to your function, you'll need to keep all your resources in place to build on what you've already done.

Otherwise, you can use the following steps to delete the function app and its related resources to avoid incurring any further costs.

1. In Visual Studio Code, press `F1` to open the command palette. In the command palette, search for and select `Azure: Open in portal`.
2. Choose your function app and press `Enter`. The function app page opens in the Azure portal.
3. In the **Overview** tab, select the named link next to **Resource group**.

4. On the **Resource group** page, review the list of included resources, and verify that they're the ones you want to delete.

5. Select **Delete resource group**, and follow the instructions.

Deletion may take a couple of minutes. When it's done, a notification appears for a few seconds. You can also select the bell icon at the top of the page to view the notification.

For more information about Functions costs, see [Estimating Consumption plan costs](#).

Use Azure Event Grid to route Blob storage events to web endpoint (Azure portal)

Article • 11/27/2023

Event Grid is a fully managed service that enables you to easily manage events across many different Azure services and applications. It simplifies building event-driven and serverless applications. For an overview of the service, see [Event Grid overview](#).

In this article, you use the Azure portal to do the following tasks:

1. Create a Blob storage account.
2. Subscribe to events for that blob storage.
3. Trigger an event by uploading a file to the blob storage.
4. View the result in a handler web app. Typically, you send events to an endpoint that processes the event data and takes actions. To keep it simple, you send events to a web app that collects and displays the messages.

If you don't have an [Azure subscription](#), create an [Azure free account](#) before you begin.

When you're finished, you see that the event data has been sent to the web app.

Create a storage account

1. Sign in to [Azure portal](#).
 2. To create a Blob storage, select **Create a resource**.
 3. In the **Search**, enter **Storage account**, and select **Storage account** from the result list.

Windows Server 2019 Datacenter

Ubuntu Server 20.04 LTS

Web App

4. On the **Storage account** page, select **Create** to start creating the storage account.

To subscribe to events, create either a general-purpose v2 storage account or a Blob storage account.

5. On the **Create storage account** page, do the following steps:

a. Select your Azure subscription.

b. For **Resource group**, create a new resource group or select an existing one.

c. Enter the name for your storage account.

d. Select the **Region** in which you want the storage account to be created.

e. For **Redundancy**, select **Locally-redundant storage (LRS)** from the drop-down list.

f. Select **Review** at the bottom of the page.

Create a storage account ...

Basics Advanced Networking Data protection Encryption Tags Review

Azure Storage is a Microsoft-managed service providing cloud storage that is highly available, secure, durable, scalable, and redundant. Azure Storage includes Azure Blobs (objects), Azure Data Lake Storage Gen2, Azure Files, Azure Queues, and Azure Tables. The cost of your storage account depends on the usage and the options you choose below. [Learn more about Azure storage accounts](#)

Project details

Select the subscription in which to create the new storage account. Choose a new or existing resource group to organize and manage your storage account together with other resources.

Region ⓘ * (US) East US

Performance ⓘ * Standard: Recommended for most scenarios (general-purpose v2 account)
 Premium: Recommended for scenarios that require low latency.

Redundancy ⓘ * Locally-redundant storage (LRS)

Review < Previous Next : Advanced >

g. On the **Review** page, review the settings, and select **Create**.

① Note

Only storage accounts of kind **StorageV2 (general purpose v2)** and **BlobStorage** support event integration. **Storage (general purpose v1)** does *not* support integration with Event Grid.

6. The deployment takes a few minutes to complete. On the **Deployment** page, select **Go to resource**.

The screenshot shows the 'Overview' tab for a deployment named 'spstorageaccount1027_1666928259897'. The main content area displays a green checkmark icon followed by the text 'Your deployment is complete'. Below this, it lists deployment details: 'Deployment name: spstorageaccount1027_1666928259897', 'Subscription: Visual Studio Enterprise Subscription', and 'Resource group: spegridrg'. There are two expandable sections: 'Deployment details' and 'Next steps'. A prominent blue button labeled 'Go to resource' is centered below the deployment details. At the bottom, there are links for 'Give feedback' and 'Tell us about your experience with deployment'.

7. On the **Storage account** page, select **Events** on the left menu.

The screenshot shows the 'Events' page for a storage account named 'spstorageaccount1027'. The left sidebar has a red box around the 'Events' link under the 'Storage account' section. The main content area features a large heading 'Events, automated.' and a descriptive text about using Event Grid for automation. It includes links for 'Event Subscription', 'Refresh', and 'Feedback'. Below this, there's a section for creating logic apps to respond to events. At the bottom, there's a diagram illustrating the flow of events from a source through a cloud icon to a sink, with binary code (0s and 1s) shown inside the cloud.

8. Keep this page in the web browser open.

Create a message endpoint

Before subscribing to the events for the Blob storage, let's create the endpoint for the event message. Typically, the endpoint takes actions based on the event data. To simplify this quickstart, you deploy a [prebuilt web app](#) that displays the event messages. The deployed solution includes an App Service plan, an App Service web app, and source code from GitHub.

1. Select **Deploy to Azure** to deploy the solution to your subscription.

2. On the **Custom deployment** page, do the following steps:

- a. For **Resource group**, select the resource group that you created when creating the storage account. It will be easier for you to clean up after you're done with the tutorial by deleting the resource group.
- b. For **Site Name**, enter a name for the web app.
- c. For **Hosting plan name**, enter a name for the App Service plan to use for hosting the web app.
- d. Select **Review + create**.

Review + create

3. On the **Review + create** page, select **Create**.

4. The deployment takes a few minutes to complete. On the **Deployment** page, select **Go to resource group**.

The screenshot shows the Microsoft Azure Deployment Overview page for a template named "Microsoft.Template-20221027235018". The main message is "Your deployment is complete". Deployment details include the name, subscription, and resource group. There are sections for "Deployment details" and "Next steps", with a prominent blue button labeled "Go to resource group". Below the main content are links to "Give feedback" and "Tell us about your experience with deployment".

5. On the **Resource group** page, in the list of resources, select the web app that you created. You also see the App Service plan and the storage account in this list.

The screenshot shows the Microsoft Azure Resource Group Overview page for a group named "contosoegriddrg". The main area displays a list of resources, including an Event Grid Topic, an App Service, and an App Service plan. The "contosoegridviewer" resource is highlighted with a red box. The left sidebar contains navigation links for Overview, Activity log, Access control (IAM), Tags, Resource visualizer, Events, Settings, Deployments, Security, Deployment stacks, Policies, Properties, Locks, Cost Management, Cost analysis, Cost alerts (preview), Budgets, and Advisor recommendations.

6. On the **App Service** page for your web app, select the URL to navigate to the web site. The URL should be in this format: `https://<your-site-name>.azurewebsites.net`.

The screenshot shows the Azure portal's configuration page for a web app named 'contosoegridviewer'. On the left, there's a navigation menu with options like Overview, Activity log, Access control (IAM), Tags, Diagnose and solve problems, Microsoft Defender for Cloud, Events (preview), Deployment, and Deployment slots. The 'Overview' tab is selected. On the right, under the 'Essentials' section, there are several settings: Resource group (contosoegridrg), Status (Running), Location (East US), Subscription (Visual Studio Enterprise Subscription). To the right of these, there's a 'Default domain' field containing 'contosoegridviewer.azurewebsites.net', which is highlighted with a red rectangular box. Other settings listed include App Service Plan (contosositeplan), Operating System (Windows), and Health Check (Not Configured). A 'JSON View' link is located at the top right of the essentials panel.

7. Confirm that you see the site but no events have been posted to it yet.

The screenshot shows a browser window with the URL 'https://contosoegridviewer.azurewebsites.net'. The page title is 'Azure Event Grid Viewer' and features a blue icon of two overlapping arrows. Below the title, there's a large empty white area where event logs would normally appear. In the bottom-left corner of this area, there's a light blue callout box with the title 'Important' in bold. The text inside the box reads: 'Keep the Azure Event Grid Viewer window open so that you can see events as they are posted.'

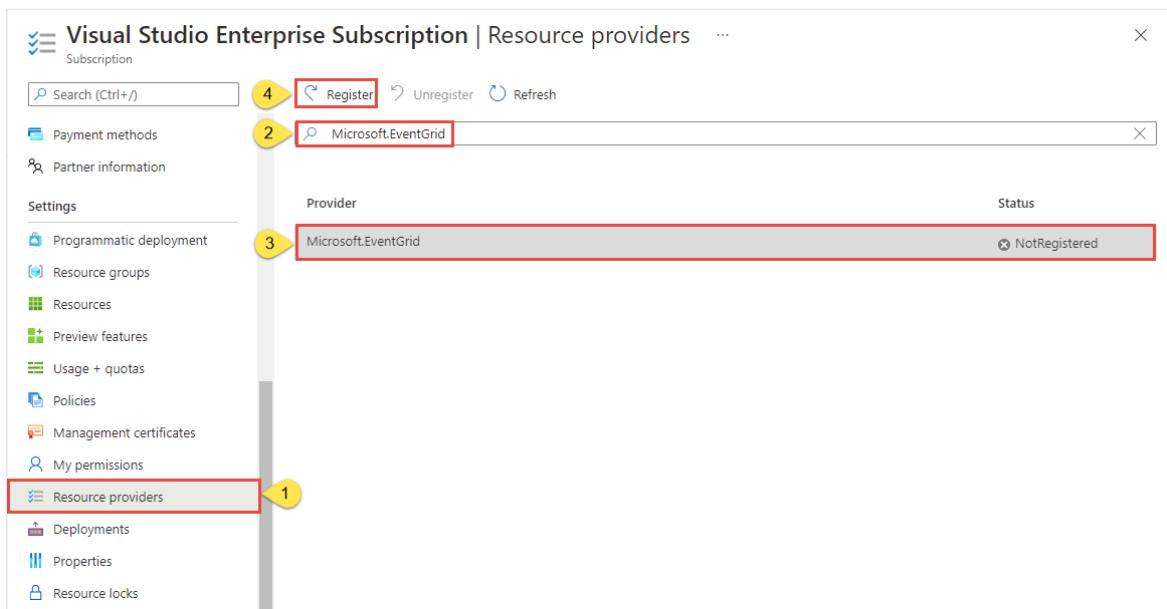

Register the Event Grid resource provider

Unless you've used Event Grid before, you'll need to register the Event Grid resource provider. If you've used Event Grid before, skip to the next section.

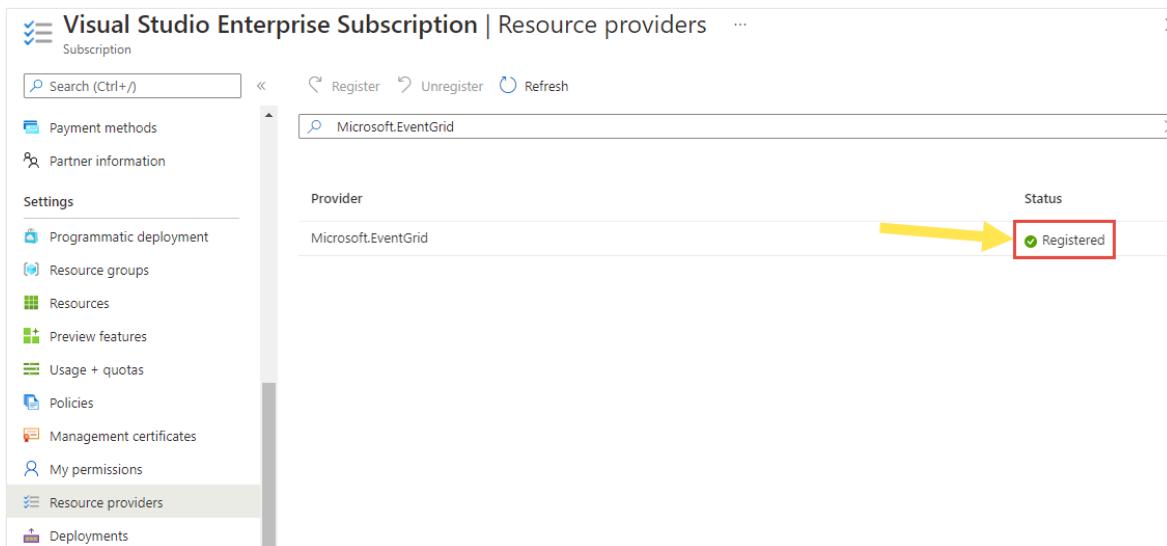

In the Azure portal, do the following steps:

1. On the left menu, select **Subscriptions**.
2. Select the **subscription** you want to use for Event Grid from the subscription list.
3. On the **Subscription** page, select **Resource providers** under **Settings** on the left menu.
4. Search for **Microsoft.EventGrid**, and confirm that the **Status** is **Not Registered**.
5. Select **Microsoft.EventGrid** in the provider list.

6. Select Register on the command bar.

7. Refresh to make sure the status of Microsoft.EventGrid is changed to Registered.

Subscribe to the Blob storage

You subscribe to a topic to tell Event Grid which events you want to track, and where to send the events.

1. If you closed the **Storage account** page, navigate to your Azure Storage account that you created earlier. On the left menu, select **All resources** and select your storage account.
2. On the **Storage account** page, select **Events** on the left menu.
3. Select **More Options**, and **Web Hook**. You're sending events to your viewer app using a web hook for the endpoint.

The screenshot shows the Azure Storage account 'spstorageaccount1027' Events page. The left sidebar contains navigation links: Overview, Activity log, Tags, Diagnose and solve problems, Access Control (IAM), Data migration, **Events** (highlighted with a red box and the number 1), and Storage browser. The main content area features a heading 'Events, automated.' and a brief description of Azure Event Grid. Below this, it says 'Azure Event Grid natively supports these resources as event handlers. Learn more'. It lists four options: Logic Apps, Azure Function, More Options (highlighted with a red box and the number 2), and Web Hook (highlighted with a red box and the number 3). Each option has a description and a small icon.

Event Handler	Description
Logic Apps	Use events as a trigger for executing a Logic App, starting Azure-wide workflows and automation.
Azure Function	Use events as a trigger for executing an Azure Function, which enables serverless custom code execution.
Web Hook	Send events as HTTP pushes to a Web Hook endpoint, both within or outside of Azure.
Storage Queues	Send events as messages to a Storage Queue, providing decoupling and in-motion storage.

4. On the **Create Event Subscription** page, do the following steps:

- Enter a **name** for the event subscription.
- Enter a **name** for the **system topic**. To learn about system topics, see [Overview of system topics](#).

7. View your web app again, and notice that a subscription validation event has been sent to it. Select the eye icon to expand the event data. Event Grid sends the validation event so the endpoint can verify that it wants to receive event data. The web app includes code to validate the subscription.

Event Type	Subject
Microsoft.EventGrid.SubscriptionValidationEvent	<pre>[{ "id": "6a7d9e9f-3a33-4da3-aa8e-c1e7bb9764d6", "topic": "/subscriptions/0000000000-0000-0000-0000-000000000000/resourceGroups/spegridrg/providers/Microsoft.Storage/storageAccounts/spstorageaccount1127", "subject": "", "data": { "validationCode": "7F1D940E-3161-4082-A61D-26778CB7484B", "validationUrl": "https://rp-eastus.eventgrid.azure.net:553/events/subscriptions/spegridsubscription/validate?id=7F1D940E-3161-4082-A61D-26778CB7484B&t=2023-11-27T19:40:07.6384543Z&apiVersion=2023-1-15-preview&token=RMzbApTOhQH00c4JYjtzudlWpt8YK%2bGUkIV1m%2bN7rVs%3d" }, "eventType": "Microsoft.EventGrid.SubscriptionValidationEvent", "eventTime": "2023-11-27T19:40:07.6384543Z", "metadataVersion": "1", "dataVersion": "2" }]</pre>

Now, let's trigger an event to see how Event Grid distributes the message to your endpoint.

Send an event to your endpoint

You trigger an event for the Blob storage by uploading a file. The file doesn't need any specific content.

1. In the Azure portal, navigate to your Blob storage account, and select **Containers** on the left menu.
2. Select **+ Container**. Give your container a name, and use any access level, and select **Create**.

The screenshot shows the 'Containers' blade for the storage account 'spstorageaccount1027'. The left sidebar has 'Containers' selected (1). The top navigation bar includes a search bar, a '+ Container' button (2), and other account management links. A modal window titled 'New container' is open, prompting for a name ('eventcontainer') (3). The 'Public access level' dropdown is set to 'Private (no anonymous access)' (4). The main table lists existing containers like '\$logs'.

3. Select your new container.

The screenshot shows the 'Containers' blade for the same storage account. The left sidebar still has 'Containers' selected (1). The main table now lists two containers: '\$logs' and 'eventcontainer' (2). The 'eventcontainer' row is highlighted with a red border.

4. To upload a file, select **Upload**. On the **Upload blob** page, browse and select a file that you want to upload for testing, and then select **Upload** on that page.

The screenshot shows the 'eventcontainer' blade and an open 'Upload blob' dialog. The left sidebar of the container blade has 'Overview' selected (1). The top navigation bar includes a search bar, an 'Upload' button (2), and other container management links. The 'Upload blob' dialog shows a file 'Kitchen Cabinet.png' selected for upload (3). The 'Advanced' section is collapsed (4).

5. Browse to your test file and upload it.
6. You've triggered the event, and Event Grid sent the message to the endpoint you configured when subscribing. The message is in the JSON format and it contains an array with one or more events. In the following example, the JSON message contains an array with one event. View your web app and notice that a **blob created** event was received.

The screenshot shows the Azure Event Grid Viewer interface. At the top, there's a header with the title "Azure Event Grid Viewer". Below the header, there's a table with two columns: "Event Type" and "Subject". Under "Event Type", there's a Microsoft Storage icon followed by the text "Microsoft.Storage.BlobCreated". Under "Subject", there's the URL "/blobServices/default/containers/eventcontainer/blobs/Kitchen Cabinet.png". Below the table, a large JSON object is displayed, representing the event payload. The JSON starts with a brace and includes fields like "topic", "subject", "eventType", "id", "data", and "sequenceNumber". The "data" field is expanded to show detailed information about the blob, including its API ("PutBlob"), client request ID ("37bdc77e-f589-4b32-8d9c-bd55e956f02c"), request ID ("0bbfffb35-b01e-0087-496d-21739b06261d"), eTag ("0x8DBEF84A251A6A8"), content type ("image/png"), content length (777113), blob type ("BlockBlob"), URL ("https://spstorageaccount1127.blob.core.windows.net/eventcontainer/Kitchen Cabinet.png"), and storage diagnostics. The JSON ends with a brace. At the bottom of the viewer, there's another row with a Microsoft EventGrid icon and the text "Microsoft.EventGrid.SubscriptionValidationEvent".

```
{  
    "topic": "/subscriptions/000000000-0000-0000-0000-000000000000/resourceGroups/spegridrg/providers/Microsoft.Storage/storageAccounts/spstorageaccount1127",  
    "subject": "/blobServices/default/containers/eventcontainer/blobs/Kitchen Cabinet.png",  
    "eventType": "Microsoft.Storage.BlobCreated",  
    "id": "0bbfffb35-b01e-0087-496d-21739b06261d",  
    "data": {  
        "api": "PutBlob",  
        "clientRequestId": "37bdc77e-f589-4b32-8d9c-bd55e956f02c",  
        "requestId": "0bbfffb35-b01e-0087-496d-21739b000000",  
        "eTag": "0x8DBEF84A251A6A8",  
        "contentType": "image/png",  
        "contentLength": 777113,  
        "blobType": "BlockBlob",  
        "url": "https://spstorageaccount1127.blob.core.windows.net/eventcontainer/Kitchen Cabinet.png",  
        "sequencer": "00000000000000000000000000000371490000000003d83cd7",  
        "storageDiagnostics": {  
            "batchId": "9b6af860-d006-0081-006d-214024000000"  
        }  
    },  
    "dataVersion": "",  
    "metadataVersion": "1",  
    "eventTime": "2023-11-27T20:08:34.1048753Z"  
}  
Microsoft.EventGrid.SubscriptionValidationEvent
```

Clean up resources

If you plan to continue working with this event, don't clean up the resources created in this article. Otherwise, delete the resources you created in this article.

Select the resource group, and select **Delete resource group**.

Next steps

Now that you know how to create custom topics and event subscriptions, learn more about what Event Grid can help you do:

- [About Event Grid](#)
- [Route Blob storage events to a custom web endpoint](#)

- Monitor virtual machine changes with Azure Event Grid and Logic Apps
 - Stream big data into a data warehouse

Tutorial: Add Azure OpenAI text completion hints to your functions in Visual Studio Code

Article • 07/12/2024

This article shows you how to use Visual Studio Code to add an HTTP endpoint to the function app you created in the previous quickstart article. When triggered, this new HTTP endpoint uses an [Azure OpenAI text completion input binding](#) to get text completion hints from your data model.

During this tutorial, you learn how to accomplish these tasks:

- ✓ Create resources in Azure OpenAI.
- ✓ Deploy a model in OpenAI the resource.
- ✓ Set access permissions to the model resource.
- ✓ Enable your function app to connect to OpenAI.
- ✓ Add OpenAI bindings to your HTTP triggered function.

1. Check prerequisites

- Complete the steps in [part 1 of the Visual Studio Code quickstart](#).
- Obtain access to Azure OpenAI in your Azure subscription. If you haven't already been granted access, complete [this form](#) to request access.
- Install [.NET Core CLI tools](#).
- The [Azurite storage emulator](#). While you can also use an actual Azure Storage account, the article assumes you're using this emulator.

2. Create your Azure OpenAI resources

The following steps show how to create an Azure OpenAI data model in the Azure portal.

1. Sign in with your Azure subscription in the [Azure portal](#).
2. Select **Create a resource** and search for the **Azure OpenAI**. When you locate the service, select **Create**.

3. On the **Create Azure OpenAI** page, provide the following information for the fields on the **Basics** tab:

[Expand table](#)

Field	Description
Subscription	Your subscription, which has been onboarded to use Azure OpenAI.
Resource group	The resource group you created for the function app in the previous article. You can find this resource group name by right-clicking the function app in the Azure Resources browser, selecting properties, and then searching for the <code>resourceGroup</code> setting in the returned JSON resource file.
Region	Ideally, the same location as the function app.
Name	A descriptive name for your Azure OpenAI Service resource, such as <code>mySampleOpenAI</code> .
Pricing Tier	The pricing tier for the resource. Currently, only the Standard tier is available for the Azure OpenAI Service. For more info on pricing visit the Azure OpenAI pricing page

Create Azure OpenAI

...

1 Basics

2 Network

3 Tags

4 Review + submit

Enable new business solutions with OpenAI's language generation capabilities powered by GPT-3 models. These models have been pretrained with trillions of words and can easily adapt to your scenario with a few short examples provided at inference. Apply them to numerous scenarios, from summarization to content and code generation.

Project details

Select the subscription to manage deployed resources and costs. Use resource groups like folders to organize and manage all your resources.

Subscription * ⓘ

OpenAI Test Subscription

Resource group * ⓘ

test-resource-group

[Create new](#)

Instance details

Region * ⓘ

South Central US

Name * ⓘ

azure-openai-test-001

Pricing tier * ⓘ

Standard S0

[View full pricing details](#)

Content review policy

To detect and mitigate harmful use of the Azure OpenAI Service, Microsoft logs the content you send to the Completions and image generations APIs as well as the content it sends back. If content is flagged by the service's filters, it may be reviewed by a Microsoft full-time employee.

[Learn more about how Microsoft processes, uses, and stores your data](#)

[Apply for modified content filters and abuse monitoring](#)

[Review the Azure OpenAI code of conduct](#)

[Previous](#)

[Next](#)

4. Select **Next** twice to accept the default values for both the **Network** and **Tags** tabs.

The service you create doesn't have any network restrictions, including from the internet.

5. Select **Next** a final time to move to the final stage in the process: **Review + submit**.

6. Confirm your configuration settings, and select **Create**.

The Azure portal displays a notification when the new resource is available. Select **Go to resource** in the notification or search for your new Azure OpenAI resource by name.

7. In the Azure OpenAI resource page for your new resource, select **Click here to view endpoints** under **Essentials > Endpoints**. Copy the **endpoint URL** and the **keys**. Save these values, you need them later.

Now that you have the credentials to connect to your model in Azure OpenAI, you need to set these access credentials in application settings.

3. Deploy a model

Now you can deploy a model. You can select from one of several available models in Azure OpenAI Studio.

To deploy a model, follow these steps:

1. Sign in to [Azure OpenAI Studio](#).
2. Choose the subscription and the Azure OpenAI resource you created, and select **Use resource**.
3. Under **Management** select **Deployments**.
4. Select **Create new deployment** and configure the following fields:

[] [Expand table](#)

Field	Description
Deployment name	Choose a name carefully. The deployment name is used in your code to call the model by using the client libraries and the REST APIs, so you must save for use later on.
Select a model	Model availability varies by region. For a list of available models per region, see Model summary table and region availability .

i Important

When you access the model via the API, you need to refer to the deployment name rather than the underlying model name in API calls, which is one of the key differences between OpenAI and Azure OpenAI. OpenAI only requires the model name. Azure OpenAI always requires deployment name, even when using the model parameter. In our docs, we often have examples where deployment names are represented as identical to model names to help indicate which model works with a particular API endpoint. Ultimately your

deployment names can follow whatever naming convention is best for your use case.

5. Accept the default values for the rest of the setting and select **Create**.

The deployments table shows a new entry that corresponds to your newly created model.

You now have everything you need to add Azure OpenAI-based text completion to your function app.

4. Update application settings

1. In Visual Studio Code, open the local code project you created when you completed the [previous article](#).
2. In the local.settings.json file in the project root folder, update the `AzureWebJobsStorage` setting to `UseDevelopmentStorage=true`. You can skip this step if the `AzureWebJobsStorage` setting in *local.settings.json* is set to the connection string for an existing Azure Storage account instead of `UseDevelopmentStorage=true`.
3. In the local.settings.json file, add these settings values:
 - `AZURE_OPENAI_ENDPOINT`: required by the binding extension. Set this value to the endpoint of the Azure OpenAI resource you created earlier.
 - `AZURE_OPENAI_KEY`: required by the binding extension. Set this value to the key for the Azure OpenAI resource.
 - `CHAT_MODEL_DEPLOYMENT_NAME`: used to define the input binding. Set this value to the name you chose for your model deployment.
4. Save the file. When you deploy to Azure, you must also add these settings to your function app.

5. Register binding extensions

Because you're using an Azure OpenAI output binding, you must have the corresponding bindings extension installed before you run the project.

Except for HTTP and timer triggers, bindings are implemented as extension packages. To add the Azure OpenAI extension package to your project, run this [dotnet add package](#) command in the **Terminal** window:

Bash

```
dotnet add package Microsoft.Azure.Functions.Worker.Extensions.OpenAI --  
prerelease
```

Now, you can use the Azure OpenAI output binding in your project.

6. Return text completion from the model

The code you add creates a `whois` HTTP function endpoint in your existing project. In this function, data passed in a URL `name` parameter of a GET request is used to dynamically create a completion prompt. This dynamic prompt is bound to a text completion input binding, which returns a response from the model based on the prompt. The completion from the model is returned in the HTTP response.

1. In your existing `HttpExample` class file, add this `using` statement:

C#

```
using  
Microsoft.Azure.Functions.Worker.Extensions.OpenAI.TextCompletion;
```

2. In the same file, add this code that defines a new HTTP trigger endpoint named `whois`:

C#

```
[Function(nameof(WhoIs))]  
public IActionResult WhoIs([HttpTrigger(AuthorizationLevel.Function,  
Route = "whois/{name}")] HttpRequest req,  
[TextCompletionInput("Who is {name}?", Model =  
"%CHAT_MODEL_DEPLOYMENT_NAME%")] TextCompletionResponse response)  
{  
    if(!String.IsNullOrEmpty(response.Content))  
    {  
        return new OkObjectResult(response.Content);  
    }  
    else  
    {  
        return new NotFoundObjectResult("Something went wrong.");  
    }  
}
```

7. Run the function

1. In Visual Studio Code, Press F1 and in the command palette type `Azurite: Start` and press Enter to start the Azurite storage emulator.
2. Press `F5` to start the function app project and Core Tools in debug mode.
3. With the Core Tools running, send a GET request to the `whois` endpoint function, with a name in the path, like this URL:

```
http://localhost:7071/api/whois/<NAME>
```

Replace the `<NAME>` string with the value you want passed to the `"Who is {name}?"` prompt. The `<NAME>` must be the URL-encoded name of a public figure, like `Abraham%20Lincoln`.

The response you see is the text completion response from your Azure OpenAI model.

4. After a response is returned, press `Ctrl + C` to stop Core Tools.

8. Clean up resources

In Azure, *resources* refer to function apps, functions, storage accounts, and so forth. They're grouped into *resource groups*, and you can delete everything in a group by deleting the group.

You created resources to complete these quickstarts. You could be billed for these resources, depending on your [account status](#) and [service pricing](#). If you don't need the resources anymore, here's how to delete them:

1. In Visual Studio Code, press `F1` to open the command palette. In the command palette, search for and select `Azure: Open in portal`.
2. Choose your function app and press `Enter`. The function app page opens in the Azure portal.
3. In the **Overview** tab, select the named link next to **Resource group**.

The screenshot shows the Azure portal interface for an App Service named 'myfunctionapp'. The left sidebar has a 'Functions' section with 'Overview', 'Activity log', 'Access control (IAM)', 'Tags', 'Diagnose and solve problems', and 'Security'. Below that is another 'Functions' section with 'Functions', 'App keys', 'App files', and 'Proxies'. The main pane shows the 'Overview' tab for a resource group named 'myResourceGroup'. The resource group details include:

Setting	Value
Status	Running
Location	Central US
Subscription	Visual Studio Enterprise
Subscription ID	11111111-1111-1111-1111-111111111111
Tags	Click here to add tags
URL	https://myfunctionapp.azurewebsites.net
Operating System	Windows
App Service Plan	ASP-myResourceGroup-a285 (Y1: 0)
Properties	See More
Runtime version	3.0.13139.0

At the bottom of the main pane, there are tabs for Metrics, Features (8), Notifications (0), and Quickstart.

4. On the **Resource group** page, review the list of included resources, and verify that they're the ones you want to delete.

5. Select **Delete resource group**, and follow the instructions.

Deletion may take a couple of minutes. When it's done, a notification appears for a few seconds. You can also select the bell icon at the top of the page to view the notification.

Tutorial: Apply machine learning models in Azure Functions with Python and TensorFlow

Article • 03/09/2023

In this article, you learn how to use Python, TensorFlow, and Azure Functions with a machine learning model to classify an image based on its contents. Because you do all work locally and create no Azure resources in the cloud, there is no cost to complete this tutorial.

- ✓ Initialize a local environment for developing Azure Functions in Python.
- ✓ Import a custom TensorFlow machine learning model into a function app.
- ✓ Build a serverless HTTP API for classifying an image as containing a dog or a cat.
- ✓ Consume the API from a web app.

Prerequisites

- An Azure account with an active subscription. [Create an account for free](#).
- [Python 3.7.4](#). (Python 3.7.4 and Python 3.6.x are verified with Azure Functions; Python 3.8 and later versions are not yet supported.)
- The [Azure Functions Core Tools](#)
- A code editor such as [Visual Studio Code](#)

Prerequisite check

1. In a terminal or command window, run `func --version` to check that the Azure Functions Core Tools are version 2.7.1846 or later.
2. Run `python --version` (Linux/MacOS) or `py --version` (Windows) to check your Python version reports 3.7.x.

Clone the tutorial repository

1. In a terminal or command window, clone the following repository using Git:

```
git clone https://github.com/Azure-Samples/functions-python-tensorflow-tutorial.git
```

2. Navigate into the folder and examine its contents.

```
cd functions-python-tensorflow-tutorial
```

- *start* is your working folder for the tutorial.
- *end* is the final result and full implementation for your reference.
- *resources* contains the machine learning model and helper libraries.
- *frontend* is a website that calls the function app.

Create and activate a Python virtual environment

Navigate to the *start* folder and run the following commands to create and activate a virtual environment named `.venv`. Be sure to use Python 3.7, which is supported by Azure Functions.

bash

```
Bash
```

```
cd start
python -m venv .venv
source .venv/bin/activate
```

If Python didn't install the `venv` package on your Linux distribution, run the following command:

Bash

```
sudo apt-get install python3-venv
```

You run all subsequent commands in this activated virtual environment. (To exit the virtual environment, run `deactivate`.)

Create a local functions project

In Azure Functions, a function project is a container for one or more individual functions that each responds to a specific trigger. All functions in a project share the same local

and hosting configurations. In this section, you create a function project that contains a single boilerplate function named `classify` that provides an HTTP endpoint. You add more specific code in a later section.

1. In the *start* folder, use the Azure Functions Core Tools to initialize a Python function app:

```
func init --worker-runtime python
```

After initialization, the *start* folder contains various files for the project, including configurations files named `local.settings.json` and `host.json`. Because `local.settings.json` can contain secrets downloaded from Azure, the file is excluded from source control by default in the `.gitignore` file.

 **Tip**

Because a function project is tied to a specific runtime, all the functions in the project must be written with the same language.

2. Add a function to your project by using the following command, where the `--name` argument is the unique name of your function and the `--template` argument specifies the function's trigger. `func new` create a subfolder matching the function name that contains a code file appropriate to the project's chosen language and a configuration file named `function.json`.

```
func new --name classify --template "HTTP trigger"
```

This command creates a folder matching the name of the function, `classify`. In that folder are two files: `__init__.py`, which contains the function code, and `function.json`, which describes the function's trigger and its input and output bindings. For details on the contents of these files, see [Examine the file contents](#) in the Python quickstart.

Run the function locally

1. Start the function by starting the local Azure Functions runtime host in the *start* folder:

```
func start
```

2. Once you see the `classify` endpoint appear in the output, navigate to the URL, <http://localhost:7071/api/classify?name=Azure>. The message "Hello Azure!" should appear in the output.
3. Use **Ctrl-C** to stop the host.

Import the TensorFlow model and add helper code

To modify the `classify` function to classify an image based on its contents, you use a pre-built TensorFlow model that was trained with and exported from Azure Custom Vision Service. The model, which is contained in the `resources` folder of the sample you cloned earlier, classifies an image based on whether it contains a dog or a cat. You then add some helper code and dependencies to your project.

To build your own model using the free tier of the Custom Vision Service, follow the instructions in the [sample project repository](#).

Tip

If you want to host your TensorFlow model independent of the function app, you can instead mount a file share containing your model to your Linux function app. To learn more, see [Mount a file share to a Python function app using Azure CLI](#).

1. In the `start` folder, run following command to copy the model files into the `classify` folder. Be sure to include `*` in the command.

```
bash
```

```
Bash
```

```
cp ../resources/model/* classify
```

2. Verify that the `classify` folder contains files named `model.pb` and `labels.txt`. If not, check that you ran the command in the `start` folder.

3. In the *start* folder, run the following command to copy a file with helper code into the *classify* folder:

```
bash
```

```
Bash
```

```
cp ../resources/predict.py classify
```

4. Verify that the *classify* folder now contains a file named *predict.py*.
5. Open *start/requirements.txt* in a text editor and add the following dependencies required by the helper code:

```
txt
```

```
tensorflow==1.14  
Pillow  
requests
```

6. Save *requirements.txt*.
7. Install the dependencies by running the following command in the *start* folder. Installation may take a few minutes, during which time you can proceed with modifying the function in the next section.

```
pip install --no-cache-dir -r requirements.txt
```

On Windows, you may encounter the error, "Could not install packages due to an EnvironmentError: [Errno 2] No such file or directory:" followed by a long pathname to a file like *sharded Mutable Dense Hashtable.cpython-37.pyc*. Typically, this error happens because the depth of the folder path becomes too long. In this case, set the registry key

`HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\FileSystem@LongPathsEnabled` to `1` to enable long paths. Alternately, check where your Python interpreter is installed. If that location has a long path, try reinstalling in a folder with a shorter path.

 Tip

When calling upon `predict.py` to make its first prediction, a function named `_initialize` loads the TensorFlow model from disk and caches it in global variables. This caching speeds up subsequent predictions. For more information on using global variables, refer to the [Azure Functions Python developer guide](#).

Update the function to run predictions

1. Open `classify/_init_.py` in a text editor and add the following lines after the existing `import` statements to import the standard JSON library and the `predict` helpers:

Python

```
import logging
import azure.functions as func
import json

# Import helper script
from .predict import predict_image_from_url
```

2. Replace the entire contents of the `main` function with the following code:

Python

```
def main(req: func.HttpRequest) -> func.HttpResponse:
    image_url = req.params.get('img')
    logging.info('Image URL received: ' + image_url)

    results = predict_image_from_url(image_url)

    headers = {
        "Content-type": "application/json",
        "Access-Control-Allow-Origin": "*"
    }

    return func.HttpResponse(json.dumps(results), headers = headers)
```

This function receives an image URL in a query string parameter named `img`. It then calls `predict_image_from_url` from the helper library to download and classify the image using the TensorFlow model. The function then returns an HTTP response with the results.

 **Important**

Because this HTTP endpoint is called by a web page hosted on another domain, the response includes an `Access-Control-Allow-Origin` header to satisfy the browser's Cross-Origin Resource Sharing (CORS) requirements.

In a production application, change `*` to the web page's specific origin for added security.

3. Save your changes, then assuming that dependencies have finished installing, start the local function host again with `func start`. Be sure to run the host in the `start` folder with the virtual environment activated. Otherwise the host will start, but you will see errors when invoking the function.

```
func start
```

4. In a browser, open the following URL to invoke the function with the URL of a cat image and confirm that the returned JSON classifies the image as a cat.

```
http://localhost:7071/api/classify?  
img=https://raw.githubusercontent.com/Azure-Samples/functions-python-  
tensorflow-tutorial/master/resources/assets/samples/cat1.png
```

5. Keep the host running because you use it in the next step.

Run the local web app front end to test the function

To test invoking the function endpoint from another web app, there's a simple app in the repository's `frontend` folder.

1. Open a new terminal or command prompt and activate the virtual environment (as described earlier under [Create and activate a Python virtual environment](#)).
2. Navigate to the repository's `frontend` folder.
3. Start an HTTP server with Python:

```
bash
```

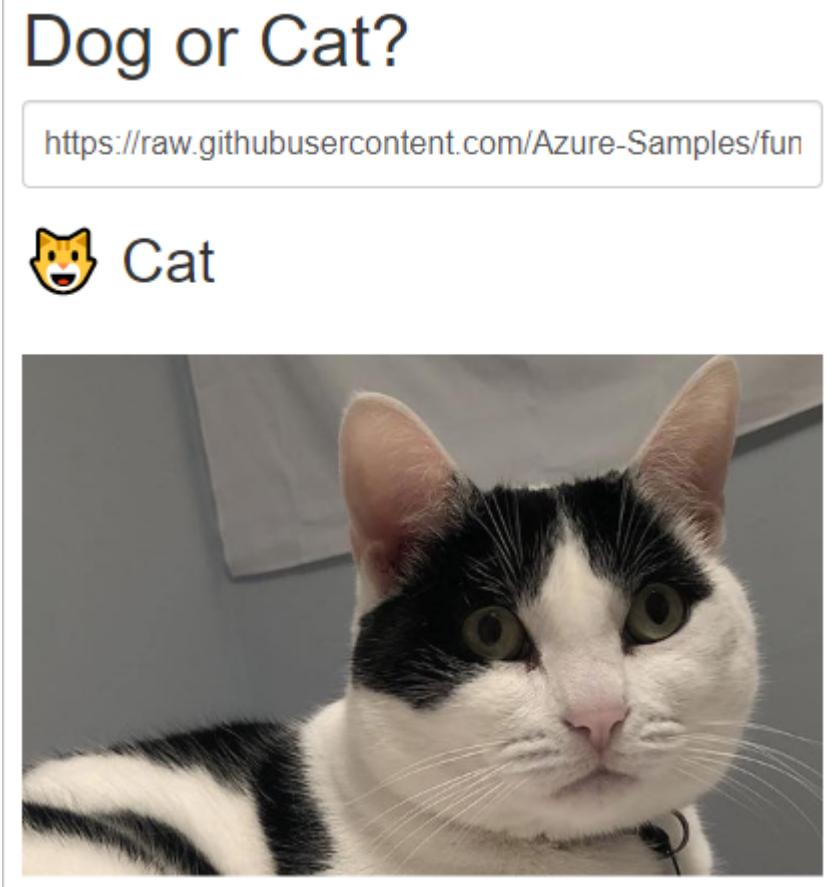

```
Bash
```

```
python -m http.server
```

4. In a browser, navigate to `localhost:8000`, then enter one of the following photo URLs into the textbox, or use the URL of any publicly accessible image.

- `https://raw.githubusercontent.com/Azure-Samples/functions-python-tensorflow-tutorial/master/resources/assets/samples/cat1.png`
- `https://raw.githubusercontent.com/Azure-Samples/functions-python-tensorflow-tutorial/master/resources/assets/samples/cat2.png`
- `https://raw.githubusercontent.com/Azure-Samples/functions-python-tensorflow-tutorial/master/resources/assets/samples/dog1.png`
- `https://raw.githubusercontent.com/Azure-Samples/functions-python-tensorflow-tutorial/master/resources/assets/samples/dog2.png`

5. Select **Submit** to invoke the function endpoint to classify the image.

If the browser reports an error when you submit the image URL, check the terminal in which you're running the function app. If you see an error like "No module found 'PIL'", you may have started the function app in the `start` folder without first activating the virtual environment you created earlier. If you still see errors, run `pip`

```
install -r requirements.txt again with the virtual environment activated and look for errors.
```

ⓘ Note

The model always classifies the content of the image as a cat or a dog, regardless of whether the image contains either, defaulting to dog. Images of tigers and panthers, for example, typically classify as cat, but images of elephants, carrots, or airplanes classify as dog.

Clean up resources

Because the entirety of this tutorial runs locally on your machine, there are no Azure resources or services to clean up.

Next steps

In this tutorial, you learned how to build and customize an HTTP API endpoint with Azure Functions to classify images using a TensorFlow model. You also learned how to call the API from a web app. You can use the techniques in this tutorial to build out APIs of any complexity, all while running on the serverless compute model provided by Azure Functions.

[Deploy the function to Azure Functions using the Azure CLI Guide](#)

Tutorial: Deploy a pre-trained image classification model to Azure Functions with PyTorch

Article • 03/09/2023

In this article, you learn how to use Python, PyTorch, and Azure Functions to load a pre-trained model for classifying an image based on its contents. Because you do all work locally and create no Azure resources in the cloud, there's no cost to complete this tutorial.

- ✓ Initialize a local environment for developing Azure Functions in Python.
- ✓ Import a pre-trained PyTorch machine learning model into a function app.
- ✓ Build a serverless HTTP API for classifying an image as one of 1000 ImageNet classes ↗ .
- ✓ Consume the API from a web app.

Prerequisites

- An Azure account with an active subscription. [Create an account for free ↗](#).
- [Python 3.7.4 or above ↗](#). (Python 3.8.x and Python 3.6.x are also verified with Azure Functions.)
- The [Azure Functions Core Tools](#)
- A code editor such as [Visual Studio Code ↗](#)

Prerequisite check

1. In a terminal or command window, run `func --version` to check that the Azure Functions Core Tools are version 2.7.1846 or later.
2. Run `python --version` (Linux/MacOS) or `py --version` (Windows) to check your Python version reports 3.7.x.

Clone the tutorial repository

1. In a terminal or command window, clone the following repository using Git:

```
git clone https://github.com/Azure-Samples/functions-python-pytorch-tutorial.git
```

2. Navigate into the folder and examine its contents.

```
cd functions-python-pytorch-tutorial
```

- *start* is your working folder for the tutorial.
- *end* is the final result and full implementation for your reference.
- *resources* contains the machine learning model and helper libraries.
- *frontend* is a website that calls the function app.

Create and activate a Python virtual environment

Navigate to the *start* folder and run the following commands to create and activate a virtual environment named `.venv`.

bash

Bash

```
cd start
python -m venv .venv
source .venv/bin/activate
```

If Python didn't install the `venv` package on your Linux distribution, run the following command:

Bash

```
sudo apt-get install python3-venv
```

You run all subsequent commands in this activated virtual environment. (To exit the virtual environment, run `deactivate`.)

Create a local functions project

In Azure Functions, a function project is a container for one or more individual functions that each responds to a specific trigger. All functions in a project share the same local and hosting configurations. In this section, you create a function project that contains a single boilerplate function named `classify` that provides an HTTP endpoint. You add more specific code in a later section.

1. In the `start` folder, use the Azure Functions Core Tools to initialize a Python function app:

```
func init --worker-runtime python
```

After initialization, the `start` folder contains various files for the project, including configurations files named `local.settings.json` and `host.json`. Because `local.settings.json` can contain secrets downloaded from Azure, the file is excluded from source control by default in the `.gitignore` file.

 **Tip**

Because a function project is tied to a specific runtime, all the functions in the project must be written with the same language.

2. Add a function to your project by using the following command, where the `--name` argument is the unique name of your function and the `--template` argument specifies the function's trigger. `func new` create a subfolder matching the function name that contains a code file appropriate to the project's chosen language and a configuration file named `function.json`.

```
func new --name classify --template "HTTP trigger"
```

This command creates a folder matching the name of the function, `classify`. In that folder are two files: `__init__.py`, which contains the function code, and `function.json`, which describes the function's trigger and its input and output bindings. For details on the contents of these files, see [Examine the file contents](#) in the Python quickstart.

Run the function locally

1. Start the function by starting the local Azure Functions runtime host in the *start* folder:

```
func start
```

2. Once you see the `classify` endpoint appear in the output, navigate to the URL, `http://localhost:7071/api/classify?name=Azure`. The message "Hello Azure!" should appear in the output.

3. Use **Ctrl-C** to stop the host.

Import the PyTorch model and add helper code

To modify the `classify` function to classify an image based on its contents, you use a pre-trained [ResNet](#) model. The pre-trained model, which comes from [PyTorch](#), classifies an image into 1 of 1000 [ImageNet classes](#). You then add some helper code and dependencies to your project.

1. In the *start* folder, run the following command to copy the prediction code and labels into the *classify* folder.

```
bash
Bash
cp ../resources/predict.py classify
cp ../resources/labels.txt classify
```

2. Verify that the *classify* folder contains files named *predict.py* and *labels.txt*. If not, check that you ran the command in the *start* folder.
3. Open *start/requirements.txt* in a text editor and add the dependencies required by the helper code, which should look like:

```
txt
azure-functions
requests
-f https://download.pytorch.org/whl/torch_stable.html
torch==1.13.0+cpu
torchvision==0.14.0+cpu
```

💡 Tip

The versions of torch and torchvision must match values listed in the version table of the [PyTorch vision repo](#).

4. Save *requirements.txt*, then run the following command from the *start* folder to install the dependencies.

```
pip install --no-cache-dir -r requirements.txt
```

Installation may take a few minutes, during which time you can proceed with modifying the function in the next section.

💡 Tip

On Windows, you may encounter the error, "Could not install packages due to an EnvironmentError: [Errno 2] No such file or directory:" followed by a long pathname to a file like *sharded Mutable Dense Hashtable.cpython-37.pyc*.

Typically, this error happens because the depth of the folder path becomes too long. In this case, set the registry key

`HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\FileSystem@LongPathsEnabled` to 1 to enable long paths. Alternately, check where your Python interpreter is installed. If that location has a long path, try reinstalling in a folder with a shorter path.

Update the function to run predictions

1. Open *classify/_init_.py* in a text editor and add the following lines after the existing `import` statements to import the standard JSON library and the *predict* helpers:

Python

```
import logging
import azure.functions as func
import json
```

```
# Import helper script
from .predict import predict_image_from_url
```

2. Replace the entire contents of the `main` function with the following code:

Python

```
def main(req: func.HttpRequest) -> func.HttpResponse:
    image_url = req.params.get('img')
    logging.info('Image URL received: ' + image_url)

    results = predict_image_from_url(image_url)

    headers = {
        "Content-type": "application/json",
        "Access-Control-Allow-Origin": "*"
    }

    return func.HttpResponse(json.dumps(results), headers = headers)
```

This function receives an image URL in a query string parameter named `img`. It then calls `predict_image_from_url` from the helper library to download and classify the image using the PyTorch model. The function then returns an HTTP response with the results.

 **Important**

Because this HTTP endpoint is called by a web page hosted on another domain, the response includes an `Access-Control-Allow-Origin` header to satisfy the browser's Cross-Origin Resource Sharing (CORS) requirements.

In a production application, change `*` to the web page's specific origin for added security.

3. Save your changes, then assuming that dependencies have finished installing, start the local function host again with `func start`. Be sure to run the host in the `start` folder with the virtual environment activated. Otherwise the host will start, but you'll see errors when invoking the function.

```
func start
```

4. In a browser, open the following URL to invoke the function with the URL of a Bernese Mountain Dog image and confirm that the returned JSON classifies the image as a Bernese Mountain Dog.

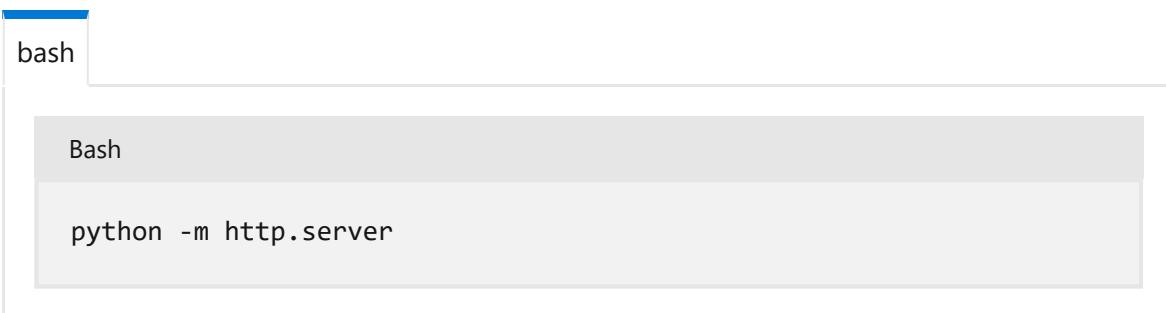

```
http://localhost:7071/api/classify?  
img=https://raw.githubusercontent.com/Azure-Samples/functions-python-  
pytorch-tutorial/master/resources/assets/Bernese-Mountain-Dog-  
Temperament-long.jpg
```

5. Keep the host running because you use it in the next step.

Run the local web app front end to test the function

To test invoking the function endpoint from another web app, there's a simple app in the repository's *frontend* folder.

1. Open a new terminal or command prompt and activate the virtual environment (as described earlier under [Create and activate a Python virtual environment](#)).
2. Navigate to the repository's *frontend* folder.
3. Start an HTTP server with Python:

```
bash  
Bash  
python -m http.server
```

4. In a browser, navigate to `localhost:8000`, then enter one of the following photo URLs into the textbox, or use the URL of any publicly accessible image.

- `https://raw.githubusercontent.com/Azure-Samples/functions-python-
pytorch-tutorial/master/resources/assets/Bernese-Mountain-Dog-
Temperament-long.jpg`
- `https://github.com/Azure-Samples/functions-python-pytorch-
tutorial/blob/master/resources/assets/bald-eagle.jpg?raw=true`
- `https://raw.githubusercontent.com/Azure-Samples/functions-python-
pytorch-tutorial/master/resources/assets/penguin.jpg`

5. Select **Submit** to invoke the function endpoint to classify the image.

Run PyTorch Image Classification

<https://raw.githubusercontent.com/Azure-Samples/functions-image-classification/master/submit.html>

king penguin, *Aptenodytes patagonica*

If the browser reports an error when you submit the image URL, check the terminal in which you're running the function app. If you see an error like "No module found 'PIL'", you may have started the function app in the *start* folder without first activating the virtual environment you created earlier. If you still see errors, run `pip install -r requirements.txt` again with the virtual environment activated and look for errors.

Clean up resources

Because the entirety of this tutorial runs locally on your machine, there are no Azure resources or services to clean up.

Next steps

In this tutorial, you learned how to build and customize an HTTP API endpoint with Azure Functions to classify images using a PyTorch model. You also learned how to call the API from a web app. You can use the techniques in this tutorial to build out APIs of any complexity, all while running on the serverless compute model provided by Azure Functions.

Tutorial: Deploy Azure Functions as IoT Edge modules

Article • 06/10/2024

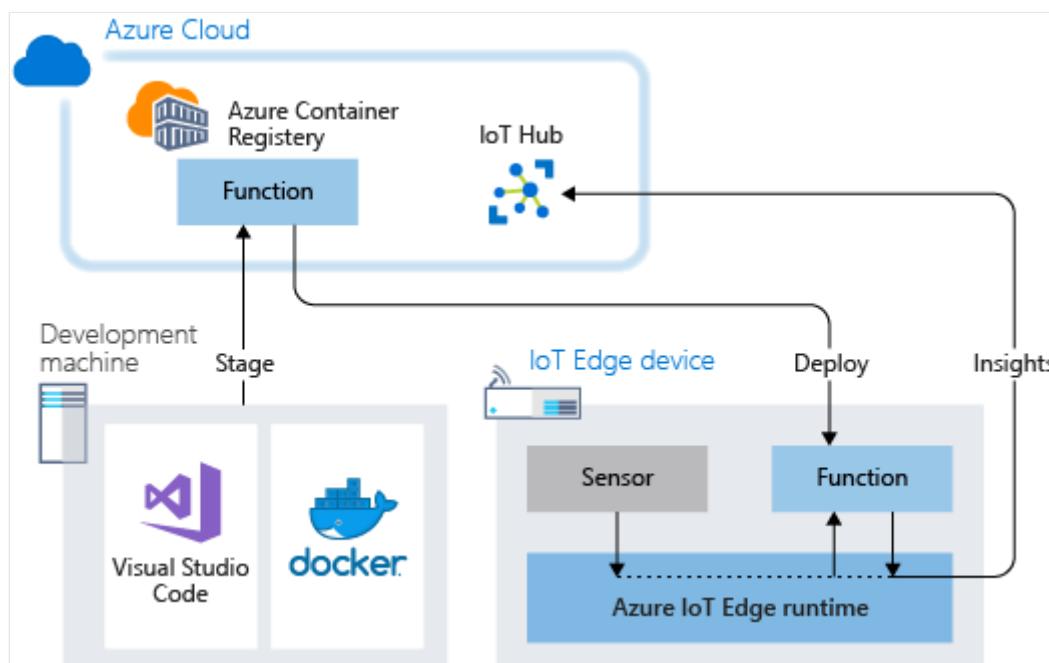

Applies to: ✓ IoT Edge 1.5 ✓ IoT Edge 1.4

ⓘ Important

IoT Edge 1.5 LTS and IoT Edge 1.4 LTS are [supported releases](#). IoT Edge 1.4 LTS is end of life on November 12, 2024. If you are on an earlier release, see [Update IoT Edge](#).

You can use Azure Functions to deploy code that implements your business logic directly to your Azure IoT Edge devices. This tutorial walks you through creating and deploying an Azure Function that filters sensor data on the simulated IoT Edge device. You use the simulated IoT Edge device that you created in the quickstarts. In this tutorial, you learn how to:

- ✓ Use Visual Studio Code to create an Azure Function.
- ✓ Use Visual Studio Code and Docker to create a Docker image and publish it to a container registry.
- ✓ Deploy the module from the container registry to your IoT Edge device.
- ✓ View filtered data.

The Azure Function that you create in this tutorial filters the temperature data that's generated by your device. The Function only sends messages upstream to Azure IoT

Hub when the temperature is above a specified threshold.

If you don't have an [Azure subscription](#), create an [Azure free account](#) before you begin.

Prerequisites

Before beginning this tutorial, do the tutorial to set up your development environment for Linux container development: [Develop Azure IoT Edge modules using Visual Studio Code](#). After completing that tutorial, you should have the following prerequisites in place:

- A free or standard-tier [IoT Hub](#) in Azure.
- An AMD64 device running Azure IoT Edge with Linux containers. You can use the quickstart to set up a [Linux device](#) or [Windows device](#).
- A container registry, like [Azure Container Registry](#).
- [Visual Studio Code](#) configured with the [Azure IoT Edge](#) and [Azure IoT Hub](#) extensions. The *Azure IoT Edge tools for Visual Studio Code* extension is in [maintenance mode](#).
- Download and install a [Docker compatible container management system](#) on your development machine. Configure it to run Linux containers.

To develop an IoT Edge module with Azure Functions, install additional prerequisites on your development machine:

- [C# for Visual Studio Code \(powered by OmniSharp\) extension](#).
- [The .NET Core SDK](#).

Create a function project

The Azure IoT Edge for Visual Studio Code that you installed in the prerequisites provides management capabilities and some code templates. In this section, you use Visual Studio Code to create an IoT Edge solution that contains an Azure Function.

Create a new project

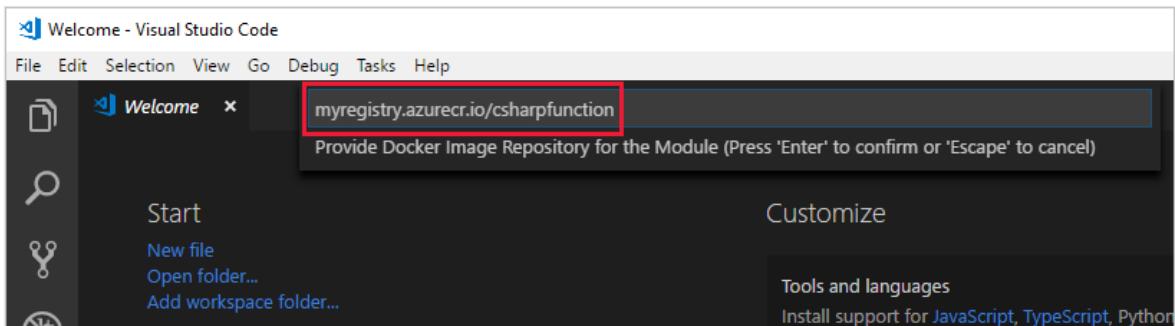

Follow these steps to create a C# Function solution template that's customizable.

1. Open Visual Studio Code on your development machine.
2. Open the Visual Studio Code command palette by selecting **View > Command Palette**.

3. In the command palette, add and run the command **Azure IoT Edge: New IoT**

Edge solution. Follow these prompts in the command palette to create your solution:

- Select a folder: choose the location on your development machine for Visual Studio Code to create the solution files.
- Provide a solution name: add a descriptive name for your solution, like **FunctionSolution**, or accept the default.|
- Select a module template: choose **Azure Functions - C#**.
- Provide a module name | Name your module **CSharpFunction**.
- Provide a Docker image repository for the module. An image repository includes the name of your container registry and the name of your container image. Your container image is pre-populated from the last step. Replace **localhost:5000** with the **Login server** value from your Azure container registry. You can retrieve the **Login server** from the **Overview** page of your container registry in the Azure portal. The final string looks like <registry name>.azurecr.io/csharpfunction.

Add your registry credentials

The environment file of your solution stores the credentials for your container registry and shares them with the IoT Edge runtime. The runtime needs these credentials to pull your private images onto your IoT Edge device.

The IoT Edge extension in Visual Studio Code tries to pull your container registry credentials from Azure and populate them in the environment file. Check to see if your credentials are already in the file. If not, add them now:

1. In the Visual Studio Code explorer, open the `.env` file.
2. Update the fields with the **username** and **password** values that you copied from your Azure container registry. You can find them again by going to your container registry in Azure and looking on the **Settings > Access keys** page.
3. Save this file.

(!) Note

This tutorial uses admin login credentials for Azure Container Registry, which are convenient for development and test scenarios. When you're ready for production scenarios, we recommend a least-privilege authentication option like service principals. For more information, see [Manage access to your container registry](#).

Set target architecture to AMD64

Running Azure Functions modules on IoT Edge is supported only on Linux AMD64 based containers. The default target architecture for Visual Studio Code is Linux AMD64, but we set it explicitly to Linux AMD64 here.

1. Open the command palette and search for **Azure IoT Edge: Set Default Target Platform for Edge Solution**.
2. In the command palette, select the AMD64 target architecture from the list of options.

Update the module with custom code

Let's add some additional code so your **CSharpFunction** module processes the messages at the edge before forwarding them to IoT Hub.

1. In the Visual Studio Code explorer, open **modules > CSharpFunction > CSharpFunction.cs**.
2. Replace the contents of the **CSharpFunction.cs** file with the following code. This code receives telemetry about ambient and machine temperature, and only forwards the message on to IoT Hub if the machine temperature is above a defined threshold.

C#

```
using System;
using System.Collections.Generic;
using System.IO;
using System.Text;
using System.Threading.Tasks;
using Microsoft.Azure.Devices.Client;
using Microsoft.Azure.WebJobs;
using Microsoft.Azure.WebJobs.EdgeHub;
using Microsoft.Azure.WebJobs.Host;
using Microsoft.Extensions.Logging;
```

```

using Newtonsoft.Json;

namespace Functions.Samples
{
    public static class CSharpFunction
    {
        [FunctionName("CSharpFunction")]
        public static async Task FilterMessageAndSendMessage(
            [EdgeHubTrigger("input1")] Message messageReceived,
            [EdgeHub(OutputName = "output1")] IAsyncCollector<Message>
output,
            ILogger logger)
        {
            const int temperatureThreshold = 20;
            byte[] messageBytes = messageReceived.GetBytes();
            var messageString =
                System.Text.Encoding.UTF8.GetString(messageBytes);

            if (!string.IsNullOrEmpty(messageString))
            {
                logger.LogInformation("Info: Received one non-empty
message");
                // Get the body of the message and deserialize it.
                var messageBody =
                    JsonConvert.DeserializeObject<MessageBody>(messageString);

                if (messageBody != null &&
messageBody.machine.temperature > temperatureThreshold)
                {
                    // Send the message to the output as the
temperature value is greater than the threshold.
                    using (var filteredMessage = new
Message(messageBytes))
                    {
                        // Copy the properties of the original message
into the new Message object.
                        foreach (KeyValuePair<string, string> prop in
messageReceived.Properties)
                            {filteredMessage.Properties.Add(prop.Key,
prop.Value);}
                        // Add a new property to the message to
indicate it is an alert.
                        filteredMessage.Properties.Add("MessageType",
"Alert");
                        // Send the message.
                        await output.AddAsync(filteredMessage);
                        logger.LogInformation("Info: Received and
transferred a message with temperature above the threshold");
                    }
                }
            }
        }
    }
    //Define the expected schema for the body of incoming messages.
    class MessageBody

```

```
{  
    public Machine machine {get; set;}  
    public Ambient ambient {get; set;}  
    public string timeCreated {get; set;}  
}  
class Machine  
{  
    public double temperature {get; set;}  
    public double pressure {get; set;}  
}  
class Ambient  
{  
    public double temperature {get; set;}  
    public int humidity {get; set;}  
}  
}
```

3. Save the file.

Build and push your IoT Edge solution

In the previous section, you created an IoT Edge solution and modified the **CSharpFunction** to filter out messages with reported machine temperatures below the acceptable threshold. Now you need to build the solution as a container image and push it to your container registry.

1. Open the Visual Studio Code integrated terminal by selecting **View > Terminal**.
2. Sign in to Docker by entering the following command in the terminal. Sign in with the username, password, and login server from your Azure container registry. You can retrieve these values from the **Access keys** section of your registry in the Azure portal.

Bash

```
docker login -u <ACR username> -p <ACR password> <ACR login server>
```

You may receive a security warning recommending the use of `--password-stdin`. While that best practice is recommended for production scenarios, it's outside the scope of this tutorial. For more information, see the [docker login](#) reference.

3. In the Visual Studio Code explorer, right-click the **deployment.template.json** file and select **Build and Push IoT Edge Solution**.

The build and push command starts three operations. First, it creates a new folder in the solution called **config** that holds the full deployment manifest, which is built

out of information in the deployment template and other solution files. Second, it runs `docker build` to build the container image based on the appropriate dockerfile for your target architecture. Then, it runs `docker push` to push the image repository to your container registry.

This process may take several minutes the first time, but is faster the next time that you run the commands.

View your container image

Visual Studio Code outputs a success message when your container image is pushed to your container registry. If you want to confirm the successful operation for yourself, you can view the image in the registry.

1. In the Azure portal, browse to your Azure container registry.
2. Select **Services > Repositories**.
3. You should see the **csharpfunction** repository in the list. Select this repository to see more details.
4. In the **Tags** section, you should see the **0.0.1-amd64** tag. This tag indicates the version and platform of the image that you built. These values are set in the `module.json` file in the `CSharpFunction` folder.

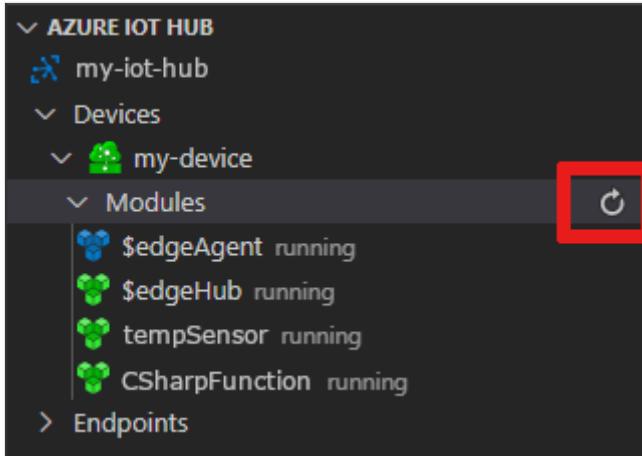

Deploy and run the solution

You can use the Azure portal to deploy your Function module to an IoT Edge device like you did in the quickstart. You can also deploy and monitor modules from within Visual Studio Code. The following sections use the Azure IoT Edge and IoT Hub for Visual Studio Code that was listed in the prerequisites. Install the extensions now, if you haven't already.

1. In the Visual Studio Code explorer, under the **Azure IoT Hub** section, expand **Devices** to see your list of IoT devices.
2. Right-click the name of your IoT Edge device, and then select **Create Deployment for Single Device**.
3. Browse to the solution folder that contains the **CSharpFunction**. Open the config folder, select the `deployment.amd64.json` file, and then choose **Select Edge Deployment Manifest**.
4. Under your device, expand **Modules** to see a list of deployed and running modules. Select the refresh button. You should see the new **CSharpFunction**

running along with the `SimulatedTemperatureSensor` module and the `$edgeAgent` and `$edgeHub`.

It may take a few moments for the new modules to show up. Your IoT Edge device has to retrieve its new deployment information from IoT Hub, start the new containers, and then report the status back to IoT Hub.

View the generated data

You can see all of the messages that arrive at your IoT hub from all your devices by running **Azure IoT Hub: Start Monitoring Built-in Event Endpoint** in the command palette. To stop monitoring messages, run the command **Azure IoT Hub: Stop Monitoring Built-in Event Endpoint** in the command palette.

You can also filter the view to see all of the messages that arrive at your IoT hub from a specific device. Right-click the device in the **Azure IoT Hub > Devices** section of the Visual Studio Code explorer and select **Start Monitoring Built-in Event Endpoint**.

Clean up resources

If you plan to continue to the next recommended article, you can keep the resources and configurations that you created and reuse them. You can also keep using the same IoT Edge device as a test device.

Otherwise, you can delete the local configurations and the Azure resources that you created in this article to avoid charges.

Delete Azure resources

Deleting Azure resources and resource groups is irreversible. Make sure that you don't accidentally delete the wrong resource group or resources. If you created the IoT hub

inside an existing resource group that has resources that you want to keep, delete only the IoT hub resource itself, not the resource group.

To delete the resources:

1. Sign in to the [Azure portal](#), and then select **Resource groups**.
2. Select the name of the resource group that contains your IoT Edge test resources.
3. Review the list of resources that are contained in your resource group. If you want to delete all of them, you can select **Delete resource group**. If you want to delete only some of them, you can click into each resource to delete them individually.

Next steps

In this tutorial, you created an Azure Function module with code to filter raw data that's generated by your IoT Edge device.

Continue on to the next tutorials to learn other ways that Azure IoT Edge can help you turn data into business insights at the edge.

Tutorial: Create a function in Java with an Event Hub trigger and an Azure Cosmos DB output binding

Article • 02/14/2024

This tutorial shows you how to use Azure Functions to create a Java function that analyzes a continuous stream of temperature and pressure data. Event hub events that represent sensor readings trigger the function. The function processes the event data, then adds status entries to an Azure Cosmos DB instance.

In this tutorial, you'll:

- ✓ Create and configure Azure resources using the Azure CLI.
- ✓ Create and test Java functions that interact with these resources.
- ✓ Deploy your functions to Azure and monitor them with Application Insights.

If you don't have an [Azure subscription](#), create an [Azure free account](#) before you begin.

Prerequisites

To complete this tutorial, you must have the following installed:

- [Java Developer Kit](#), version 8
- [Apache Maven](#), version 3.0 or above
- [Azure Functions Core Tools](#) version 2.6.666 or above
- Use the Bash environment in [Azure Cloud Shell](#). For more information, see [Quickstart for Bash in Azure Cloud Shell](#).

 [Launch Cloud Shell](#) 

- If you prefer to run CLI reference commands locally, [install](#) the Azure CLI. If you're running on Windows or macOS, consider running Azure CLI in a Docker container. For more information, see [How to run the Azure CLI in a Docker container](#).
 - If you're using a local installation, sign in to the Azure CLI by using the [az login](#) command. To finish the authentication process, follow the steps displayed in your terminal. For other sign-in options, see [Sign in with the Azure CLI](#).

- When you're prompted, install the Azure CLI extension on first use. For more information about extensions, see [Use extensions with the Azure CLI](#).
- Run `az version` to find the version and dependent libraries that are installed. To upgrade to the latest version, run `az upgrade`.

ⓘ Important

The `JAVA_HOME` environment variable must be set to the install location of the JDK to complete this tutorial.

If you prefer to use the code for this tutorial directly, see the [java-functions-eventhub-cosmosdb](#) sample repo.

Create Azure resources

In this tutorial, you'll need these resources:

- A resource group to contain the other resources
- An Event Hubs namespace, event hub, and authorization rule
- An Azure Cosmos DB account, database, and collection
- A function app and a storage account to host it

The following sections show you how to create these resources using the Azure CLI.

Set environment variables

Next, create some environment variables for the names and location of the resources you'll create. Use the following commands, replacing the `<value>` placeholders with values of your choosing. Values should conform to the [naming rules and restrictions for Azure resources](#). For the `LOCATION` variable, use one of the values produced by the `az functionapp list-consumption-locations` command.

Bash

Bash

```
RESOURCE_GROUP=<value>
EVENT_HUB_NAMESPACE=<value>
EVENT_HUB_NAME=<value>
EVENT_HUB_AUTHORIZATION_RULE=<value>
COSMOS_DB_ACCOUNT=<value>
```

```
STORAGE_ACCOUNT=<value>
FUNCTION_APP=<value>
LOCATION=<value>
```

The rest of this tutorial uses these variables. Be aware that these variables persist only for the duration of your current Azure CLI or Cloud Shell session. You will need to run these commands again if you use a different local terminal window or your Cloud Shell session times out.

Create a resource group

Azure uses resource groups to collect all related resources in your account. That way, you can view them as a unit and delete them with a single command when you're done with them.

Use the following command to create a resource group:

Bash

Azure CLI

```
az group create \
--name $RESOURCE_GROUP \
--location $LOCATION
```

Create an event hub

Next, create an Azure Event Hubs namespace, event hub, and authorization rule using the following commands:

Bash

Azure CLI

```
az eventhubs namespace create \
--resource-group $RESOURCE_GROUP \
--name $EVENT_HUB_NAMESPACE
az eventhubs eventhub create \
--resource-group $RESOURCE_GROUP \
--name $EVENT_HUB_NAME \
--namespace-name $EVENT_HUB_NAMESPACE \
--message-retention 1
az eventhubs eventhub authorization-rule create \
```

```
--resource-group $RESOURCE_GROUP \
--name $EVENT_HUB_AUTHORIZATION_RULE \
--eventhub-name $EVENT_HUB_NAME \
--namespace-name $EVENT_HUB_NAMESPACE \
--rights Listen Send
```

The Event Hubs namespace contains the actual event hub and its authorization rule. The authorization rule enables your functions to send messages to the hub and listen for the corresponding events. One function sends messages that represent telemetry data. Another function listens for events, analyzes the event data, and stores the results in Azure Cosmos DB.

Create an Azure Cosmos DB

Next, create an Azure Cosmos DB account, database, and collection using the following commands:

Bash

Azure CLI

```
az cosmosdb create \
--resource-group $RESOURCE_GROUP \
--name $COSMOS_DB_ACCOUNT
az cosmosdb sql database create \
--resource-group $RESOURCE_GROUP \
--account-name $COSMOS_DB_ACCOUNT \
--name TelemetryDb
az cosmosdb sql container create \
--resource-group $RESOURCE_GROUP \
--account-name $COSMOS_DB_ACCOUNT \
--database-name TelemetryDb \
--name TelemetryInfo \
--partition-key-path '/temperatureStatus'
```

The `partition-key-path` value partitions your data based on the `temperatureStatus` value of each item. The partition key enables Azure Cosmos DB to increase performance by dividing your data into distinct subsets that it can access independently.

Create a storage account and function app

Next, create an Azure Storage account, which is required by Azure Functions, then create the function app. Use the following commands:

Bash

Azure CLI

```
az storage account create \
    --resource-group $RESOURCE_GROUP \
    --name $STORAGE_ACCOUNT \
    --sku Standard_LRS
az functionapp create \
    --resource-group $RESOURCE_GROUP \
    --name $FUNCTION_APP \
    --storage-account $STORAGE_ACCOUNT \
    --consumption-plan-location $LOCATION \
    --runtime java \
    --functions-version 3
```

When the `az functionapp create` command creates your function app, it also creates an Application Insights resource with the same name. The function app is automatically configured with a setting named `APPINSIGHTS_INSTRUMENTATIONKEY` that connects it to Application Insights. You can view app telemetry after you deploy your functions to Azure, as described later in this tutorial.

Configure your function app

Your function app will need to access the other resources to work correctly. The following sections show you how to configure your function app so that it can run on your local machine.

Retrieve resource connection strings

Use the following commands to retrieve the storage, event hub, and Azure Cosmos DB connection strings and save them in environment variables:

Bash

Azure CLI

```
AZURE_WEB_JOBS_STORAGE=$( \
    az storage account show-connection-string \
        --name $STORAGE_ACCOUNT \
        --query connectionString \
        --output tsv)
echo $AZURE_WEB_JOBS_STORAGE
EVENT_HUB_CONNECTION_STRING=$( \
```

```
az eventhubs eventhub authorization-rule keys list \
    --resource-group $RESOURCE_GROUP \
    --name $EVENT_HUB_AUTHORIZATION_RULE \
    --eventhub-name $EVENT_HUB_NAME \
    --namespace-name $EVENT_HUB_NAMESPACE \
    --query primaryConnectionString \
    --output tsv)
echo $EVENT_HUB_CONNECTION_STRING
COSMOS_DB_CONNECTION_STRING=$( \
    az cosmosdb keys list \
    --resource-group $RESOURCE_GROUP \
    --name $COSMOS_DB_ACCOUNT \
    --type connection-strings \
    --query 'connectionStrings[0].connectionString' \
    --output tsv)
echo $COSMOS_DB_CONNECTION_STRING
```

These variables are set to values retrieved from Azure CLI commands. Each command uses a JMESPath query to extract the connection string from the JSON payload returned. The connection strings are also displayed using `echo` so you can confirm that they've been retrieved successfully.

Update your function app settings

Next, use the following command to transfer the connection string values to app settings in your Azure Functions account:

Bash

Azure CLI

```
az functionapp config appsettings set \
    --resource-group $RESOURCE_GROUP \
    --name $FUNCTION_APP \
    --settings \
        AzureWebJobsStorage=$AZURE_WEB_JOBS_STORAGE \
        EventHubConnectionString=$EVENT_HUB_CONNECTION_STRING \
        CosmosDBConnectionString=$COSMOS_DB_CONNECTION_STRING
```

Your Azure resources have now been created and configured to work properly together.

Create and test your functions

Next, you'll create a project on your local machine, add Java code, and test it. You'll use commands that work with the Azure Functions Plugin for Maven and the Azure Functions Core Tools. Your functions will run locally, but will use the cloud-based resources you've created. After you get the functions working locally, you can use Maven to deploy them to the cloud and watch your data and analytics accumulate.

If you used Cloud Shell to create your resources, then you won't be connected to Azure locally. In this case, use the `az login` command to launch the browser-based login process. Then if necessary, set the default subscription with `az account set --subscription` followed by the subscription ID. Finally, run the following commands to recreate some environment variables on your local machine. Replace the `<value>` placeholders with the same values you used previously.

Bash

Bash

```
RESOURCE_GROUP=<value>
FUNCTION_APP=<value>
```

Create a local functions project

Use the following Maven command to create a functions project and add the required dependencies.

Bash

```
mvn archetype:generate --batch-mode \
-DarchetypeGroupId=com.microsoft.azure \
-DarchetypeArtifactId=azure-functions-archetype \
-DappName=$FUNCTION_APP \
-DresourceGroup=$RESOURCE_GROUP \
-DappRegion=$LOCATION \
-DgroupId=com.example \
-DartifactId=telemetry-functions
```

This command generates several files inside a `telemetry-functions` folder:

- A `pom.xml` file for use with Maven

- A `local.settings.json` file to hold app settings for local testing
- A `host.json` file that enables the Azure Functions Extension Bundle, required for Azure Cosmos DB output binding in your data analysis function
- A `Function.java` file that includes a default function implementation
- A few test files that this tutorial doesn't need

To avoid compilation errors, you'll need to delete the test files. Run the following commands to navigate to the new project folder and delete the test folder:

```
Bash
Bash
cd telemetry-functions
rm -r src/test
```

Retrieve your function app settings for local use

For local testing, your function project will need the connection strings that you added to your function app in Azure earlier in this tutorial. Use the following Azure Functions Core Tools command, which retrieves all the function app settings stored in the cloud and adds them to your `local.settings.json` file:

```
Bash
Bash
func azure functionapp fetch-app-settings $FUNCTION_APP
```

Add Java code

Next, open the `Function.java` file and replace the contents with the following code.

```
Java
package com.example;

import com.example.TelemetryItem.Status;
import com.microsoft.azure.functions.annotation.Cardinality;
import com.microsoft.azure.functions.annotation.CosmosDBOutput;
import com.microsoft.azure.functions.annotation.EventHubOutput;
```

```
import com.microsoft.azure.functions.annotation.EventHubTrigger;
import com.microsoft.azure.functions.annotation.FunctionName;
import com.microsoft.azure.functions.annotation.TimerTrigger;
import com.microsoft.azure.functions.ExecutionContext;
import com.microsoft.azure.functions.OutputBinding;

public class Function {

    @FunctionName("generateSensorData")
    @EventHubOutput(
        name = "event",
        eventHubName = "", // blank because the value is included in the
    connection string
        connection = "EventHubConnectionString")
    public TelemetryItem generateSensorData(
        @TimerTrigger(
            name = "timerInfo",
            schedule = "*/*/*/*/*") // every 10 seconds
            String timerInfo,
        final ExecutionContext context) {

        context.getLogger().info("Java Timer trigger function executed at: "
            + java.time.LocalDateTime.now());
        double temperature = Math.random() * 100;
        double pressure = Math.random() * 50;
        return new TelemetryItem(temperature, pressure);
    }

    @FunctionName("processSensorData")
    public void processSensorData(
        @EventHubTrigger(
            name = "msg",
            eventHubName = "", // blank because the value is included in the
    connection string
            cardinality = Cardinality.ONE,
            connection = "EventHubConnectionString")
            TelemetryItem item,
        @CosmosDBOutput(
            name = "databaseOutput",
            databaseName = "TelemetryDb",
            containerName = "TelemetryInfo",
            connection = "CosmosDBConnectionString")
            OutputBinding<TelemetryItem> document,
        final ExecutionContext context) {

        context.getLogger().info("Event hub message received: " +
item.toString());

        if (item.getPressure() > 30) {
            item.setNormalPressure(false);
        } else {
            item.setNormalPressure(true);
        }

        if (item.getTemperature() < 40) {
```

```

        item.setTemperatureStatus(status.COOL);
    } else if (item.getTemperature() > 90) {
        item.setTemperatureStatus(status.HOT);
    } else {
        item.setTemperatureStatus(status.WARM);
    }

    document.setValue(item);
}
}

```

As you can see, this file contains two functions, `generateSensorData` and `processSensorData`. The `generateSensorData` function simulates a sensor that sends temperature and pressure readings to the event hub. A timer trigger runs the function every 10 seconds, and an event hub output binding sends the return value to the event hub.

When the event hub receives the message, it generates an event. The `processSensorData` function runs when it receives the event. It then processes the event data and uses an Azure Cosmos DB output binding to send the results to Azure Cosmos DB.

The data used by these functions is stored using a class called `TelemetryItem`, which you'll need to implement. Create a new file called `TelemetryItem.java` in the same location as `Function.java` and add the following code:

Java

```

package com.example;

public class TelemetryItem {

    private String id;
    private double temperature;
    private double pressure;
    private boolean isNormalPressure;
    private status temperatureStatus;
    static enum status {
        COOL,
        WARM,
        HOT
    }

    public TelemetryItem(double temperature, double pressure) {
        this.temperature = temperature;
        this.pressure = pressure;
    }

    public String getId() {

```

```
        return id;
    }

    public double getTemperature() {
        return temperature;
    }

    public double getPressure() {
        return pressure;
    }

    @Override
    public String toString() {
        return "TelemetryItem{id=" + id + ",temperature="
            + temperature + ",pressure=" + pressure + "}";
    }

    public boolean isNormalPressure() {
        return isNormalPressure;
    }

    public void setNormalPressure(boolean isNormal) {
        this.isNormalPressure = isNormal;
    }

    public status getTemperatureStatus() {
        return temperatureStatus;
    }

    public void setTemperatureStatus(status temperatureStatus) {
        this.temperatureStatus = temperatureStatus;
    }
}
```

Run locally

You can now build and run the functions locally and see data appear in your Azure Cosmos DB.

Use the following Maven commands to build and run the functions:

Bash

Bash

```
mvn clean package
mvn azure-functions:run
```

After some build and startup messages, you'll see output similar to the following example for each time the functions run:

```
Output

[10/22/19 4:01:30 AM] Executing 'Functions.generateSensorData'
(Reason='Timer fired at 2019-10-21T21:01:30.0016769-07:00', Id=c1927c7f-
4f70-4a78-83eb-bc077d838410)
[10/22/19 4:01:30 AM] Java Timer trigger function executed at: 2019-10-
21T21:01:30.015
[10/22/19 4:01:30 AM] Function "generateSensorData" (Id: c1927c7f-4f70-4a78-
83eb-bc077d838410) invoked by Java Worker
[10/22/19 4:01:30 AM] Executed 'Functions.generateSensorData' (Succeeded,
Id=c1927c7f-4f70-4a78-83eb-bc077d838410)
[10/22/19 4:01:30 AM] Executing 'Functions.processSensorData' (Reason='',
Id=f4c3b4d7-9576-45d0-9c6e-85646bb52122)
[10/22/19 4:01:30 AM] Event hub message received: TelemetryItem=
{id=null,temperature=32.728691307527015,pressure=10.122563042388165}

9c6e-85646bb52122) invoked by Java Worker
[10/22/19 4:01:38 AM] Executed 'Functions.processSensorData' (Succeeded,
Id=1cf0382b-0c98-4cc8-9240-ee2a2f71800d)
```

You can then go to the [Azure portal](#) and navigate to your Azure Cosmos DB account. Select **Data Explorer**, expand **TelemetryInfo**, then select **Items** to view your data when it arrives.

The screenshot shows the Microsoft Azure Data Explorer interface for the 'weatherdata123 - Data Explorer' account. The left sidebar lists various monitoring and management options like Overview, Activity log, Access control (IAM), Tags, Diagnose and solve problems, Quick start, Notifications, and Data Explorer. The 'Data Explorer' option is highlighted with a red box. The main area shows the 'SQL API' interface for the 'TelemetryDb' database. Under 'TelemetryInfo', the 'Items' collection is selected, also highlighted with a red box. A table titled 'Items' displays several rows of sensor data. One row is expanded to show its JSON structure:

id	/temp...
75964b75...	WARM
d1bbc4f2...	HOT
5b75dad6...	WARM
3d5e7408...	WARM
76dd38f1...	COOL
38da208b...	COOL

Row 12 (highlighted) shows the expanded JSON data:

```
1 "temperature": 47.967774187747615,
2 "pressure": 19.179577577377465,
3 "isNormalPressure": true,
4 "temperatureStatus": "WARM",
5 "id": "3d5e7408-4536-40c1-ab49-5cc2b92
6 "_rid": "3fRaAK+T9gIEAAAAAAA==",
7 "_self": " dbs/3fRaAK+/colls/3fRaAK+T9
8 "_etag": "3002e2ef-0000-0700-0000-5c
9 "_attachments": "attachments/",
10 "_ts": 1572063509
```

Deploy to Azure and view app telemetry

Finally, you can deploy your app to Azure and verify that it continues to work the same way it did locally.

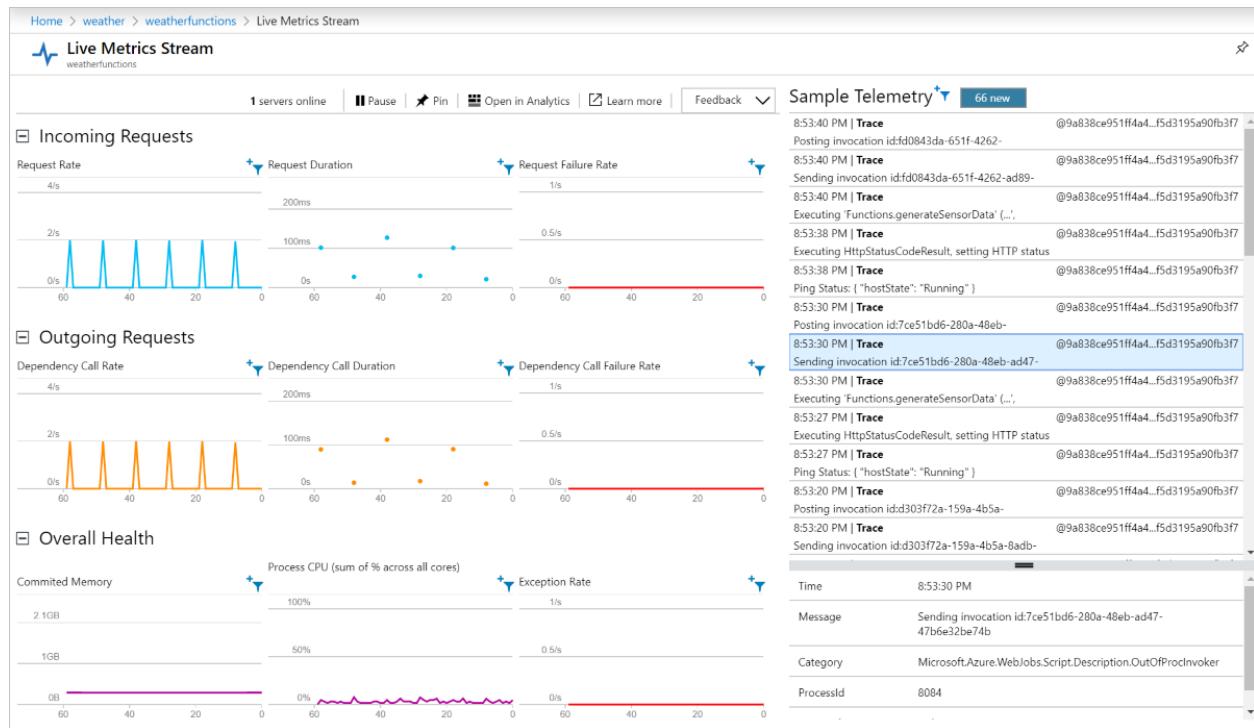

Deploy your project to Azure using the following command:

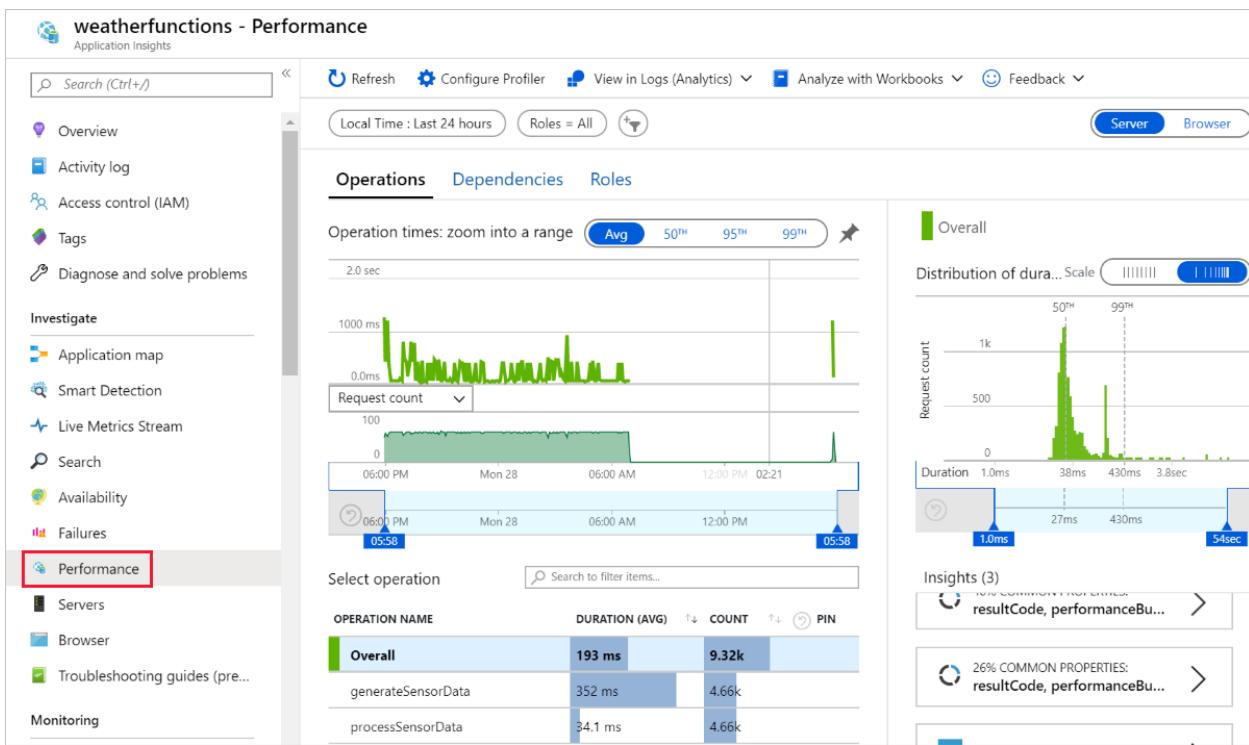

```
Bash
Bash
mvn azure-functions:deploy
```

Your functions now run in Azure, and continue to accumulate data in your Azure Cosmos DB. You can view your deployed function app in the Azure portal, and view app telemetry through the connected Application Insights resource, as shown in the following screenshots:

Live Metrics Stream:

Performance:

Clean up resources

When you're finished with the Azure resources you created in this tutorial, you can delete them using the following command:

```
Bash
```

```
Azure CLI
```

```
az group delete --name $RESOURCE_GROUP
```

Next steps

In this tutorial, you learned how to create an Azure Function that handles Event Hub events and updates an Azure Cosmos DB instance. For more information, see the [Azure Functions Java developer guide](#). For information on the annotations used, see the [com.microsoft.azure.functions.annotation](#) reference.

This tutorial used environment variables and application settings to store secrets such as connection strings. For information on storing these secrets in Azure Key Vault, see [Use Key Vault references for App Service and Azure Functions](#).

Next, learn how to use Azure Pipelines CI/CD for automated deployment:

[Build and deploy Java to Azure Functions](#)

Azure CLI Samples

Article • 04/22/2024

These end-to-end Azure CLI scripts are provided to help you learn how to provision and managing the Azure resources required by Azure Functions. You must use the [Azure Functions Core Tools](#) to create actual Azure Functions code projects from the command line on your local computer and deploy code to these Azure resources. For a complete end-to-end example of developing and deploying from the command line using both Core Tools and the Azure CLI, see one of these language-specific command line quickstarts:

- [C#](#)
- [Java](#)
- [JavaScript](#)
- [PowerShell](#)
- [Python](#)
- [TypeScript](#)

The following table includes links to bash scripts that you can use to create and manage the Azure resources required by Azure Functions using the Azure CLI.

[+] Expand table

Create app	Description
Create a function app for serverless execution	Create a function app in a Consumption plan.
Create a serverless Python function app	Create a Python function app in a Consumption plan.

Create a function app for serverless code execution

Article • 01/13/2023

This Azure Functions sample script creates a function app, which is a container for your functions. The function app is created using the [Consumption plan](#), which is ideal for event-driven serverless workloads.

If you don't have an [Azure subscription](#), create an [Azure free account](#) before you begin.

Prerequisites

- Use the Bash environment in [Azure Cloud Shell](#). For more information, see [Quickstart for Bash in Azure Cloud Shell](#).
A blue rectangular button with a white 'A' icon on the left, the text 'Launch Cloud Shell' in the center, and a small blue square with a white arrow icon on the right.
- If you prefer to run CLI reference commands locally, [install](#) the Azure CLI. If you're running on Windows or macOS, consider running Azure CLI in a Docker container. For more information, see [How to run the Azure CLI in a Docker container](#).
 - If you're using a local installation, sign in to the Azure CLI by using the `az login` command. To finish the authentication process, follow the steps displayed in your terminal. For other sign-in options, see [Sign in with the Azure CLI](#).
 - When you're prompted, install the Azure CLI extension on first use. For more information about extensions, see [Use extensions with the Azure CLI](#).
 - Run `az version` to find the version and dependent libraries that are installed. To upgrade to the latest version, run [`az upgrade`](#).

Sample script

Launch Azure Cloud Shell

The Azure Cloud Shell is a free interactive shell that you can use to run the steps in this article. It has common Azure tools preinstalled and configured to use with your account.

To open the Cloud Shell, just select **Try it** from the upper right corner of a code block. You can also launch Cloud Shell in a separate browser tab by going to <https://shell.azure.com>.

When Cloud Shell opens, verify that **Bash** is selected for your environment. Subsequent sessions will use Azure CLI in a Bash environment, Select **Copy** to copy the blocks of code, paste it into the Cloud Shell, and press **Enter** to run it.

Sign in to Azure

Cloud Shell is automatically authenticated under the initial account signed-in with. Use the following script to sign in using a different subscription, replacing <Subscription ID> with your Azure Subscription ID. If you don't have an [Azure subscription](#), create an [Azure free account](#) before you begin.

```
Azure CLI

subscription=<subscriptionId> # add subscription here

az account set -s $subscription # ...or use 'az login'
```

For more information, see [set active subscription](#) or [log in interactively](#)

Run the script

```
Azure CLI

# Function app and storage account names must be unique.

# Variable block
let "randomIdentifier=$RANDOM*$RANDOM"
location="eastus"
resourceGroup="msdocs-azure-functions-rg-$randomIdentifier"
tag="create-function-app-consumption"
storage="msdocsaccount$randomIdentifier"
functionApp="msdocs-serverless-function-$randomIdentifier"
skuStorage="Standard_LRS"
functionsVersion="4"

# Create a resource group
echo "Creating $resourceGroup in \"$location\"..."
az group create --name $resourceGroup --location "$location" --tags $tag

# Create an Azure storage account in the resource group.
echo "Creating $storage"
az storage account create --name $storage --location "$location" --resource-group $resourceGroup --sku $skuStorage
```

```
# Create a serverless function app in the resource group.  
echo "Creating $functionApp"  
az functionapp create --name $functionApp --storage-account $storage --  
consumption-plan-location "$location" --resource-group $resourceGroup --  
functions-version $functionsVersion
```

Clean up resources

Use the following command to remove the resource group and all resources associated with it using the [az group delete](#) command - unless you have an ongoing need for these resources. Some of these resources may take a while to create, as well as to delete.

Azure CLI

```
az group delete --name $resourceGroup
```

Sample reference

Each command in the table links to command specific documentation. This script uses the following commands:

Command	Notes
az group create	Creates a resource group in which all resources are stored.
az storage account create	Creates an Azure Storage account.
az functionapp create	Creates a function app.

Next steps

For more information on the Azure CLI, see [Azure CLI documentation](#).

Additional Azure Functions CLI script samples can be found in the [Azure Functions documentation](#).

Create a serverless Python function app using Azure CLI

Article • 01/13/2023

This Azure Functions sample script creates a function app, which is a container for your functions. This script creates an Azure Function app using the [Consumption plan](#).

ⓘ Note

The function app created runs on Python version 3.9. Python version 3.7 and 3.8 are also supported by Azure Functions.

If you don't have an [Azure subscription](#), create an [Azure free account](#) before you begin.

Prerequisites

- Use the Bash environment in [Azure Cloud Shell](#). For more information, see [Quickstart for Bash in Azure Cloud Shell](#).
A blue rectangular button with a white 'A' icon on the left and the text 'Launch Cloud Shell' in white. To the right of the text is a small blue square with a white right-pointing arrow.
- If you prefer to run CLI reference commands locally, [install](#) the Azure CLI. If you're running on Windows or macOS, consider running Azure CLI in a Docker container. For more information, see [How to run the Azure CLI in a Docker container](#).
 - If you're using a local installation, sign in to the Azure CLI by using the [az login](#) command. To finish the authentication process, follow the steps displayed in your terminal. For other sign-in options, see [Sign in with the Azure CLI](#).
 - When you're prompted, install the Azure CLI extension on first use. For more information about extensions, see [Use extensions with the Azure CLI](#).
 - Run [az version](#) to find the version and dependent libraries that are installed. To upgrade to the latest version, run [az upgrade](#).

Sample script

[Launch Azure Cloud Shell](#)

The Azure Cloud Shell is a free interactive shell that you can use to run the steps in this article. It has common Azure tools preinstalled and configured to use with your account.

To open the Cloud Shell, just select Try it from the upper right corner of a code block. You can also launch Cloud Shell in a separate browser tab by going to <https://shell.azure.com>.

When Cloud Shell opens, verify that **Bash** is selected for your environment. Subsequent sessions will use Azure CLI in a Bash environment, Select **Copy** to copy the blocks of code, paste it into the Cloud Shell, and press **Enter** to run it.

Sign in to Azure

Cloud Shell is automatically authenticated under the initial account signed-in with. Use the following script to sign in using a different subscription, replacing <Subscription ID> with your Azure Subscription ID. If you don't have an [Azure subscription](#), create an [Azure free account](#) before you begin.

```
Azure CLI
```

```
subscription=<subscriptionId> # add subscription here  
az account set -s $subscription # ...or use 'az login'
```

For more information, see [set active subscription](#) or [log in interactively](#)

Run the script

```
Azure CLI
```

```
# Function app and storage account names must be unique.  
  
# Variable block  
let "randomIdentifier=$RANDOM*$RANDOM"  
location="eastus"  
resourceGroup="msdocs-azure-functions-rg-$randomIdentifier"  
tag="create-function-app-consumption-python"  
storage="msdocsaccount$randomIdentifier"  
functionApp="msdocs-serverless-python-function-$randomIdentifier"  
skuStorage="Standard_LRS"  
functionsVersion="4"  
pythonVersion="3.9" #Allowed values: 3.7, 3.8, and 3.9  
  
# Create a resource group  
echo "Creating $resourceGroup in \"$location\"..."  
az group create --name $resourceGroup --location "$location" --tags $tag
```

```
# Create an Azure storage account in the resource group.  
echo "Creating $storage"  
az storage account create --name $storage --location "$location" --resource-group $resourceGroup --sku $skuStorage  
  
# Create a serverless python function app in the resource group.  
echo "Creating $functionApp"  
az functionapp create --name $functionApp --storage-account $storage --consumption-plan-location "$location" --resource-group $resourceGroup --os-type Linux --runtime python --runtime-version $pythonVersion --functions-version $functionsVersion
```

Clean up resources

Use the following command to remove the resource group and all resources associated with it using the [az group delete](#) command - unless you have an ongoing need for these resources. Some of these resources may take a while to create, as well as to delete.

Azure CLI

```
az group delete --name $resourceGroup
```

Sample reference

Each command in the table links to command specific documentation. This script uses the following commands:

Command	Notes
az group create	Creates a resource group in which all resources are stored.
az storage account create	Creates an Azure Storage account.
az functionapp create	Creates a function app.

Next steps

For more information on the Azure CLI, see [Azure CLI documentation](#).

Additional Azure Functions CLI script samples can be found in the [Azure Functions documentation](#).

Create a function app in a Premium plan - Azure CLI

Article • 01/13/2023

This Azure Functions sample script creates a function app, which is a container for your functions. The function app that is created uses a [scalable Premium plan](#).

If you don't have an [Azure subscription](#), create an [Azure free account](#) before you begin.

Prerequisites

- Use the Bash environment in [Azure Cloud Shell](#). For more information, see [Quickstart for Bash in Azure Cloud Shell](#).
A blue rectangular button with a white 'A' icon and the text 'Launch Cloud Shell'. To the right of the button is a small blue square icon with a white arrow pointing outwards.
A blue rectangular button with a white 'A' icon and the text 'Launch Cloud Shell'. To the right of the button is a small blue square icon with a white arrow pointing outwards.
- If you prefer to run CLI reference commands locally, [install](#) the Azure CLI. If you're running on Windows or macOS, consider running Azure CLI in a Docker container. For more information, see [How to run the Azure CLI in a Docker container](#).
 - If you're using a local installation, sign in to the Azure CLI by using the `az login` command. To finish the authentication process, follow the steps displayed in your terminal. For other sign-in options, see [Sign in with the Azure CLI](#).
 - When you're prompted, install the Azure CLI extension on first use. For more information about extensions, see [Use extensions with the Azure CLI](#).
 - Run `az version` to find the version and dependent libraries that are installed. To upgrade to the latest version, run `az upgrade`.

Sample script

Launch Azure Cloud Shell

The Azure Cloud Shell is a free interactive shell that you can use to run the steps in this article. It has common Azure tools preinstalled and configured to use with your account.

To open the Cloud Shell, just select Try it from the upper right corner of a code block. You can also launch Cloud Shell in a separate browser tab by going to

<https://shell.azure.com>.

When Cloud Shell opens, verify that **Bash** is selected for your environment. Subsequent sessions will use Azure CLI in a Bash environment. Select **Copy** to copy the blocks of code, paste it into the Cloud Shell, and press **Enter** to run it.

Sign in to Azure

Cloud Shell is automatically authenticated under the initial account signed-in with. Use the following script to sign in using a different subscription, replacing <Subscription ID> with your Azure Subscription ID. If you don't have an [Azure subscription](#), create an [Azure free account](#) before you begin.

Azure CLI

```
subscription=<subscriptionId> # add subscription here  
az account set -s $subscription # ...or use 'az login'
```

For more information, see [set active subscription](#) or [log in interactively](#)

Run the script

Azure CLI

```
# Function app and storage account names must be unique.  
  
# Variable block  
let "randomIdentifier=$RANDOM*$RANDOM"  
location="eastus"  
resourceGroup="msdocs-azure-functions-rg-$randomIdentifier"  
tag="create-function-app-premium-plan"  
storage="msdocsaccount$randomIdentifier"  
premiumPlan="msdocs-premium-plan-$randomIdentifier"  
functionApp="msdocs-function-$randomIdentifier"  
skuStorage="Standard_LRS" # Allowed values: Standard_LRS, Standard_GRS,  
Standard_RAGRS, Standard_ZRS, Premium_LRS, Premium_ZRS, Standard_GZRS,  
Standard_RAGZRS  
skuPlan="EP1"  
functionsVersion="4"  
  
# Create a resource group  
echo "Creating $resourceGroup in \"$location\"..."  
az group create --name $resourceGroup --location "$location" --tags $tag  
  
# Create an Azure storage account in the resource group.  
echo "Creating $storage"
```

```

az storage account create --name $storage --location "$location" --resource-group $resourceGroup --sku $skuStorage

# Create a Premium plan
echo "Creating $premiumPlan"
az functionapp plan create --name $premiumPlan --resource-group $resourceGroup --location "$location" --sku $skuPlan

# Create a Function App
echo "Creating $functionApp"
az functionapp create --name $functionApp --storage-account $storage --plan $premiumPlan --resource-group $resourceGroup --functions-version $functionsVersion

```

Clean up resources

Use the following command to remove the resource group and all resources associated with it using the `az group delete` command - unless you have an ongoing need for these resources. Some of these resources may take a while to create, as well as to delete.

Azure CLI

```
az group delete --name $resourceGroup
```

Sample reference

Each command in the table links to command specific documentation. This script uses the following commands:

Command	Notes
az group create	Creates a resource group in which all resources are stored.
az storage account create	Creates an Azure Storage account.
az functionapp plan create	Creates a Premium plan in a specific SKU .
az functionapp create	Creates a function app in the App Service plan.

Create a Function App in an App Service plan

Article • 01/13/2023

This Azure Functions sample script creates a function app, which is a container for your functions. The function app that is created uses a dedicated App Service plan, which means your server resources are always on.

If you don't have an [Azure subscription](#), create an [Azure free account](#) before you begin.

Prerequisites

- Use the Bash environment in [Azure Cloud Shell](#). For more information, see [Quickstart for Bash in Azure Cloud Shell](#).
A blue rectangular button with a white 'A' icon and the text 'Launch Cloud Shell'. To the right of the button is a small blue square with a white right-pointing arrow.
- If you prefer to run CLI reference commands locally, [install](#) the Azure CLI. If you're running on Windows or macOS, consider running Azure CLI in a Docker container. For more information, see [How to run the Azure CLI in a Docker container](#).
 - If you're using a local installation, sign in to the Azure CLI by using the `az login` command. To finish the authentication process, follow the steps displayed in your terminal. For other sign-in options, see [Sign in with the Azure CLI](#).
 - When you're prompted, install the Azure CLI extension on first use. For more information about extensions, see [Use extensions with the Azure CLI](#).
 - Run `az version` to find the version and dependent libraries that are installed. To upgrade to the latest version, run [`az upgrade`](#).

Sample script

Launch Azure Cloud Shell

The Azure Cloud Shell is a free interactive shell that you can use to run the steps in this article. It has common Azure tools preinstalled and configured to use with your account.

To open the Cloud Shell, just select **Try it** from the upper right corner of a code block. You can also launch Cloud Shell in a separate browser tab by going to <https://shell.azure.com>.

When Cloud Shell opens, verify that **Bash** is selected for your environment. Subsequent sessions will use Azure CLI in a Bash environment, Select **Copy** to copy the blocks of code, paste it into the Cloud Shell, and press **Enter** to run it.

Sign in to Azure

Cloud Shell is automatically authenticated under the initial account signed-in with. Use the following script to sign in using a different subscription, replacing <Subscription ID> with your Azure Subscription ID. If you don't have an [Azure subscription](#), create an [Azure free account](#) before you begin.

```
Azure CLI

subscription=<subscriptionId> # add subscription here

az account set -s $subscription # ...or use 'az login'
```

For more information, see [set active subscription](#) or [log in interactively](#)

Run the script

```
Azure CLI

# Function app and storage account names must be unique.

# Variable block
let "randomIdentifier=$RANDOM*$RANDOM"
location="eastus"
resourceGroup="msdocs-azure-functions-rg-$randomIdentifier"
tag="create-function-app-consumption"
storage="msdocsaccount$randomIdentifier"
appServicePlan="msdocs-app-service-plan-$randomIdentifier"
functionApp="msdocs-serverless-function-$randomIdentifier"
skuStorage="Standard_LRS"
skuPlan="B1"
functionsVersion="4"

# Create a resource group
echo "Creating $resourceGroup in \"$location\"..."
az group create --name $resourceGroup --location "$location" --tags $tag

# Create an Azure storage account in the resource group.
echo "Creating $storage"
```

```

az storage account create --name $storage --location "$location" --resource-group $resourceGroup --sku $skuStorage

# Create an App Service plan
echo "Creating $appServicePlan"
az functionapp plan create --name $appServicePlan --resource-group $resourceGroup --location "$location" --sku $skuPlan

# Create a Function App
echo "Creating $functionApp"
az functionapp create --name $functionApp --storage-account $storage --plan $appServicePlan --resource-group $resourceGroup --functions-version $functionsVersion

```

Clean up resources

Use the following command to remove the resource group and all resources associated with it using the `az group delete` command - unless you have an ongoing need for these resources. Some of these resources may take a while to create, as well as to delete.

Azure CLI

```
az group delete --name $resourceGroup
```

Sample reference

Each command in the table links to command specific documentation. This script uses the following commands:

Command	Notes
az group create	Creates a resource group in which all resources are stored.
az storage account create	Creates an Azure Storage account.
az functionapp plan create	Creates a Premium plan.
az functionapp create	Creates a function app in the App Service plan.

Next steps

For more information on the Azure CLI, see [Azure CLI documentation](#).

Additional Azure Functions CLI script samples can be found in the [Azure Functions documentation](#).

Create a function app with a named Storage account connection

Article • 01/13/2023

This Azure Functions sample script creates a function app and connects the function to an Azure Storage account. The created app setting that contains the storage connection string can be used with a [storage trigger or binding](#).

If you don't have an [Azure subscription](#), create an [Azure free account](#) before you begin.

Prerequisites

- Use the Bash environment in [Azure Cloud Shell](#). For more information, see [Quickstart for Bash in Azure Cloud Shell](#).
A blue rectangular button with a white 'A' icon and the text 'Launch Cloud Shell'. To the right of the button is a small blue square with a white right-pointing arrow.
- If you prefer to run CLI reference commands locally, [install](#) the Azure CLI. If you're running on Windows or macOS, consider running Azure CLI in a Docker container. For more information, see [How to run the Azure CLI in a Docker container](#).
 - If you're using a local installation, sign in to the Azure CLI by using the `az login` command. To finish the authentication process, follow the steps displayed in your terminal. For other sign-in options, see [Sign in with the Azure CLI](#).
 - When you're prompted, install the Azure CLI extension on first use. For more information about extensions, see [Use extensions with the Azure CLI](#).
 - Run `az version` to find the version and dependent libraries that are installed. To upgrade to the latest version, run [`az upgrade`](#).

Sample script

Launch Azure Cloud Shell

The Azure Cloud Shell is a free interactive shell that you can use to run the steps in this article. It has common Azure tools preinstalled and configured to use with your account.

To open the Cloud Shell, just select **Try it** from the upper right corner of a code block. You can also launch Cloud Shell in a separate browser tab by going to <https://shell.azure.com>.

When Cloud Shell opens, verify that **Bash** is selected for your environment. Subsequent sessions will use Azure CLI in a Bash environment, Select **Copy** to copy the blocks of code, paste it into the Cloud Shell, and press **Enter** to run it.

Sign in to Azure

Cloud Shell is automatically authenticated under the initial account signed-in with. Use the following script to sign in using a different subscription, replacing <Subscription ID> with your Azure Subscription ID. If you don't have an [Azure subscription](#), create an [Azure free account](#) before you begin.

```
Azure CLI

subscription=<subscriptionId> # add subscription here

az account set -s $subscription # ...or use 'az login'
```

For more information, see [set active subscription](#) or [log in interactively](#)

Run the script

```
Azure CLI

# Function app and storage account names must be unique.

# Variable block
let "randomIdentifier=$RANDOM*$RANDOM"
location="eastus"
resourceGroup="msdocs-azure-functions-rg-$randomIdentifier"
tag="create-function-app-connect-to-storage-account"
storage="msdocsaccount$randomIdentifier"
functionApp="msdocs-serverless-function-$randomIdentifier"
skuStorage="Standard_LRS"
functionsVersion="4"

# Create a resource group
echo "Creating $resourceGroup in \"$location\"..."
az group create --name $resourceGroup --location "$location" --tags $tag

# Create an Azure storage account in the resource group.
echo "Creating $storage"
az storage account create --name $storage --location "$location" --resource-group $resourceGroup --sku $skuStorage
```

```

# Create a serverless function app in the resource group.
echo "Creating $functionApp"
az functionapp create --name $functionApp --resource-group $resourceGroup --
storage-account $storage --consumption-plan-location "$location" --
functions-version $functionsVersion

# Get the storage account connection string.
connstr=$(az storage account show-connection-string --name $storage --
resource-group $resourceGroup --query connectionString --output tsv)

# Update function app settings to connect to the storage account.
az functionapp config appsettings set --name $functionApp --resource-group
$resourceGroup --settings StorageConStr=$connstr

```

Clean up resources

Use the following command to remove the resource group and all resources associated with it using the [az group delete](#) command - unless you have an ongoing need for these resources. Some of these resources may take a while to create, as well as to delete.

Azure CLI

```
az group delete --name $resourceGroup
```

Sample reference

This script uses the following commands. Each command in the table links to command specific documentation.

Command	Notes
az group create	Create a resource group with location.
az storage account create	Create a storage account.
az functionapp create	Creates a function app in the serverless Consumption plan .
az storage account show-connection-string	Gets the connection string for the account.
az functionapp config appsettings set	Sets the connection string as an app setting in the function app.

Next steps

For more information on the Azure CLI, see [Azure CLI documentation](#).

Additional Azure Functions CLI script samples can be found in the [Azure Functions documentation](#).

Create an Azure Function that connects to an Azure Cosmos DB

Article • 01/13/2023

This Azure Functions sample script creates a function app and connects the function to an Azure Cosmos DB database. It makes the connection using an Azure Cosmos DB endpoint and access key that it adds to app settings. The created app setting that contains the connection can be used with an [Azure Cosmos DB trigger or binding](#).

If you don't have an [Azure subscription](#), create an [Azure free account](#) before you begin.

Prerequisites

- Use the Bash environment in [Azure Cloud Shell](#). For more information, see [Quickstart for Bash in Azure Cloud Shell](#).
A blue rectangular button with a white 'A' icon and the text 'Launch Cloud Shell'. To the right of the text is a small blue square with a white right-pointing arrow.
- If you prefer to run CLI reference commands locally, [install](#) the Azure CLI. If you're running on Windows or macOS, consider running Azure CLI in a Docker container. For more information, see [How to run the Azure CLI in a Docker container](#).
 - If you're using a local installation, sign in to the Azure CLI by using the [az login](#) command. To finish the authentication process, follow the steps displayed in your terminal. For other sign-in options, see [Sign in with the Azure CLI](#).
 - When you're prompted, install the Azure CLI extension on first use. For more information about extensions, see [Use extensions with the Azure CLI](#).
 - Run [az version](#) to find the version and dependent libraries that are installed. To upgrade to the latest version, run [az upgrade](#).

Sample script

Launch Azure Cloud Shell

The Azure Cloud Shell is a free interactive shell that you can use to run the steps in this article. It has common Azure tools preinstalled and configured to use with your account.

To open the Cloud Shell, just select **Try it** from the upper right corner of a code block. You can also launch Cloud Shell in a separate browser tab by going to <https://shell.azure.com>.

When Cloud Shell opens, verify that **Bash** is selected for your environment. Subsequent sessions will use Azure CLI in a Bash environment, Select **Copy** to copy the blocks of code, paste it into the Cloud Shell, and press **Enter** to run it.

Sign in to Azure

Cloud Shell is automatically authenticated under the initial account signed-in with. Use the following script to sign in using a different subscription, replacing <Subscription ID> with your Azure Subscription ID. If you don't have an [Azure subscription](#), create an [Azure free account](#) before you begin.

```
Azure CLI

subscription=<subscriptionId> # add subscription here

az account set -s $subscription # ...or use 'az login'
```

For more information, see [set active subscription](#) or [log in interactively](#)

Run the script

```
Azure CLI

# Function app and storage account names must be unique.

# Variable block
let "randomIdentifier=$RANDOM*$RANDOM"
location="eastus"
resourceGroup="msdocs-azure-functions-rg-$randomIdentifier"
tag="create-function-app-connect-to-cosmos-db"
storage="msdocsaccount$randomIdentifier"
functionApp="msdocs-serverless-function-$randomIdentifier"
skuStorage="Standard_LRS"
functionsVersion="4"

# Create a resource group
echo "Creating $resourceGroup in \"$location\"..."
az group create --name $resourceGroup --location "$location" --tags $tag

# Create a storage account for the function app.
echo "Creating $storage"
az storage account create --name $storage --location "$location" --resource-group $resourceGroup --sku $skuStorage
```

```

# Create a serverless function app in the resource group.
echo "Creating $functionApp"
az functionapp create --name $functionApp --resource-group $resourceGroup --
storage-account $storage --consumption-plan-location "$location" --
functions-version $functionsVersion

# Create an Azure Cosmos DB database account using the same function app
# name.
echo "Creating $functionApp"
az cosmosdb create --name $functionApp --resource-group $resourceGroup

# Get the Azure Cosmos DB connection string.
endpoint=$(az cosmosdb show --name $functionApp --resource-group
$resourceGroup --query documentEndpoint --output tsv)
echo $endpoint

key=$(az cosmosdb keys list --name $functionApp --resource-group
$resourceGroup --query primaryMasterKey --output tsv)
echo $key

# Configure function app settings to use the Azure Cosmos DB connection
# string.
az functionapp config appsettings set --name $functionApp --resource-group
$resourceGroup --setting CosmosDB_Endpoint=$endpoint CosmosDB_Key=$key

```

Clean up resources

Use the following command to remove the resource group and all resources associated with it using the [az group delete](#) command - unless you have an ongoing need for these resources. Some of these resources may take a while to create, as well as to delete.

Azure CLI

```
az group delete --name $resourceGroup
```

Sample reference

Command	Notes
az group create	Create a resource group with location
az storage accounts create	Create a storage account
az functionapp create	Creates a function app in the serverless Consumption plan .
az cosmosdb create	Create an Azure Cosmos DB database.

Command	Notes
<code>az cosmosdb show</code>	Gets the database account connection.
<code>az cosmosdb list-keys</code>	Gets the keys for the database.
<code>az functionapp config appsettings set</code>	Sets the connection string as an app setting in the function app.

Mount a file share to a Python function app using Azure CLI

Article • 01/13/2023

This Azure Functions sample script creates a function app using the [Consumption plan](#) and creates a share in Azure Files. It then mounts the share so that the data can be accessed by your functions.

ⓘ Note

The function app created runs on Python version 3.9. Azure Functions also [supports Python versions 3.7 and 3.8](#).

If you don't have an [Azure subscription](#), create an [Azure free account](#) before you begin.

Prerequisites

- Use the Bash environment in [Azure Cloud Shell](#). For more information, see [Quickstart for Bash in Azure Cloud Shell](#).
[A Launch Cloud Shell](#)
- If you prefer to run CLI reference commands locally, [install](#) the Azure CLI. If you're running on Windows or macOS, consider running Azure CLI in a Docker container. For more information, see [How to run the Azure CLI in a Docker container](#).
 - If you're using a local installation, sign in to the Azure CLI by using the `az login` command. To finish the authentication process, follow the steps displayed in your terminal. For other sign-in options, see [Sign in with the Azure CLI](#).
 - When you're prompted, install the Azure CLI extension on first use. For more information about extensions, see [Use extensions with the Azure CLI](#).
 - Run `az version` to find the version and dependent libraries that are installed. To upgrade to the latest version, run `az upgrade`.

Sample script

Launch Azure Cloud Shell

The Azure Cloud Shell is a free interactive shell that you can use to run the steps in this article. It has common Azure tools preinstalled and configured to use with your account.

To open the Cloud Shell, just select **Try it** from the upper right corner of a code block. You can also launch Cloud Shell in a separate browser tab by going to <https://shell.azure.com>.

When Cloud Shell opens, verify that **Bash** is selected for your environment. Subsequent sessions will use Azure CLI in a Bash environment. Select **Copy** to copy the blocks of code, paste it into the Cloud Shell, and press **Enter** to run it.

Sign in to Azure

Cloud Shell is automatically authenticated under the initial account signed-in with. Use the following script to sign in using a different subscription, replacing <Subscription ID> with your Azure Subscription ID. If you don't have an [Azure subscription](#), create an [Azure free account](#) before you begin.

```
Azure CLI

subscription=<subscriptionId> # add subscription here

az account set -s $subscription # ...or use 'az login'
```

For more information, see [set active subscription](#) or [log in interactively](#)

Run the script

```
Azure CLI

# Function app and storage account names must be unique.

# Variable block
let "randomIdentifier=$RANDOM*$RANDOM"
location="eastus"
resourceGroup="msdocs-azure-functions-rg-$randomIdentifier"
tag="functions-cli-mount-files-storage-linux"
export AZURE_STORAGE_ACCOUNT="msdocsstorage$randomIdentifier"
functionApp="msdocs-serverless-function-$randomIdentifier"
skuStorage="Standard_LRS"
functionsVersion="4"
pythonVersion="3.9" #Allowed values: 3.7, 3.8, and 3.9
share="msdocs-fileshare-$randomIdentifier"
directory="msdocs-directory-$randomIdentifier"
```

```

shareId="msdocs-share-$randomIdentifier"
mountPath="/mounted-$randomIdentifier"

# Create a resource group
echo "Creating $resourceGroup in \"$location\"..."
az group create --name $resourceGroup --location "$location" --tags $tag

# Create an Azure storage account in the resource group.
echo "Creating $AZURE_STORAGE_ACCOUNT"
az storage account create --name $AZURE_STORAGE_ACCOUNT --location
"$location" --resource-group $resourceGroup --sku $skuStorage

# Set the storage account key as an environment variable.
export AZURE_STORAGE_KEY=$(az storage account keys list -g $resourceGroup -n
$AZURE_STORAGE_ACCOUNT --query '[0].value' -o tsv)

# Create a serverless function app in the resource group.
echo "Creating $functionApp"
az functionapp create --name $functionApp --storage-account
$AZURE_STORAGE_ACCOUNT --consumption-plan-location "$location" --resource-
group $resourceGroup --os-type Linux --runtime python --runtime-version

--access-key $AZURE_STORAGE_KEY

# List webapp storage account
az webapp config storage-account list --resource-group $resourceGroup --name
$functionApp

```

Clean up resources

Use the following command to remove the resource group and all resources associated with it using the `az group delete` command - unless you have an ongoing need for these

resources. Some of these resources may take a while to create, as well as to delete.

Azure CLI

```
az group delete --name $resourceGroup
```

Sample reference

Each command in the table links to command specific documentation. This script uses the following commands:

Command	Notes
az group create	Creates a resource group in which all resources are stored.
az storage account create	Creates an Azure Storage account.
az functionapp create	Creates a function app.
az storage share create	Creates an Azure Files share in storage account.
az storage directory create	Creates a directory in the share.
az webapp config storage-account add	Mounts the share to the function app.
az webapp config storage-account list	Shows file shares mounted to the function app.

Next steps

For more information on the Azure CLI, see [Azure CLI documentation](#).

Additional Azure Functions CLI script samples can be found in the [Azure Functions documentation](#).

Create a function app in Azure that is deployed from GitHub

Article • 01/13/2023

This Azure Functions sample script creates a function app using the [Consumption plan](#), along with its related resources. The script also configures your function code for continuous deployment from a public GitHub repository. There is also commented out code for using a private GitHub repository.

If you don't have an [Azure subscription](#), create an [Azure free account](#) before you begin.

Prerequisites

- Use the Bash environment in [Azure Cloud Shell](#). For more information, see [Quickstart for Bash in Azure Cloud Shell](#).
A blue rectangular button with a white 'A' icon and the text 'Launch Cloud Shell'. To the right of the text is a small blue square with a white right-pointing arrow.
- If you prefer to run CLI reference commands locally, [install](#) the Azure CLI. If you're running on Windows or macOS, consider running Azure CLI in a Docker container. For more information, see [How to run the Azure CLI in a Docker container](#).
 - If you're using a local installation, sign in to the Azure CLI by using the [az login](#) command. To finish the authentication process, follow the steps displayed in your terminal. For other sign-in options, see [Sign in with the Azure CLI](#).
 - When you're prompted, install the Azure CLI extension on first use. For more information about extensions, see [Use extensions with the Azure CLI](#).
 - Run [az version](#) to find the version and dependent libraries that are installed. To upgrade to the latest version, run [az upgrade](#).

Sample script

Launch Azure Cloud Shell

The Azure Cloud Shell is a free interactive shell that you can use to run the steps in this article. It has common Azure tools preinstalled and configured to use with your account.

To open the Cloud Shell, just select **Try it** from the upper right corner of a code block. You can also launch Cloud Shell in a separate browser tab by going to <https://shell.azure.com>.

When Cloud Shell opens, verify that **Bash** is selected for your environment. Subsequent sessions will use Azure CLI in a Bash environment, Select **Copy** to copy the blocks of code, paste it into the Cloud Shell, and press **Enter** to run it.

Sign in to Azure

Cloud Shell is automatically authenticated under the initial account signed-in with. Use the following script to sign in using a different subscription, replacing <Subscription ID> with your Azure Subscription ID. If you don't have an [Azure subscription](#), create an [Azure free account](#) before you begin.

```
Azure CLI

subscription=<subscriptionId> # add subscription here

az account set -s $subscription # ...or use 'az login'
```

For more information, see [set active subscription](#) or [log in interactively](#)

Run the script

```
Azure CLI

# Function app and storage account names must be unique.
let "randomIdentifier=$RANDOM*$RANDOM"
location=eastus
resourceGroup="msdocs-azure-functions-rg-$randomIdentifier"
tag="deploy-function-app-with-function-github"
storage="msdocs$randomIdentifier"
skuStorage="Standard_LRS"
functionApp=mygithubfunc$randomIdentifier
functionsVersion="4"
runtime="node"
# Public GitHub repository containing an Azure Functions code project.
gitrepo=https://github.com/Azure-Samples/functions-quickstart-javascript
## Enable authenticated git deployment in your subscription when using a
private repo.
#token=<Replace with a GitHub access token when using a private repo.>
#az functionapp deployment source update-token \
# --git-token $token

# Create a resource group.
```

```

echo "Creating $resourceGroup in """$location""""...
az group create --name $resourceGroup --location "$location" --tags $tag

# Create an Azure storage account in the resource group.
echo "Creating $storage"
az storage account create --name $storage --location "$location" --resource-group $resourceGroup --sku $skuStorage

# Create a function app with source files deployed from the specified GitHub repo.
echo "Creating $functionApp"
az functionapp create --name $functionApp --storage-account $storage --consumption-plan-location "$location" --resource-group $resourceGroup --deployment-source-url $gitrepo --deployment-source-branch main --functions-version $functionsVersion --runtime $runtime

# Connect to function application
curl -s "https://$functionApp.azurewebsites.net/api/httpexample?name=Azure"

```

Clean up resources

Use the following command to remove the resource group and all resources associated with it using the [az group delete](#) command - unless you have an ongoing need for these resources. Some of these resources may take a while to create, as well as to delete.

Azure CLI

```
az group delete --name $resourceGroup
```

Sample reference

Each command in the table links to command specific documentation. This script uses the following commands:

Command	Notes
az group create	Creates a resource group in which all resources are stored.
az storage account create	Creates the storage account required by the function app.
az functionapp create	Creates a function app in the serverless Consumption plan and associates it with a Git or Mercurial repository.

Next steps

For more information on the Azure CLI, see [Azure CLI documentation](#).

Additional Azure Functions CLI script samples can be found in the [Azure Functions documentation](#).

Create function app resources in Azure using PowerShell

Article • 05/02/2023

The Azure PowerShell example scripts in this article create function apps and other resources required to host your functions in Azure. A function app provides an execution context in which your functions are executed. All functions running in a function app share the same resources and connections, and they're all scaled together.

After the resources are created, you can deploy your project files to the new function app. To learn more, see [Deployment methods](#).

Every function app requires your PowerShell scripts to create the following resources:

Resource	cmdlet	Description
Resource group	<code>New-AzResourceGroup</code>	Creates a resource group in which you'll create your function app.
Storage account	<code>New-AzStorageAccount</code>	Creates a storage account used by your function app. Storage account names must be between 3 and 24 characters in length and can contain numbers and lowercase letters only. You can also use an existing account, which must meet the storage account requirements .
App Service plan	<code>New-AzFunctionAppPlan</code>	Explicitly creates a hosting plan, which defines how resources are allocated to your function app. Used only when hosting in a Premium or Dedicated plan. You won't use this cmdlet when hosting in a serverless Consumption plan , since Consumption plans are created when you run <code>New-AzFunctionApp</code> . For more information, see Azure Functions hosting options .
Function app	<code>New-AzFunctionApp</code>	Creates the function app using the required resources. The <code>-Name</code> parameter must be a globally unique name across all of Azure App Service. Valid characters in <code>-Name</code> are <code>a-z</code> (case insensitive), <code>0-9</code> , and <code>-</code> . Most examples create a function app that supports C# functions. You can change the language by using the <code>-Runtime</code> parameter, with supported values of <code>DotNet</code> , <code>Java</code> , <code>Node</code> , <code>PowerShell</code> , and <code>Python</code> . Use the <code>-RuntimeVersion</code> to choose a specific language version .

This article contains the following examples:

- [Create a serverless function app for C#](#)
- [Create a serverless function app for Python](#)

- Create a scalable function app in a Premium plan
- Create a function app in a Dedicated plan
- Create a function app with a named Storage connection
- Create a function app with an Azure Cosmos DB connection
- Create a function app with continuous deployment
- Create a serverless Python function app and mount file share

Prerequisites

- If you choose to use Azure PowerShell locally:
 - [Install the Az PowerShell module.](#)
 - Connect to your Azure account using the [Connect-AzAccount](#) cmdlet.
- If you choose to use Azure Cloud Shell:
 - See [Overview of Azure Cloud Shell](#) for more information.

If you don't have an [Azure subscription](#), create an [Azure free account](#) before you begin.

Create a serverless function app for C#

The following script creates a serverless C# function app in the default Consumption plan:

```
azurepowershell-interactive

# Function app and storage account names must be unique.

# Variable block
$randomIdentifier = Get-Random
$location = "eastus"
$resourceGroup = "msdocs-azure-functions-rg-$randomIdentifier"
$tag = @{script = "create-function-app-consumption"}
$storage = "msdocsaccount$randomIdentifier"
$functionApp = "msdocs-serverless-function-$randomIdentifier"
$skuStorage = "Standard_LRS"
$functionsVersion = "4"

# Create a resource group
Write-Host "Creating $resourceGroup in $location..."
New-AzResourceGroup -Name $resourceGroup -Location $location -Tag $tag

# Create an Azure storage account in the resource group.
Write-Host "Creating $storage"
New-AzStorageAccount -Name $storage -Location $location -ResourceGroupName
$resourceGroup -SkuName $skuStorage
```

```
# Create a serverless function app in the resource group.  
Write-Host "Creating $functionApp"  
New-AzFunctionApp -Name $functionApp -StorageAccountName $storage -Location  
$location -ResourceGroupName $resourceGroup -Runtime DotNet -  
FunctionsVersion $functionsVersion
```

Create a serverless function app for Python

The following script creates a serverless Python function app in a Consumption plan:

```
azurepowershell-interactive  
  
# Function app and storage account names must be unique.  
  
# Variable block  
$randomIdentifier = Get-Random  
$location = "eastus"  
$resourceGroup = "msdocs-azure-functions-rg-$randomIdentifier"  
$tag = @{script = "create-function-app-consumption-python"}  
$storage = "msdocsaccount$randomIdentifier"  
$functionApp = "msdocs-serverless-python-function-$randomIdentifier"  
$skuStorage = "Standard_LRS"  
$functionsVersion = "4"  
$pythonVersion = "3.9" #Allowed values: 3.7, 3.8, and 3.9  
  
# Create a resource group  
Write-Host "Creating $resourceGroup in $location..."  
New-AzResourceGroup -Name $resourceGroup -Location $location -Tag $tag  
  
# Create an Azure storage account in the resource group.  
Write-Host "Creating $storage"  
New-AzStorageAccount -Name $storage -Location $location -ResourceGroupName  
$resourceGroup -SkuName $skuStorage  
  
# Create a serverless Python function app in the resource group.  
Write-Host "Creating $functionApp"  
New-AzFunctionApp -Name $functionApp -StorageAccountName $storage -Location  
$location -ResourceGroupName $resourceGroup -OSType Linux -Runtime Python -  
RuntimeVersion $pythonVersion -FunctionsVersion $functionsVersion
```

Create a scalable function app in a Premium plan

The following script creates a C# function app in an Elastic Premium plan that supports [dynamic scale](#):

```
azurepowershell-interactive
```

```

# Function app and storage account names must be unique.

# Variable block
$randomIdentifier = Get-Random
.setLocation = "eastus"
$resourceGroup = "msdocs-azure-functions-rg-$randomIdentifier"
$tag = @{script = "create-function-app-premium-plan"}
$storage = "msdocsaccount$randomIdentifier"
$premiumPlan = "msdocs-premium-plan-$randomIdentifier"
$functionApp = "msdocs-function-$randomIdentifier"
$skuStorage = "Standard_LRS" # Allowed values: Standard_LRS, Standard_GRS,
Standard_RAGRS, Standard_ZRS, Premium_LRS, Premium_ZRS, Standard_GZRS,
Standard_RAGZRS
$skuPlan = "EP1"
$functionsVersion = "4"

# Create a resource group
Write-Host "Creating $resourceGroup in $location..."
New-AzResourceGroup -Name $resourceGroup -Location $location -Tag $tag

# Create an Azure storage account in the resource group.
Write-Host "Creating $storage"
New-AzStorageAccount -Name $storage -Location $location -ResourceGroupName
$resourceGroup -SkuName $skuStorage

# Create a Premium plan
Write-Host "Creating $premiumPlan"
New-AzFunctionAppPlan -Name $premiumPlan -ResourceGroupName $resourceGroup -
Location $location -Sku $skuPlan -WorkerType Windows

# Create a Function App
Write-Host "Creating $functionApp"
New-AzFunctionApp -Name $functionApp -StorageAccountName $storage -PlanName
$premiumPlan -ResourceGroupName $resourceGroup -Runtime DotNet -
FunctionsVersion $functionsVersion

```

Create a function app in a Dedicated plan

The following script creates a function app hosted in a Dedicated plan, which isn't scaled dynamically by Functions:

azurepowershell-interactive

```

# Function app and storage account names must be unique.

# Variable block
$randomIdentifier = Get-Random
.setLocation = "eastus"
$resourceGroup = "msdocs-azure-functions-rg-$randomIdentifier"
$tag = @{script = "create-function-app-app-service-plan"}
$storage = "msdocsaccount$randomIdentifier"

```

```

$appServicePlan = "msdocs-app-service-plan-$randomIdentifier"
$functionApp = "msdocs-serverless-function-$randomIdentifier"
$skuStorage = "Standard_LRS"
$skuPlan = "B1"
$functionsVersion = "4"

# Create a resource group
Write-Host "Creating $resourceGroup in $location..."
New-AzResourceGroup -Name $resourceGroup -Location $location -Tag $tag

# Create an Azure storage account in the resource group.
Write-Host "Creating $storage"
New-AzStorageAccount -Name $storage -Location $location -ResourceGroupName
$resourceGroup -SkuName $skuStorage

# Create an App Service plan
Write-Host "Creating $appServicePlan"
New-AzFunctionAppPlan -Name $appServicePlan -ResourceGroupName
$resourceGroup -Location $location -Sku $skuPlan -WorkerType Windows

# Create a Function App
Write-Host "Creating $functionApp"
New-AzFunctionApp -Name $functionApp -StorageAccountName $storage -PlanName
$appServicePlan -ResourceGroupName $resourceGroup -Runtime DotNet -
FunctionsVersion $functionsVersion

```

Create a function app with a named Storage connection

The following script creates a function app with a named Storage connection in application settings:

azurepowershell-interactive

```

# Function app and storage account names must be unique.

# Variable block
$randomIdentifier = Get-Random
$location = "eastus"
$resourceGroup = "msdocs-azure-functions-rg-$randomIdentifier"
$tag = @{script = "create-function-app-connect-to-storage-account"}
$storage = "msdocsaccount$randomIdentifier"
$functionApp = "msdocs-serverless-function-$randomIdentifier"
$skuStorage = "Standard_LRS"
$functionsVersion = "4"

# Create a resource group
Write-Host "Creating $resourceGroup in $location..."
New-AzResourceGroup -Name $resourceGroup -Location $location -Tag $tag

```

```

# Create an Azure storage account in the resource group.
Write-Host "Creating $storage"
New-AzStorageAccount -Name $storage -Location $location -ResourceGroupName
$resourceGroup -SkuName $skuStorage

# Create a serverless function app in the resource group.
Write-Host "Creating $functionApp"
New-AzFunctionApp -Name $functionApp -StorageAccountName $storage -Location
$location -ResourceGroupName $resourceGroup -Runtime DotNet -
FunctionsVersion $functionsVersion

# Get the storage account connection string.
$connstr = (Get-AzStorageAccount -StorageAccountName $storage -
ResourceGroupName $resourceGroup).Context.ConnectionString

# Update function app settings to connect to the storage account.
Update-AzFunctionAppSetting -Name $functionApp -ResourceGroupName
$resourceGroup -AppSetting @{StorageConStr = $connstr}

```

Create a function app with an Azure Cosmos DB connection

The following script creates a function app and a connected Azure Cosmos DB account:

azurepowershell-interactive

```

# Function app and storage account names must be unique.

# Variable block
$randomIdentifier = Get-Random
.setLocation = "eastus"
$resourceGroup = "msdocs-azure-functions-rg-$randomIdentifier"
$tag = @{script = "create-function-app-connect-to-cosmos-db"}
$storage = "msdocsaccount$randomIdentifier"
$functionApp = "msdocs-serverless-function-$randomIdentifier"
$skuStorage = "Standard_LRS"
$functionsVersion = "4"

# Create a resource group
Write-Host "Creating $resourceGroup in $location..."
New-AzResourceGroup -Name $resourceGroup -Location $location -Tag $tag

# Create an Azure storage account in the resource group.
Write-Host "Creating $storage"
New-AzStorageAccount -Name $storage -Location $location -ResourceGroupName
$resourceGroup -SkuName $skuStorage

# Create a serverless function app in the resource group.
Write-Host "Creating $functionApp"
New-AzFunctionApp -Name $functionApp -StorageAccountName $storage -Location
$location -ResourceGroupName $resourceGroup -Runtime DotNet -

```

```

FunctionsVersion $functionsVersion

# Create an Azure Cosmos DB database account using the same function app
# name.
Write-Host "Creating $functionApp"
New-AzCosmosDBAccount -Name $functionApp -ResourceGroupName $resourceGroup -
Location $location

# Get the Azure Cosmos DB connection string.
$endpoint = (Get-AzCosmosDBAccount -Name $functionApp -ResourceGroupName
$resourceGroup).DocumentEndpoint
Write-Host $endpoint

$key = (Get-AzCosmosDBAccountKey -Name $functionApp -ResourceGroupName
$resourceGroup).PrimaryMasterKey
Write-Host $key

# Configure function app settings to use the Azure Cosmos DB connection
# string.
Update-AzFunctionAppSetting -Name $functionApp -ResourceGroupName
$resourceGroup -AppSetting @{CosmosDB_Endpoint = $endpoint; CosmosDB_Key =
$key}

```

Create a function app with continuous deployment

The following script creates a function app that has continuous deployment configured to publish from a public GitHub repository:

```

azurepowershell-interactive

# Function app and storage account names must be unique.

# Variable block
$randomIdentifier = Get-Random
$location = "eastus"
$resourceGroup = "msdocs-azure-functions-rg-$randomIdentifier"
$tag = @{script = "deploy-function-app-with-function-github"}
$storage = "msdocsaccount$randomIdentifier"
$functionApp = "mygithubfunc$randomIdentifier"
$skuStorage = "Standard_LRS"
$functionsVersion = "4"
$runtime = "Node"
# Public GitHub repository containing an Azure Functions code project.
$gitrepo = "https://github.com/Azure-Samples/functions-quickstart-
javascript"
<# Set GitHub personal access token (PAT) to enable authenticated GitHub
deployment in your subscription when using a private repo.
$token = <Replace with a GitHub access token when using a private repo.>
$propertiesObject = @{

```

```

        token = $token
    }

Set-AzResource -PropertyObject $propertiesObject -ResourceId
/providers/Microsoft.Web/sourcecontrols/GitHub -ApiVersion 2018-02-01 -Force
#>

# Create a resource group
Write-Host "Creating $resourceGroup in $location..."
New-AzResourceGroup -Name $resourceGroup -Location $location -Tag $tag

# Create an Azure storage account in the resource group.
Write-Host "Creating $storage"
New-AzStorageAccount -Name $storage -Location $location -ResourceGroupName
$resourceGroup -SkuName $skuStorage

# Create a function app in the resource group.
Write-Host "Creating $functionApp"
New-AzFunctionApp -Name $functionApp -StorageAccountName $storage -Location
$location -ResourceGroupName $resourceGroup -Runtime $runtime -
FunctionsVersion $functionsVersion

# Configure GitHub deployment from a public GitHub repo and deploy once.
$propertiesObject = @{
    repoUrl = $gitrepo
    branch = 'main'
    isManualIntegration = $True # $False when using a private repo
}

Set-AzResource -PropertyObject $propertiesObject -ResourceGroupName
$resourceGroup -ResourceType Microsoft.Web/sites/sourcecontrols -
ResourceName $functionApp/web -ApiVersion 2018-02-01 -Force

# Connect to function application
Invoke-RestMethod -Uri
"https://$functionApp.azurewebsites.net/api/httpexample?name=Azure"

```

Create a serverless Python function app and mount file share

The following script creates a Python function app on Linux and creates and mounts an external Azure Files share:

azurepowershell-interactive

```

# Function app and storage account names must be unique.

# Variable block
$randomIdentifier = Get-Random
$location = "eastus"

```

```

$resourceGroup = "msdocs-azure-functions-rg-$randomIdentifier"
$tag = @{script = "functions-cli-mount-files-storage-linux"}
$storage = "msdocsaccount$randomIdentifier"
$functionApp = "msdocs-serverless-function-$randomIdentifier"
$skuStorage = "Standard_LRS"
$functionsVersion = "4"
$pythonVersion = "3.9" #Allowed values: 3.7, 3.8, and 3.9
$share = "msdocs-fileshare-$randomIdentifier"
$directory = "msdocs-directory-$randomIdentifier"
$shareId = "msdocs-share-$randomIdentifier"
$mountPath = "/mounted-$randomIdentifier"

# Create a resource group
Write-Host "Creating $resourceGroup in $location..."
New-AzResourceGroup -Name $resourceGroup -Location $location -Tag $tag

# Create an Azure storage account in the resource group.
Write-Host "Creating $storage"
New-AzStorageAccount -Name $storage -Location $location -ResourceGroupName
$resourceGroup -SkuName $skuStorage

# Get the storage account key.
$keys = Get-AzStorageAccountKey -Name $storage -ResourceGroupName
$resourceGroup
$storageKey = $keys[0].Value

## Create a serverless Python function app in the resource group.
Write-Host "Creating $functionApp"
New-AzFunctionApp -Name $functionApp -StorageAccountName $storage -Location
$location -ResourceGroupName $resourceGroup -OSType Linux -Runtime Python -
RuntimeVersion $pythonVersion -FunctionsVersion $functionsVersion

# Create a share in Azure Files.
Write-Host "Creating $share"
$storageContext = New-AzStorageContext -StorageAccountName $storage -
StorageAccountKey $storageKey
New-AzStorageShare -Name $share -Context $storageContext

# Create a directory in the share.
Write-Host "Creating $directory in $share"
New-AzStorageDirectory -ShareName $share -Path $directory -Context
$storageContext

# Add a storage account configuration to the function app
Write-Host "Adding $storage configuration"
$storagePath = New-AzWebAppAzureStoragePath -Name $shareId -Type AzureFiles
-ShareName $share -AccountName $storage -MountPath $mountPath -AccessKey
$storageKey
Set-AzWebApp -Name $functionApp -ResourceGroupName $resourceGroup -
AzureStoragePath $storagePath

# Get a function app's storage account configurations.
(Get-AzWebApp -Name $functionApp -ResourceGroupName
$resourceGroup).AzureStoragePath

```

Mounted file shares are only supported on Linux. For more information, see [Mount file shares](#).

Clean up resources

In the preceding steps, you created Azure resources in a resource group. If you don't expect to need these resources in the future, delete the resource group by running the following PowerShell command:

Azure CLI

```
Remove-AzResourceGroup -Name myResourceGroup
```

This command may take a minute to run.

Next steps

For more information on Azure PowerShell, see [Azure PowerShell documentation](#).

Best practices for reliable Azure Functions

Article • 07/12/2022

Azure Functions is an event-driven, compute-on-demand experience that extends the existing Azure App Service application platform with capabilities to implement code triggered by events occurring in Azure, in third-party service, and in on-premises systems. Functions lets you build solutions by connecting to data sources or messaging solutions, which makes it easier to process and react to events. Functions runs on Azure data centers, which are complex with many integrated components. In a hosted cloud environment, it's expected that VMs can occasionally restart or move, and systems upgrades will occur. Your functions apps also likely depend on external APIs, Azure Services, and other databases, which are also prone to periodic unreliability.

This article details some best practices for designing and deploying efficient function apps that remain healthy and perform well in a cloud-based environment.

Choose the correct hosting plan

When you create a function app in Azure, you must choose a hosting plan for your app. The plan you choose has an effect on performance, reliability, and cost. There are three basic hosting plans available for Functions:

- [Consumption plan](#)
- [Premium plan](#)
- [Dedicated \(App Service\) plan](#)

All hosting plans are generally available (GA) when running either Linux or Windows.

In the context of the App Service platform, the Premium plan used to dynamically host your functions is the Elastic Premium plan (EP). There are other Dedicated (App Service) plans called Premium. To learn more, see the [Premium plan](#) article.

The hosting plan you choose determines the following behaviors:

- How your function app is scaled based on demand and how instances allocation is managed.
- The resources available to each function app instance.
- Support for advanced functionality, such as Azure Virtual Network connectivity.

To learn more about choosing the correct hosting plan and for a detailed comparison between the plans, see [Azure Functions hosting options](#).

It's important that you choose the correct plan when you create your function app. Functions provides a limited ability to switch your hosting plan, primarily between Consumption and Elastic Premium plans. To learn more, see [Plan migration](#).

Configure storage correctly

Functions requires a storage account be associated with your function app. The storage account connection is used by the Functions host for operations such as managing triggers and logging function executions. It's also used when dynamically scaling function apps. To learn more, see [Storage considerations for Azure Functions](#).

A misconfigured file system or storage account in your function app can affect the performance and availability of your functions. For help with troubleshooting an incorrectly configured storage account, see the [storage troubleshooting](#) article.

Storage connection settings

Function apps that scale dynamically can run either from an Azure Files endpoint in your storage account or from the file servers associated with your scaled-out instances. This behavior is controlled by the following application settings:

- `WEBSITE_CONTENTAZUREFILECONNECTIONSTRING`
- `WEBSITE_CONTENTSHARE`

These settings are only supported when you are running in a Premium plan or in a Consumption plan on Windows.

When you create your function app either in the Azure portal or by using Azure CLI or Azure PowerShell, these settings are created for your function app when needed. When you create your resources from an Azure Resource Manager template (ARM template), you need to also include `WEBSITE_CONTENTAZUREFILECONNECTIONSTRING` in the template.

On your first deployment using an ARM template, don't include `WEBSITE_CONTENTSHARE`, which is generated for you.

You can use the following ARM template examples to help correctly configure these settings:

- [Consumption plan ↗](#)
- [Dedicated plan ↗](#)

- Premium plan with VNET integration ↗
- Consumption plan with a deployment slot ↗

Storage account configuration

When creating a function app, you must create or link to a general-purpose Azure Storage account that supports Blob, Queue, and Table storage. Functions relies on Azure Storage for operations such as managing triggers and logging function executions. The storage account connection string for your function app is found in the `AzureWebJobsStorage` and `WEBSITE_CONTENTAZUREFILECONNECTIONSTRING` application settings.

Keep in mind the following considerations when creating this storage account:

- To reduce latency, create the storage account in the same region as the function app.
- To improve performance in production, use a separate storage account for each function app. This is especially true with Durable Functions and Event Hub triggered functions.
- For Event Hub triggered functions, don't use an account with [Data Lake Storage enabled](#) ↗.

Handling large data sets

When running on Linux, you can add extra storage by mounting a file share. Mounting a share is a convenient way for a function to process a large existing data set. To learn more, see [Mount file shares](#).

Organize your functions

As part of your solution, you likely develop and publish multiple functions. These functions are often combined into a single function app, but they can also run in separate function apps. In Premium and Dedicated (App Service) hosting plans, multiple function apps can also share the same resources by running in the same plan. How you group your functions and function apps can impact the performance, scaling, configuration, deployment, and security of your overall solution.

For Consumption and Premium plan, all functions in a function app are dynamically scaled together.

For more information on how to organize your functions, see [Function organization best practices](#).

Optimize deployments

When deploying a function app, it's important to keep in mind that the unit of deployment for functions in Azure is the function app. All functions in a function app are deployed at the same time, usually from the same deployment package.

Consider these options for a successful deployment:

- Have your functions run from the deployment package. This [run from package approach](#) provides the following benefits:
 - Reduces the risk of file copy locking issues.
 - Can be deployed directly to a production app, which does trigger a restart.
 - Know that all files in the package are available to your app.
 - Improves the performance of ARM template deployments.
 - May reduce cold-start times, particularly for JavaScript functions with large npm package trees.
- Consider using [continuous deployment](#) to connect deployments to your source control solution. Continuous deployments also let you run from the deployment package.
- For [Premium plan hosting](#), consider adding a warmup trigger to reduce latency when new instances are added. To learn more, see [Azure Functions warm-up trigger](#).
- To minimize deployment downtime and to be able to roll back deployments, consider using deployment slots. To learn more, see [Azure Functions deployment slots](#).

Write robust functions

There are several design principles you can follow when writing your function code that help with general performance and availability of your functions. These principles include:

- [Avoid long running functions](#).
- [Plan cross-function communication](#).
- [Write functions to be stateless](#).
- [Write defensive functions](#).

Because transient failures are common in cloud computing, you should use a [retry pattern](#) when accessing cloud-based resources. Many triggers and bindings already implement retry.

Design for security

Security is best considered during the planning phase and not after your functions are ready to go. To Learn how to securely develop and deploy functions, see [Securing Azure Functions](#).

Consider concurrency

As demand builds on your function app as a result of incoming events, function apps running in Consumption and Premium plans are scaled out. It's important to understand how your function app responds to load and how the triggers can be configured to handle incoming events. For a general overview, see [Event-driven scaling in Azure Functions](#).

Dedicated (App Service) plans require you to provide for scaling out your function apps.

Worker process count

In some cases, it's more efficient to handle the load by creating multiple processes, called language worker processes, in the instance before scale-out. The maximum number of language worker processes allowed is controlled by the `FUNCTIONS_WORKER_PROCESS_COUNT` setting. The default for this setting is `1`, which means that multiple processes aren't used. After the maximum number of processes are reached, the function app is scaled out to more instances to handle the load. This setting doesn't apply for [C# class library functions](#), which run in the host process.

When using `FUNCTIONS_WORKER_PROCESS_COUNT` on a Premium plan or Dedicated (App Service) plan, keep in mind the number of cores provided by your plan. For example, the Premium plan `EP2` provides two cores, so you should start with a value of `2` and increase by two as needed, up to the maximum.

Trigger configuration

When planning for throughput and scaling, it's important to understand how the different types of triggers process events. Some triggers allow you to control the batching behaviors and manage concurrency. Often adjusting the values in these

options can help each instance scale appropriately for the demands of the invoked functions. These configuration options are applied to all triggers in a function app, and are maintained in the host.json file for the app. See the Configuration section of the specific trigger reference for settings details.

To learn more about how Functions processes message streams, see [Azure Functions reliable event processing](#).

Plan for connections

Function apps running in [Consumption plan](#) are subject to connection limits. These limits are enforced on a per-instance basis. Because of these limits and as a general best practice, you should optimize your outbound connections from your function code. To learn more, see [Manage connections in Azure Functions](#).

Language-specific considerations

For your language of choice, keep in mind the following considerations:

C#

- [Use async code but avoid blocking calls](#).
- [Use cancellation tokens](#) (in-process only).

Maximize availability

Cold start is a key consideration for serverless architectures. To learn more, see [Cold starts](#). If cold start is a concern for your scenario, you can find a deeper dive in the post [Understanding serverless cold start](#).

Premium plan is the recommended plan for reducing cold starts while maintaining dynamic scale. You can use the following guidance to reduce cold starts and improve availability in all three hosting plans.

Plan	Guidance
------	----------

Plan	Guidance
Premium plan	<ul style="list-style-type: none"> • Implement a Warmup trigger in your function app • Set the values for Always-Ready instances and Max Burst limit • Use virtual network trigger support when using non-HTTP triggers on a virtual network
Dedicated plans	<ul style="list-style-type: none"> • Run on at least two instances with Azure App Service Health Check enabled • Implement autoscaling
Consumption plan	<ul style="list-style-type: none"> • Review your use of Singleton patterns and the concurrency settings for bindings and triggers to avoid artificially placing limits on how your function app scales. • Review the <code>functionAppScaleLimit</code> setting, which can limit scale-out • Check for a Daily Usage Quota (GB-Sec) limit set during development and testing. Consider removing this limit in production environments.

Monitor effectively

Azure Functions offers built-in integration with Azure Application Insights to monitor your function execution and traces written from your code. To learn more, see [Monitor Azure Functions](#). Azure Monitor also provides facilities for monitoring the health of the function app itself. To learn more, see [Monitoring with Azure Monitor](#).

You should be aware of the following considerations when using Application Insights integration to monitor your functions:

- Make sure that the [AzureWebJobsDashboard](#) application setting is removed. This setting was supported in older version of Functions. If it exists, removing `AzureWebJobsDashboard` improves performance of your functions.
- Review the [Application Insights logs](#). If data you expect to find is missing, consider adjusting the sampling settings to better capture your monitoring scenario. You can use the `excludedTypes` setting to exclude certain types from sampling, such as `Request` or `Exception`. To learn more, see [Configure sampling](#).

Azure Functions also allows you to [send system-generated and user-generated logs to Azure Monitor Logs](#). Integration with Azure Monitor Logs is currently in preview.

Build in redundancy

Your business needs might require that your functions always be available, even during a data center outage. To learn how to use a multi-regional approach to keep your critical functions always running, see [Azure Functions geo-disaster recovery and high-availability](#).

Next steps

[Manage your function app](#)

Improve the performance and reliability of Azure Functions

Article • 03/20/2023

This article provides guidance to improve the performance and reliability of your [serverless](#) function apps. For a more general set of Azure Functions best practices, see [Azure Functions best practices](#).

The following are best practices in how you build and architect your serverless solutions using Azure Functions.

Avoid long running functions

Large, long-running functions can cause unexpected timeout issues. To learn more about the timeouts for a given hosting plan, see [function app timeout duration](#).

A function can become large because of many Node.js dependencies. Importing dependencies can also cause increased load times that result in unexpected timeouts. Dependencies are loaded both explicitly and implicitly. A single module loaded by your code may load its own additional modules.

Whenever possible, refactor large functions into smaller function sets that work together and return responses fast. For example, a webhook or HTTP trigger function might require an acknowledgment response within a certain time limit; it's common for webhooks to require an immediate response. You can pass the HTTP trigger payload into a queue to be processed by a queue trigger function. This approach lets you defer the actual work and return an immediate response.

Make sure background tasks complete

When your function starts any tasks, callbacks, threads, processes, they must complete before your function code returns. Because Functions doesn't track these background threads, site shutdown can occur regardless of background thread status, which can cause unintended behavior in your functions.

For example, if a function starts a background task and returns a successful response before the task completes, the Functions runtime considers the execution as having completed successfully, regardless of the result of the background task. If this background task is performing essential work, it may be preempted by site shutdown, leaving that work in an unknown state.

Cross function communication

Durable Functions and Azure Logic Apps are built to manage state transitions and communication between multiple functions.

If not using Durable Functions or Logic Apps to integrate with multiple functions, it's best to use storage queues for cross-function communication. The main reason is that storage queues are cheaper and much easier to provision than other storage options.

Individual messages in a storage queue are limited in size to 64 KB. If you need to pass larger messages between functions, an Azure Service Bus queue could be used to support message sizes up to 256 KB in the Standard tier, and up to 100 MB in the Premium tier.

Service Bus topics are useful if you require message filtering before processing.

Event hubs are useful to support high volume communications.

Write functions to be stateless

Functions should be stateless and idempotent if possible. Associate any required state information with your data. For example, an order being processed would likely have an associated `state` member. A function could process an order based on that state while the function itself remains stateless.

Idempotent functions are especially recommended with timer triggers. For example, if you have something that absolutely must run once a day, write it so it can run anytime during the day with the same results. The function can exit when there's no work for a particular day. Also if a previous run failed to complete, the next run should pick up where it left off. This is particularly important for message-based bindings that retry on failure. For more information, see [Designing Azure Functions for identical input](#).

Write defensive functions

Assume your function could encounter an exception at any time. Design your functions with the ability to continue from a previous fail point during the next execution.

Consider a scenario that requires the following actions:

1. Query for 10,000 rows in a database.
2. Create a queue message for each of those rows to process further down the line.

Depending on how complex your system is, you may have: involved downstream services behaving badly, networking outages, or quota limits reached, etc. All of these can affect your function at any time. You need to design your functions to be prepared for it.

How does your code react if a failure occurs after inserting 5,000 of those items into a queue for processing? Track items in a set that you've completed. Otherwise, you might insert them again next time. This double-insertion can have a serious impact on your work flow, so [make your functions idempotent](#).

If a queue item was already processed, allow your function to be a no-op.

Take advantage of defensive measures already provided for components you use in the Azure Functions platform. For example, see [Handling poison queue messages](#) in the documentation for [Azure Storage Queue triggers and bindings](#).

For HTTP based functions consider [API versioning strategies](#) with Azure API Management. For example, if you have to update your HTTP based function app, deploy the new update to a separate function app and use API Management revisions or versions to direct clients to the new version or revision. Once all clients are using the version or revision and no more executions are left on the previous function app, you can deprovision the previous function app.

Function organization best practices

As part of your solution, you may develop and publish multiple functions. These functions are often combined into a single function app, but they can also run in separate function apps. In Premium and dedicated (App Service) hosting plans, multiple function apps can also share the same resources by running in the same plan. How you group your functions and function apps can impact the performance, scaling, configuration, deployment, and security of your overall solution. There aren't rules that apply to every scenario, so consider the information in this section when planning and developing your functions.

Organize functions for performance and scaling

Each function that you create has a memory footprint. While this footprint is usually small, having too many functions within a function app can lead to slower startup of your app on new instances. It also means that the overall memory usage of your function app might be higher. It's hard to say how many functions should be in a single app, which depends on your particular workload. However, if your function stores a lot of data in memory, consider having fewer functions in a single app.

If you run multiple function apps in a single Premium plan or dedicated (App Service) plan, these apps are all sharing the same resources allocated to the plan. If you have one function app that has a much higher memory requirement than the others, it uses a disproportionate amount of memory resources on each instance to which the app is deployed. Because this could leave less memory available for the other apps on each instance, you might want to run a high-memory-using function app like this in its own separate hosting plan.

ⓘ Note

When using the **Consumption plan**, we recommend you always put each app in its own plan, since apps are scaled independently anyway. For more information, see [Multiple apps in the same plan](#).

Consider whether you want to group functions with different load profiles. For example, if you have a function that processes many thousands of queue messages, and another that is only called occasionally but has high memory requirements, you might want to deploy them in separate function apps so they get their own sets of resources and they scale independently of each other.

Organize functions for configuration and deployment

Function apps have a `host.json` file, which is used to configure advanced behavior of function triggers and the Azure Functions runtime. Changes to the `host.json` file apply to all functions within the app. If you have some functions that need custom configurations, consider moving them into their own function app.

All functions in your local project are deployed together as a set of files to your function app in Azure. You might need to deploy individual functions separately or use features like [deployment slots](#) for some functions and not others. In such cases, you should deploy these functions (in separate code projects) to different function apps.

Organize functions by privilege

Connection strings and other credentials stored in application settings gives all of the functions in the function app the same set of permissions in the associated resource. Consider minimizing the number of functions with access to specific credentials by moving functions that don't use those credentials to a separate function app. You can always use techniques such as [function chaining](#) to pass data between functions in different function apps.

Scalability best practices

There are a number of factors that impact how instances of your function app scale. The details are provided in the documentation for [function scaling](#). The following are some best practices to ensure optimal scalability of a function app.

Share and manage connections

Reuse connections to external resources whenever possible. See [how to manage connections in Azure Functions](#).

Avoid sharing storage accounts

When you create a function app, you must associate it with a storage account. The storage account connection is maintained in the [AzureWebJobsStorage application setting](#).

To maximize performance, use a separate storage account for each function app. This is particularly important when you have Durable Functions or Event Hub triggered functions, which both generate a high volume of storage transactions. When your application logic interacts with Azure Storage, either directly (using the Storage SDK) or through one of the storage bindings, you should use a dedicated storage account. For example, if you have an Event Hub-triggered function writing some data to blob storage, use two storage accounts—one for the function app and another for the blobs being stored by the function.

Don't mix test and production code in the same function app

Functions within a function app share resources. For example, memory is shared. If you're using a function app in production, don't add test-related functions and resources to it. It can cause unexpected overhead during production code execution.

Be careful what you load in your production function apps. Memory is averaged across each function in the app.

If you have a shared assembly referenced in multiple .NET functions, put it in a common shared folder. Otherwise, you could accidentally deploy multiple versions of the same binary that behave differently between functions.

Don't use verbose logging in production code, which has a negative performance impact.

Use async code but avoid blocking calls

Asynchronous programming is a recommended best practice, especially when blocking I/O operations are involved.

In C#, always avoid referencing the `Result` property or calling `Wait` method on a `Task` instance. This approach can lead to thread exhaustion.

Tip

If you plan to use the HTTP or WebHook bindings, plan to avoid port exhaustion that can be caused by improper instantiation of `HttpClient`. For more information, see [How to manage connections in Azure Functions](#).

Use multiple worker processes

By default, any host instance for Functions uses a single worker process. To improve performance, especially with single-threaded runtimes like Python, use the `FUNCTIONS_WORKER_PROCESS_COUNT` to increase the number of worker processes per host (up to 10). Azure Functions then tries to evenly distribute simultaneous function invocations across these workers.

The `FUNCTIONS_WORKER_PROCESS_COUNT` applies to each host that Functions creates when scaling out your application to meet demand.

Receive messages in batch whenever possible

Some triggers like Event Hub enable receiving a batch of messages on a single invocation. Batching messages has much better performance. You can configure the max batch size in the `host.json` file as detailed in the [host.json reference documentation](#)

For C# functions, you can change the type to a strongly-typed array. For example, instead of `EventData sensorEvent` the method signature could be `EventData[] sensorEvent`. For other languages, you'll need to explicitly set the cardinality property in your `function.json` to `many` in order to enable batching [as shown here ↗](#).

Configure host behaviors to better handle concurrency

The `host.json` file in the function app allows for configuration of host runtime and trigger behaviors. In addition to batching behaviors, you can manage concurrency for a number of triggers. Often adjusting the values in these options can help each instance scale appropriately for the demands of the invoked functions.

Settings in the `host.json` file apply across all functions within the app, within a *single instance* of the function. For example, if you had a function app with two HTTP functions and `maxConcurrentRequests` requests set to 25, a request to either HTTP trigger would count towards the shared 25 concurrent requests. When that function app is scaled to 10 instances, the ten functions effectively allow 250 concurrent requests (10 instances * 25 concurrent requests per instance).

Other host configuration options are found in the [host.json configuration article](#).

- [Azure App Service best practices](#)

Manage connections in Azure Functions

Article • 11/18/2021

Functions in a function app share resources. Among those shared resources are connections: HTTP connections, database connections, and connections to services such as Azure Storage. When many functions are running concurrently in a Consumption plan, it's possible to run out of available connections. This article explains how to code your functions to avoid using more connections than they need.

ⓘ Note

Connection limits described in this article apply only when running in a **Consumption plan**. However, the techniques described here may be beneficial when running on any plan.

Connection limit

The number of available connections in a Consumption plan is limited partly because a function app in this plan runs in a [sandbox environment](#). One of the restrictions that the sandbox imposes on your code is a limit on the number of outbound connections, which is currently 600 active (1,200 total) connections per instance. When you reach this limit, the functions runtime writes the following message to the logs: `Host thresholds exceeded: Connections`. For more information, see the [Functions service limits](#).

This limit is per instance. When the [scale controller adds function app instances](#) to handle more requests, each instance has an independent connection limit. That means there's no global connection limit, and you can have much more than 600 active connections across all active instances.

When troubleshooting, make sure that you have enabled Application Insights for your function app. Application Insights lets you view metrics for your function apps like executions. For more information, see [View telemetry in Application Insights](#).

Static clients

To avoid holding more connections than necessary, reuse client instances rather than creating new ones with each function invocation. We recommend reusing client connections for any language that you might write your function in. For example, .NET

clients like the [HttpClient](#), [DocumentClient](#), and Azure Storage clients can manage connections if you use a single, static client.

Here are some guidelines to follow when you're using a service-specific client in an Azure Functions application:

- *Do not* create a new client with every function invocation.
- *Do* create a single, static client that every function invocation can use.
- *Consider* creating a single, static client in a shared helper class if different functions use the same service.

Client code examples

This section demonstrates best practices for creating and using clients from your function code.

HTTP requests

C#

Here's an example of C# function code that creates a static [HttpClient](#) instance:

```
C#  
  
// Create a single, static HttpClient  
private static HttpClient httpClient = new HttpClient();  
  
public static async Task Run(string input)  
{  
    var response = await httpClient.GetAsync("https://example.com");  
    // Rest of function  
}
```

A common question about [HttpClient](#) in .NET is "Should I dispose of my client?" In general, you dispose of objects that implement [IDisposable](#) when you're done using them. But you don't dispose of a static client because you aren't done using it when the function ends. You want the static client to live for the duration of your application.

Azure Cosmos DB clients

C#

[CosmosClient](#) connects to an Azure Cosmos DB instance. The Azure Cosmos DB documentation recommends that you [use a singleton Azure Cosmos DB client for the lifetime of your application](#). The following example shows one pattern for doing that in a function:

C#

```
#r "Microsoft.Azure.Cosmos"
using Microsoft.Azure.Cosmos;

private static Lazy<CosmosClient> lazyClient = new Lazy<CosmosClient>
(InitializeCosmosClient);
private static CosmosClient cosmosClient => lazyClient.Value;

private static CosmosClient InitializeCosmosClient()
{
    // Perform any initialization here
    var uri = "https://youraccount.documents.azure.com:443";
    var authKey = "authKey";

    return new CosmosClient(uri, authKey);
}

public static async Task Run(string input)
{
    Container container = cosmosClient.GetContainer("database",
"collection");
    MyItem item = new MyItem{ id = "myId", partitionKey =
"myPartitionKey", data = "example" };
    await container.UpsertItemAsync(item);

    // Rest of function
}
```

Also, create a file named "function.proj" for your trigger and add the below content :

C#

```
<Project Sdk="Microsoft.NET.Sdk">
    <PropertyGroup>
        <TargetFramework>netcoreapp3.1</TargetFramework>
    </PropertyGroup>
    <ItemGroup>
        <PackageReference Include="Microsoft.Azure.Cosmos"
Version="3.23.0" />
    </ItemGroup>
</Project>
```

SqlClient connections

Your function code can use the .NET Framework Data Provider for SQL Server ([SqlClient](#)) to make connections to a SQL relational database. This is also the underlying provider for data frameworks that rely on ADO.NET, such as [Entity Framework](#). Unlike [HttpClient](#) and [DocumentClient](#) connections, ADO.NET implements connection pooling by default. But because you can still run out of connections, you should optimize connections to the database. For more information, see [SQL Server Connection Pooling \(ADO.NET\)](#).

Tip

Some data frameworks, such as Entity Framework, typically get connection strings from the **ConnectionStrings** section of a configuration file. In this case, you must explicitly add SQL database connection strings to the **Connection strings** collection of your function app settings and in the **local.settings.json** file in your local project. If you're creating an instance of **SqlConnection** in your function code, you should store the connection string value in **Application settings** with your other connections.

Next steps

For more information about why we recommend static clients, see [Improper instantiation antipattern](#).

For more Azure Functions performance tips, see [Optimize the performance and reliability of Azure Functions](#).

Storage considerations for Azure Functions

Article • 07/30/2024

Azure Functions requires an Azure Storage account when you create a function app instance. The following storage services could be used by your function app:

[+] Expand table

Storage service	Functions usage
Azure Blob storage	Maintain bindings state and function keys ¹ . Deployment source for apps that run in a Flex Consumption plan . Used by default for task hubs in Durable Functions . Can be used to store function app code for Linux Consumption remote build or as part of external package URL deployments .
Azure Files ²	File share used to store and run your function app code in a Consumption Plan and Premium Plan .
Azure Queue storage	Used by default for task hubs in Durable Functions . Used for failure and retry handling in specific Azure Functions triggers . Used for object tracking by the Blob storage trigger .
Azure Table storage	Used by default for task hubs in Durable Functions .

1. Blob storage is the default store for function keys, but you can [configure an alternate store](#).
2. Azure Files is set up by default, but you can [create an app without Azure Files](#) under certain conditions.

Important considerations

You must strongly consider the following facts regarding the storage accounts used by your function apps:

- When your function app is hosted on the Consumption plan or Premium plan, your function code and configuration files are stored in Azure Files in the linked storage account. When you delete this storage account, the content is deleted and can't be recovered. For more information, see [Storage account was deleted](#)

- Important data, such as function code, [access keys](#), and other important service-related data, can be persisted in the storage account. You must carefully manage access to the storage accounts used by function apps in the following ways:
 - Audit and limit the access of apps and users to the storage account based on a least-privilege model. Permissions to the storage account can come from [data actions in the assigned role](#) or through permission to perform the [listKeys operation](#).
 - Monitor both control plane activity (such as retrieving keys) and data plane operations (such as writing to a blob) in your storage account. Consider maintaining storage logs in a location other than Azure Storage. For more information, see [Storage logs](#).

Storage account requirements

Storage accounts created as part of the function app create flow in the Azure portal are guaranteed to work with the new function app. When you choose to use an existing storage account, the list provided doesn't include certain unsupported storage accounts. The following restrictions apply to storage accounts used by your function app, so you must make sure an existing storage account meets these requirements:

- The account type must support Blob, Queue, and Table storage. Some storage accounts don't support queues and tables. These accounts include blob-only storage accounts and Azure Premium Storage. To learn more about storage account types, see [Storage account overview](#).
- You can't use a network-secured storage account when your function app is hosted in the [Consumption plan](#).
- When creating your function app in the portal, you're only allowed to choose an existing storage account in the same region as the function app you're creating. This is a performance optimization and not a strict limitation. To learn more, see [Storage account location](#).
- When creating your function app on a plan with [availability zone support](#) enabled, only [zone-redundant storage accounts](#) are supported.

When using deployment automation to create your function app with a network-secured storage account, you must include specific networking configurations in your ARM template or Bicep file. When you don't include these settings and resources, your automated deployment might fail in validation. For more specific ARM and Bicep

guidance, see [Secured deployments](#). For an overview on configuring storage accounts with networking, see [How to use a secured storage account with Azure Functions](#).

Storage account guidance

Every function app requires a storage account to operate. When that account is deleted, your function app won't run. To troubleshoot storage-related issues, see [How to troubleshoot storage-related issues](#). The following other considerations apply to the Storage account used by function apps.

Storage account location

For best performance, your function app should use a storage account in the same region, which reduces latency. The Azure portal enforces this best practice. If for some reason you need to use a storage account in a region different than your function app, you must create your function app outside of the portal.

The storage account must be accessible to the function app. If you need to use a secured storage account, consider [restricting your storage account to a virtual network](#).

Storage account connection setting

By default, function apps configure the `AzureWebJobsStorage` connection as a connection string stored in the [AzureWebJobsStorage application setting](#), but you can also [configure AzureWebJobsStorage to use an identity-based connection](#) without a secret.

Function apps running in a Consumption plan (Windows only) or an Elastic Premium plan (Windows or Linux) can use Azure Files to store the images required to enable dynamic scaling. For these plans, set the connection string for the storage account in the `WEBSITE_CONTENTAZUREFILECONNECTIONSTRING` setting and the name of the file share in the `WEBSITE_CONTENTSHARE` setting. This is usually the same account used for `AzureWebJobsStorage`. You can also [create a function app that doesn't use Azure Files](#), but scaling might be limited.

Note

A storage account connection string must be updated when you regenerate storage keys. [Read more about storage key management here](#).

Shared storage accounts

It's possible for multiple function apps to share the same storage account without any issues. For example, in Visual Studio you can develop multiple apps using the [Azurite storage emulator](#). In this case, the emulator acts like a single storage account. The same storage account used by your function app can also be used to store your application data. However, this approach isn't always a good idea in a production environment.

You might need to use separate storage accounts to [avoid host ID collisions](#).

Lifecycle management policy considerations

You shouldn't apply [lifecycle management policies](#) to your Blob Storage account used by your function app. Functions uses Blob storage to persist important information, such as [function access keys](#), and policies could remove blobs (such as keys) needed by the Functions host. If you must use policies, exclude containers used by Functions, which are prefixed with `azure-webjobs` or `scm`.

Storage logs

Because function code and keys might be persisted in the storage account, logging of activity against the storage account is a good way to monitor for unauthorized access. Azure Monitor resource logs can be used to track events against the storage data plane. See [Monitoring Azure Storage](#) for details on how to configure and examine these logs.

The [Azure Monitor activity log](#) shows control plane events, including the [listKeys operation](#). However, you should also configure resource logs for the storage account to track subsequent use of keys or other identity-based data plane operations. You should have at least the [StorageWrite log category](#) enabled to be able to identify modifications to the data outside of normal Functions operations.

To limit the potential impact of any broadly scoped storage permissions, consider using a nonstorage destination for these logs, such as Log Analytics. For more information, see [Monitoring Azure Blob Storage](#).

Optimize storage performance

To maximize performance, use a separate storage account for each function app. This is particularly important when you have Durable Functions or Event Hub triggered functions, which both generate a high volume of storage transactions. When your application logic interacts with Azure Storage, either directly (using the Storage SDK) or through one of the storage bindings, you should use a dedicated storage account. For example, if you have an Event Hub-triggered function writing some data to blob

storage, use two storage accounts—one for the function app and another for the blobs being stored by the function.

Consistent routing through virtual networks

Multiple function apps hosted in the same plan can also use the same storage account for the Azure Files content share (defined by

`WEBSITE_CONTENTAZUREFILECONNECTIONSTRING`). When this storage account is also secured by a virtual network, all of these apps should also use the same value for `vnetContentShareEnabled` (formerly `WEBSITE_CONTENTOVERVNET`) to guarantee that traffic is routed consistently through the intended virtual network. A mismatch in this setting between apps using the same Azure Files storage account might result in traffic being routed through public networks, which causes access to be blocked by storage account network rules.

Working with blobs

A key scenario for Functions is file processing of files in a blob container, such as for image processing or sentiment analysis. To learn more, see [Process file uploads](#).

Trigger on a blob container

There are several ways to execute your function code based on changes to blobs in a storage container. Use the following table to determine which function trigger best fits your needs:

[+] [Expand table](#)

Strategy	Container (polling)	Container (events)	Queue trigger	Event Grid
Latency	High (up to 10 min)	Low	Medium	Low
Storage account limitations	Blob-only accounts not supported ¹	general purpose v1 not supported	none	general purpose v1 not supported
Trigger type	Blob storage	Blob storage	Queue storage	Event Grid
Extension version	Any	Storage v5.x+	Any	Any

Strategy	Container (polling)	Container (events)	Queue trigger	Event Grid
Processes existing blobs	Yes	No	No	No
Filters	Blob name pattern	Event filters	n/a	Event filters
Requires event subscription	No	Yes	No	Yes
Supports Flex Consumption plan	No	Yes	Yes	Yes
Supports high-scale ²	No	Yes	Yes	Yes
Description	Default trigger behavior, which relies on polling the container for updates. For more information, see the examples in the Blob storage trigger reference .	Consumes blob storage events from an event subscription. Requires a Source parameter value of EventGrid . For more information, see Tutorial: Trigger Azure Functions on blob containers using an event subscription .	Blob name string is manually added to a storage queue when a blob is added to the container. This value is passed directly by a Queue storage trigger to a Blob storage input binding on the same function.	Provides the flexibility of triggering on events besides those coming from a storage container. Use when need to also have nonstorage events trigger your function. For more information, see How to work with Event Grid triggers and bindings in Azure Functions .

1. Blob storage input and output bindings support blob-only accounts.
2. High scale can be loosely defined as containers that have more than 100,000 blobs in them or storage accounts that have more than 100 blob updates per second.

Storage data encryption

Azure Storage encrypts all data in a storage account at rest. For more information, see [Azure Storage encryption for data at rest](#).

By default, data is encrypted with Microsoft-managed keys. For additional control over encryption keys, you can supply customer-managed keys to use for encryption of blob

and file data. These keys must be present in Azure Key Vault for Functions to be able to access the storage account. To learn more, see [Encryption at rest using customer-managed keys](#).

In-region data residency

When all customer data must remain within a single region, the storage account associated with the function app must be one with [in-region redundancy](#). An in-region redundant storage account also must be used with [Azure Durable Functions](#).

Other platform-managed customer data is only stored within the region when hosting in an internally load-balanced App Service Environment (ASE). To learn more, see [ASE zone redundancy](#).

Host ID considerations

Functions uses a host ID value as a way to uniquely identify a particular function app in stored artifacts. By default, this ID is autogenerated from the name of the function app, truncated to the first 32 characters. This ID is then used when storing per-app correlation and tracking information in the linked storage account. When you have function apps with names longer than 32 characters and when the first 32 characters are identical, this truncation can result in duplicate host ID values. When two function apps with identical host IDs use the same storage account, you get a host ID collision because stored data can't be uniquely linked to the correct function app.

Note

This same kind of host ID collision can occur between a function app in a production slot and the same function app in a staging slot, when both slots use the same storage account.

Starting with version 3.x of the Functions runtime, host ID collision is detected and a warning is logged. In version 4.x, an error is logged and the host is stopped, resulting in a hard failure. More details about host ID collision can be found in [this issue](#).

Avoiding host ID collisions

You can use the following strategies to avoid host ID collisions:

- Use a separated storage account for each function app or slot involved in the collision.

- Rename one of your function apps to a value fewer than 32 characters in length, which changes the computed host ID for the app and removes the collision.
- Set an explicit host ID for one or more of the colliding apps. To learn more, see [Host ID override](#).

ⓘ Important

Changing the storage account associated with an existing function app or changing the app's host ID can impact the behavior of existing functions. For example, a Blob storage trigger tracks whether it's processed individual blobs by writing receipts under a specific host ID path in storage. When the host ID changes or you point to a new storage account, previously processed blobs could be reprocessed.

Override the host ID

You can explicitly set a specific host ID for your function app in the application settings by using the `AzureFunctionsWebHost__hostid` setting. For more information, see [AzureFunctionsWebHost__hostid](#).

When the collision occurs between slots, you must set a specific host ID for each slot, including the production slot. You must also mark these settings as [deployment settings](#) so they don't get swapped. To learn how to create app settings, see [Work with application settings](#).

Azure Arc-enabled clusters

When your function app is deployed to an Azure Arc-enabled Kubernetes cluster, a storage account might not be required by your function app. In this case, a storage account is only required by Functions when your function app uses a trigger that requires storage. The following table indicates which triggers might require a storage account and which don't.

[] [Expand table](#)

Not required	might require storage
<ul style="list-style-type: none"> • Azure Cosmos DB • HTTP • Kafka • RabbitMQ • Service Bus 	<ul style="list-style-type: none"> • Azure SQL • Blob storage • Event Grid • Event Hubs • IoT Hub • Queue storage

Not required	might require storage
	<ul style="list-style-type: none">• SendGrid• SignalR• Table storage• Timer• Twilio

To create a function app on an Azure Arc-enabled Kubernetes cluster without storage, you must use the Azure CLI command [az functionapp create](#). The version of the Azure CLI must include version 0.1.7 or a later version of the [appservice-kube extension](#). Use the `az --version` command to verify that the extension is installed and is the correct version.

Creating your function app resources using methods other than the Azure CLI requires an existing storage account. If you plan to use any triggers that require a storage account, you should create the account before you create the function app.

Create an app without Azure Files

The Azure Files service provides a shared file system that supports high-scale scenarios. When your function app runs on Windows in an Elastic Premium or Consumption plan, an Azure Files share is created by default in your storage account. That share is used by Functions to enable certain features, like log streaming. It is also used as a shared package deployment location, which guarantees the consistency of your deployed function code across all instances.

By default, function apps hosted in Premium and Consumption plans use [zip deployment](#), with deployment packages stored in this Azure file share. This section is only relevant to these hosting plans.

Using Azure Files requires the use of a connection string, which is stored in your app settings as [WEBSITE_CONTENTAZUREFILECONNECTIONSTRING](#). Azure Files doesn't currently support identity-based connections. If your scenario requires you to not store any secrets in app settings, you must remove your app's dependency on Azure Files. You can do this by creating your app without the default Azure Files dependency.

Note

You should also consider running in your function app in the Flex Consumption plan, which is currently in preview. The Flex Consumption plan provides greater control over the deployment package, including the ability use managed identity

connections. For more information, see [Configure deployment settings](#) in the Flex Consumption article.

To run your app without the Azure file share, you must meet the following requirements:

- You must [deploy your package to a remote Azure Blob storage container](#) and then set the URL that provides access to that package as the `WEBSITE_RUN_FROM_PACKAGE` app setting. This option lets you store your app content in Blob storage instead of Azure Files, which does support [managed identities](#).

You are responsible for manually updating the deployment package and maintaining the deployment package URL, which likely contains a shared access signature (SAS).

- Your app can't rely on a shared writeable file system.
- The app can't use version 1.x of the Functions runtime.
- Log streaming experiences in clients such as the Azure portal default to file system logs. You should instead rely on Application Insights logs.

If the above requirements suit your scenario, you can proceed to create a function app without Azure Files. You can do this by creating an app without the `WEBSITE_CONTENTAZUREFILECONNECTIONSTRING` and `WEBSITE_CONTENTSHARE` app settings. To get started, generate an ARM template for a standard deployment, remove the two settings, and then deploy the modified template.

Since Azure Files is used to enable dynamic scale-out for Functions, scaling could be limited when running your app without Azure Files in the Elastic Premium plan and Consumption plans running on Windows.

Mount file shares

This functionality is current only available when running on Linux.

You can mount existing Azure Files shares to your Linux function apps. By mounting a share to your Linux function app, you can use existing machine learning models or other data in your functions. You can use the following command to mount an existing share to your Linux function app.

Azure CLI

```
az webapp config storage-account add
```

In this command, `share-name` is the name of the existing Azure Files share, and `custom-id` can be any string that uniquely defines the share when mounted to the function app. Also, `mount-path` is the path from which the share is accessed in your function app. `mount-path` must be in the format `/dir-name`, and it can't start with `/home`.

For a complete example, see the scripts in [Create a Python function app and mount an Azure Files share](#).

Currently, only a `storage-type` of `AzureFiles` is supported. You can only mount five shares to a given function app. Mounting a file share can increase the cold start time by at least 200-300 ms, or even more when the storage account is in a different region.

The mounted share is available to your function code at the `mount-path` specified. For example, when `mount-path` is `/path/to/mount`, you can access the target directory by file system APIs, as in the following Python example:

Python

```
import os
...
files_in_share = os.listdir("/path/to/mount")
```

Azure Functions error handling and retries

Article • 04/26/2024

Handling errors in Azure Functions is important to help you avoid lost data, avoid missed events, and monitor the health of your application. It's also an important way to help you understand the retry behaviors of event-based triggers.

This article describes general strategies for error handling and the available retry strategies.

ⓘ Important

Preview retry policy support for certain triggers was removed in December 2022.

Retry policies for supported triggers are now generally available (GA). For a list of extensions that currently support retry policies, see the [Retries](#) section.

Handling errors

Errors that occur in an Azure function can come from:

- Use of built-in Functions [triggers and bindings](#).
- Calls to APIs of underlying Azure services.
- Calls to REST endpoints.
- Calls to client libraries, packages, or third-party APIs.

To avoid loss of data or missed messages, it's important to practice good error handling. This table describes some recommended error-handling practices and provides links to more information.

[] [Expand table](#)

Recommendation	Details
Enable Application Insights	Azure Functions integrates with Application Insights to collect error data, performance data, and runtime logs. You should use Application Insights to discover and better understand errors that occur in your function executions. To learn more, see Monitor Azure Functions .
Use structured error handling	Capturing and logging errors is critical to monitoring the health of your application. The top-most level of any function code should include a

Recommendation	Details
	try/catch block. In the catch block, you can capture and log errors. For information about what errors might be raised by bindings, see Binding error codes . Depending on your specific retry strategy, you might also raise a new exception to run the function again.
Plan your retry strategy	Several Functions bindings extensions provide built-in support for retries and others let you define retry policies, which are implemented by the Functions runtime. For triggers that don't provide retry behaviors, you should consider implementing your own retry scheme. For more information, see Retries .
Design for idempotency	The occurrence of errors when you're processing data can be a problem for your functions, especially when you're processing messages. It's important to consider what happens when the error occurs and how to avoid duplicate processing. To learn more, see Designing Azure Functions for identical input .

Retries

There are two kinds of retries available for your functions:

- Built-in retry behaviors of individual trigger extensions
- Retry policies provided by the Functions runtime

The following table indicates which triggers support retries and where the retry behavior is configured. It also links to more information about errors that come from the underlying services.

[] [Expand table](#)

Trigger/binding	Retry source	Configuration
Azure Cosmos DB	Retry policies	Function-level
Blob Storage	Binding extension	host.json
Event Grid	Binding extension	Event subscription
Event Hubs	Retry policies	Function-level
Kafka	Retry policies	Function-level
Queue Storage	Binding extension	host.json
RabbitMQ	Binding extension	Dead letter queue ↗

Trigger/binding	Retry source	Configuration
Service Bus	Binding extension	host.json*
Timer	Retry policies	Function-level

*Requires version 5.x of the Azure Service Bus extension. In older extension versions, retry behaviors are implemented by the [Service Bus dead letter queue](#).

Retry policies

Azure Functions lets you define retry policies for specific trigger types, which are enforced by the runtime. These trigger types currently support retry policies:

- [Azure Cosmos DB](#)
- [Event Hubs](#)
- [Kafka](#)
- [Timer](#)

Retry policies aren't supported in version 1.x of the Functions runtime.

The retry policy tells the runtime to rerun a failed execution until either successful completion occurs or the maximum number of retries is reached.

A retry policy is evaluated when a function executed by a supported trigger type raises an uncaught exception. As a best practice, you should catch all exceptions in your code and raise new exceptions for any errors that you want to result in a retry.

Important

Event Hubs checkpoints aren't written until after the retry policy for the execution has completed. Because of this behavior, progress on the specific partition is paused until the current batch is done processing.

The version 5.x of the Event Hubs extension supports additional retry capabilities for interactions between the Functions host and the event hub. For more information, see `clientRetryOptions` in the [Event Hubs host.json reference](#).

Retry strategies

You can configure two retry strategies that are supported by policy:

Fixed delay

A specified amount of time is allowed to elapse between each retry.

When running in a Consumption plan, you are only billed for time your function code is executing. You aren't billed for the wait time between executions in either of these retry strategies.

Max retry counts

You can configure the maximum number of times that a function execution is retried before eventual failure. The current retry count is stored in memory of the instance.

It's possible for an instance to have a failure between retry attempts. When an instance fails during a retry policy, the retry count is lost. When there are instance failures, the Event Hubs trigger is able to resume processing and retry the batch on a new instance, with the retry count reset to zero. The timer trigger doesn't resume on a new instance.

This behavior means that the maximum retry count is a best effort. In some rare cases, an execution could be retried more than the requested maximum number of times. For Timer triggers, the retries can be less than the maximum number requested.

Retry examples

Examples are provided for both fixed delay and exponential backoff strategies. To see examples for a specific strategy, you must first select that strategy in the previous tab.

Isolated worker model

Function-level retries are supported with the following NuGet packages:

- [Microsoft.Azure.Functions.Worker.Sdk](#) >= 1.9.0
- [Microsoft.Azure.Functions.Worker.Extensions.EventHubs](#) >= 5.2.0
- [Microsoft.Azure.Functions.Worker.Extensions.Kafka](#) >= 3.8.0
- [Microsoft.Azure.Functions.Worker.Extensions.Timer](#) >= 4.2.0

C#

```
[Function(nameof(TimerFunction))]
[FixedDelayRetry(5, "00:00:10")]
public static void Run([TimerTrigger("0 */5 * * *")] TimerInfo
timerInfo,
    FunctionContext context)
```

```

{
    var logger = context.GetLogger(nameof(TimerFunction));
    logger.LogInformation($"Function Ran. Next timer schedule =
{timerInfo.ScheduleStatus.Next}");
}

```

[] [Expand table](#)

Property	Description
MaxRetryCount	Required. The maximum number of retries allowed per function execution. -1 means to retry indefinitely.
DelayInterval	The delay used between retries. Specify it as a string with the format <code>HH:mm:ss</code> .

Binding error codes

When you're integrating with Azure services, errors might originate from the APIs of the underlying services. Information that relates to binding-specific errors is available in the "Exceptions and return codes" sections of the following articles:

- [Azure Cosmos DB](#)
- [Blob Storage](#)
- [Event Grid](#)
- [Event Hubs](#)
- [IoT Hub](#)
- [Notification Hubs](#)
- [Queue Storage](#)
- [Service Bus](#)
- [Table Storage](#)

Securing Azure Functions

Article • 07/18/2024

In many ways, planning for secure development, deployment, and operation of serverless functions is much the same as for any web-based or cloud-hosted application. [Azure App Service](#) provides the hosting infrastructure for your function apps. This article provides security strategies for running your function code, and how App Service can help you secure your functions.

The platform components of App Service, including Azure VMs, storage, network connections, web frameworks, management and integration features, are actively secured and hardened. App Service goes through vigorous compliance checks on a continuous basis to make sure that:

- Your app resources are [secured ↗](#) from the other customers' Azure resources.
- [VM instances and runtime software are regularly updated](#) to address newly discovered vulnerabilities.
- Communication of secrets (such as connection strings) between your app and other Azure resources (such as [SQL Database ↗](#)) stays within Azure and doesn't cross any network boundaries. Secrets are always encrypted when stored.
- All communication over the App Service connectivity features, such as [hybrid connection](#), is encrypted.
- Connections with remote management tools like Azure PowerShell, Azure CLI, Azure SDKs, REST APIs, are all encrypted.
- 24-hour threat management protects the infrastructure and platform against malware, distributed denial-of-service (DDoS), man-in-the-middle (MITM), and other threats.

For more information on infrastructure and platform security in Azure, see [Azure Trust Center ↗](#).

For a set of security recommendations that follow the [Microsoft cloud security benchmark](#), see [Azure Security Baseline for Azure Functions](#).

Secure operation

This section guides you on configuring and running your function app as securely as possible.

Defender for Cloud

Defender for Cloud integrates with your function app in the portal. It provides, for free, a quick assessment of potential configuration-related security vulnerabilities. Function apps running in a dedicated plan can also use Defender for Cloud's enhanced security features for an extra cost. To learn more, see [Protect your Azure App Service web apps and APIs](#).

Log and monitor

One way to detect attacks is through activity monitoring and logging analytics. Functions integrates with Application Insights to collect log, performance, and error data for your function app. Application Insights automatically detects performance anomalies and includes powerful analytics tools to help you diagnose issues and to understand how your functions are used. To learn more, see [Monitor Azure Functions](#).

Functions also integrates with Azure Monitor Logs to enable you to consolidate function app logs with system events for easier analysis. You can use diagnostic settings to configure streaming export of platform logs and metrics for your functions to the destination of your choice, such as a Logs Analytics workspace. To learn more, see [Monitoring Azure Functions with Azure Monitor Logs](#).

For enterprise-level threat detection and response automation, stream your logs and events to a Logs Analytics workspace. You can then connect Microsoft Sentinel to this workspace. To learn more, see [What is Microsoft Sentinel](#).

For more security recommendations for observability, see the [Azure security baseline for Azure Functions](#).

Secure HTTP endpoints

HTTP endpoints that are exposed publicly provide a vector of attack for malicious actors. When securing your HTTP endpoints, you should use a layered security approach. These techniques can be used to reduce the vulnerability of publicly exposed HTTP endpoints, ordered from most basic to most secure and restrictive:

- [Require HTTPS](#)
- [Require access keys](#)
- [Enable App Service Authentication/Authorization](#)
- [Use Azure API Management \(APIM\) to authenticate requests](#)
- [Deploy your function app to a virtual network](#)
- [Deploy your function app in isolation](#)

Require HTTPS

By default, clients can connect to function endpoints by using both HTTP or HTTPS. You should redirect HTTP to HTTPS because HTTPS uses the SSL/TLS protocol to provide a secure connection, which is both encrypted and authenticated. To learn how, see [Enforce HTTPS](#).

When you require HTTPS, you should also require the latest TLS version. To learn how, see [Enforce TLS versions](#).

For more information, see [Secure connections \(TLS\)](#).

Function access keys

Functions lets you use keys to make it harder to access your function endpoints. Unless the HTTP access level on an HTTP triggered function is set to `anonymous`, requests must include an access key in the request. For more information, see [Work with access keys in Azure Functions](#).

While access keys can provide some mitigation for unwanted access, the only way to truly secure your function endpoints is by implementing positive authentication of clients accessing your functions. You can then make authorization decisions based on identity.

For the highest level of security, you can also secure the entire application architecture inside a virtual network [using private endpoints](#) or by [running in isolation](#).

Enable App Service Authentication/Authorization

The App Service platform lets you use Microsoft Entra ID and several third-party identity providers to authenticate clients. You can use this strategy to implement custom authorization rules for your functions, and you can work with user information from your function code. To learn more, see [Authentication and authorization in Azure App Service](#) and [Working with client identities](#).

Use Azure API Management (APIM) to authenticate requests

APIM provides various API security options for incoming requests. To learn more, see [API Management authentication policies](#). With APIM in place, you can configure your function app to accept requests only from the IP address of your APIM instance. To learn more, see [IP address restrictions](#).

Permissions

As with any application or service, the goal is run your function app with the lowest possible permissions.

User management permissions

Functions supports built-in Azure role-based access control ([Azure RBAC](#)). Azure roles supported by Functions are [Contributor](#), [Owner](#), and [Reader](#).

Permissions are effective at the function app level. The Contributor role is required to perform most function app-level tasks. You also need the Contributor role along with the [Monitoring Reader permission](#) to be able to view log data in Application Insights. Only the Owner role can delete a function app.

Organize functions by privilege

Connection strings and other credentials stored in application settings gives all of the functions in the function app the same set of permissions in the associated resource. Consider minimizing the number of functions with access to specific credentials by moving functions that don't use those credentials to a separate function app. You can always use techniques such as [function chaining](#) to pass data between functions in different function apps.

Managed identities

A managed identity from Microsoft Entra ID allows your app to easily access other Microsoft Entra protected resources such as Azure Key Vault. The identity is managed by the Azure platform and does not require you to provision or rotate any secrets. For more about managed identities in Microsoft Entra ID, see [Managed identities for Azure resources](#).

Your application can be granted two types of identities:

- A **system-assigned identity** is tied to the app and is deleted if the app is deleted. An app can only have one system-assigned identity.
- A **user-assigned identity** is a standalone Azure resource that can be assigned to your app. An app can have multiple user-assigned identities, and one user-assigned identity can be assigned to multiple Azure resources, such as two App Service apps.

Managed identities can be used in place of secrets for connections from some triggers and bindings. See [Identity-based connections](#).

For more information, see [How to use managed identities for App Service and Azure Functions](#).

Restrict CORS access

[Cross-origin resource sharing \(CORS\)](#) is a way to allow web apps running in another domain to make requests to your HTTP trigger endpoints. App Service provides built-in support for handing the required CORS headers in HTTP requests. CORS rules are defined on a function app level.

While it's tempting to use a wildcard that allows all sites to access your endpoint, this defeats the purpose of CORS, which is to help prevent cross-site scripting attacks. Instead, add a separate CORS entry for the domain of each web app that must access your endpoint.

Managing secrets

To be able to connect to the various services and resources need to run your code, function apps need to be able to access secrets, such as connection strings and service keys. This section describes how to store secrets required by your functions.

Never store secrets in your function code.

Application settings

By default, you store connection strings and secrets used by your function app and bindings as application settings. This makes these credentials available to both your function code and the various bindings used by the function. The application setting (key) name is used to retrieve the actual value, which is the secret.

For example, every function app requires an associated storage account, which is used by the runtime. By default, the connection to this storage account is stored in an application setting named `AzureWebJobsStorage`.

App settings and connection strings are stored encrypted in Azure. They're decrypted only before being injected into your app's process memory when the app starts. The encryption keys are rotated regularly. If you prefer to instead manage the secure storage of your secrets, the app setting should instead be references to Azure Key Vault.

You can also encrypt settings by default in the local.settings.json file when developing functions on your local computer. For more information, see [Encrypt the local settings file](#).

Key Vault references

While application settings are sufficient for most many functions, you may want to share the same secrets across multiple services. In this case, redundant storage of secrets results in more potential vulnerabilities. A more secure approach is to a central secret storage service and use references to this service instead of the secrets themselves.

[Azure Key Vault](#) is a service that provides centralized secrets management, with full control over access policies and audit history. You can use a Key Vault reference in the place of a connection string or key in your application settings. To learn more, see [Use Key Vault references for App Service and Azure Functions](#).

Identity-based connections

Identities may be used in place of secrets for connecting to some resources. This has the advantage of not requiring the management of a secret, and it provides more fine-grained access control and auditing.

When you're writing code that creates the connection to [Azure services that support Microsoft Entra authentication](#), you can choose to use an identity instead of a secret or connection string. Details for both connection methods are covered in the documentation for each service.

Some Azure Functions binding extensions can be configured to access services using identity-based connections. For more information, see [Configure an identity-based connection](#).

Set usage quotas

Consider setting a usage quota on functions running in a Consumption plan. When you set a daily GB-sec limit on the sum total execution of functions in your function app, execution is stopped when the limit is reached. This could potentially help mitigate against malicious code executing your functions. To learn how to estimate consumption for your functions, see [Estimating Consumption plan costs](#).

Data validation

The triggers and bindings used by your functions don't provide any additional data validation. Your code must validate any data received from a trigger or input binding. If an upstream service is compromised, you don't want unvalidated inputs flowing through your functions. For example, if your function stores data from an Azure Storage queue in a relational database, you must validate the data and parameterize your commands to avoid SQL injection attacks.

Don't assume that the data coming into your function has already been validated or sanitized. It's also a good idea to verify that the data being written to output bindings is valid.

Handle errors

While it seems basic, it's important to write good error handling in your functions. Unhandled errors bubble-up to the host and are handled by the runtime. Different bindings handle processing of errors differently. To learn more, see [Azure Functions error handling](#).

Disable remote debugging

Make sure that remote debugging is disabled, except when you are actively debugging your functions. You can disable remote debugging in the **General Settings** tab of your function app **Configuration** in the portal.

Restrict CORS access

Azure Functions supports cross-origin resource sharing (CORS). CORS is configured [in the portal](#) and through the [Azure CLI](#). The CORS allowed origins list applies at the function app level. With CORS enabled, responses include the `Access-Control-Allow-Origin` header. For more information, see [Cross-origin resource sharing](#).

Don't use wildcards in your allowed origins list. Instead, list the specific domains from which you expect to get requests.

Store data encrypted

Azure Storage encrypts all data in a storage account at rest. For more information, see [Azure Storage encryption for data at rest](#).

By default, data is encrypted with Microsoft-managed keys. For additional control over encryption keys, you can supply customer-managed keys to use for encryption of blob

and file data. These keys must be present in Azure Key Vault for Functions to be able to access the storage account. To learn more, see [Encryption at rest using customer-managed keys](#).

Secure related resources

A function app frequently depends on additional resources, so part of securing the app is securing these external resources. At a minimum, most function apps include a dependency on Application Insights and Azure Storage. Consult the [Azure security baseline for Azure Monitor](#) and the [Azure security baseline for Storage](#) for guidance on securing these resources.

Important

The storage account is used to store important app data, sometimes including the application code itself. You should limit access from other apps and users to the storage account.

You should also consult the guidance for any resource types your application logic depends on, both as triggers and bindings and from your function code.

Secure deployment

Azure Functions tooling and integration make it easy to publish local function project code to Azure. It's important to understand how deployment works when considering security for an Azure Functions topology.

Deployment credentials

App Service deployments require a set of deployment credentials. These deployment credentials are used to secure your function app deployments. Deployment credentials are managed by the App Service platform and are encrypted at rest.

There are two kinds of deployment credentials:

- **User-level credentials:** one set of credentials for the entire Azure account. It can be used to deploy to App Service for any app, in any subscription, that the Azure account has permission to access. It's the default set that's surfaced in the portal GUI (such as the [Overview](#) and [Properties](#) of the app's [resource page](#)). When a user is granted app access via Role-Based Access Control (RBAC) or coadmin

permissions, that user can use their own user-level credentials until the access is revoked. Do not share these credentials with other Azure users.

- **App-level credentials:** one set of credentials for each app. It can be used to deploy to that app only. The credentials for each app are generated automatically at app creation. They can't be configured manually, but can be reset anytime. For a user to be granted access to app-level credentials via (RBAC), that user must be contributor or higher on the app (including Website Contributor built-in role). Readers are not allowed to publish, and can't access those credentials.

At this time, Key Vault isn't supported for deployment credentials. To learn more about managing deployment credentials, see [Configure deployment credentials for Azure App Service](#).

Disable FTP

By default, each function app has an FTP endpoint enabled. The FTP endpoint is accessed using deployment credentials.

FTP isn't recommended for deploying your function code. FTP deployments are manual, and they require you to synchronize triggers. To learn more, see [FTP deployment](#).

When you're not planning on using FTP, you should disable it in the portal. If you do choose to use FTP, you should [enforce FTPS](#).

Secure the scm endpoint

Every function app has a corresponding `scm` service endpoint that is used by the Advanced Tools (Kudu) service for deployments and other App Service [site extensions](#). The scm endpoint for a function app is always a URL in the form `https://<FUNCTION_APP_NAME>.scm.azurewebsites.net`. When you use network isolation to secure your functions, you must also account for this endpoint.

By having a separate scm endpoint, you can control deployments and other advanced tools functionalities for function app that are isolated or running in a virtual network. The scm endpoint supports both basic authentication (using deployment credentials) and single sign-on with your Azure portal credentials. To learn more, see [Accessing the Kudu service](#).

Continuous security validation

Since security needs to be considered at every step in the development process, it makes sense to also implement security validations in a continuous deployment environment. This is sometimes called DevSecOps. Using Azure DevOps for your deployment pipeline lets you integrate validation into the deployment process. For more information, see [Learn how to add continuous security validation to your CI/CD pipeline](#).

Network security

Restricting network access to your function app lets you control who can access your functions endpoints. Functions leverages App Service infrastructure to enable your functions to access resources without using internet-routable addresses or to restrict internet access to a function endpoint. To learn more about these networking options, see [Azure Functions networking options](#).

Set access restrictions

Access restrictions allow you to define lists of allow/deny rules to control traffic to your app. Rules are evaluated in priority order. If there are no rules defined, then your app will accept traffic from any address. To learn more, see [Azure App Service Access Restrictions](#).

Secure the storage account

When you create a function app, you must create or link to a general-purpose Azure Storage account that supports Blob, Queue, and Table storage. You can replace this storage account with one that is secured by a virtual network with access enabled by service endpoints or private endpoints. For more information, see [Restrict your storage account to a virtual network](#).

Deploy your function app to a virtual network

[Azure Private Endpoint](#) is a network interface that connects you privately and securely to a service powered by Azure Private Link. Private Endpoint uses a private IP address from your virtual network, effectively bringing the service into your virtual network.

You can use Private Endpoint for your functions hosted in the [Premium](#) and [App Service](#) plans.

If you want to make calls to Private Endpoints, then you must make sure that your DNS lookups resolve to the private endpoint. You can enforce this behavior in one of the

following ways:

- Integrate with Azure DNS private zones. When your virtual network doesn't have a custom DNS server, this is done automatically.
- Manage the private endpoint in the DNS server used by your app. To do this you must know the private endpoint address and then point the endpoint you are trying to reach to that address using an A record.
- Configure your own DNS server to forward to [Azure DNS private zones](#).

To learn more, see [using Private Endpoints for Web Apps](#).

Deploy your function app in isolation

Azure App Service Environment provides a dedicated hosting environment in which to run your functions. These environments let you configure a single front-end gateway that you can use to authenticate all incoming requests. For more information, see [Configuring a Web Application Firewall \(WAF\) for App Service Environment](#).

Use a gateway service

Gateway services, such as [Azure Application Gateway](#) and [Azure Front Door](#) let you set up a Web Application Firewall (WAF). WAF rules are used to monitor or block detected attacks, which provide an extra layer of protection for your functions. To set up a WAF, your function app needs to be running in an ASE or using Private Endpoints (preview). To learn more, see [Using Private Endpoints](#).

Azure Functions runtime versions overview

Article • 05/13/2024

Azure Functions currently supports two versions of the runtime host. The following table details the currently supported runtime versions, their support level, and when they should be used:

[+] Expand table

Version	Support level	Description
4.x	GA	<p>Recommended runtime version for functions in all languages.</p> <p>Check out Supported language versions.</p>
1.x	GA (support ends September 14, 2026 ↗)	Supported only for C# apps that must use .NET Framework. This version is in maintenance mode, with enhancements provided only in later versions. Support will end for version 1.x on September 14, 2026. We highly recommend you migrate your apps to version 4.x , which supports .NET Framework 4.8, .NET 6, .NET 7, and .NET 8.

ⓘ Important

As of December 13, 2022, function apps running on versions 2.x and 3.x of the Azure Functions runtime have reached the end of extended support. For more information, see [Retired versions](#).

This article details some of the differences between supported versions, how you can create each version, and how to change the version on which your functions run.

Levels of support

There are two levels of support:

- **Generally available (GA)** - Fully supported and approved for production use.
- **Preview** - Not yet supported, but expected to reach GA status in the future.

Languages

All functions in a function app must share the same language. You choose the language of functions in your function app when you create the app. The language of your function app is maintained in the [FUNCTIONS_WORKER_RUNTIME](#) setting, and can't be changed when there are existing functions.

The following table shows the .NET versions supported by Azure Functions. Select your preferred development language at the top of the article.

The supported version of .NET depends on both your Functions runtime version and your chosen execution model:

Isolated worker model		
Your function code runs in a separate .NET worker process. Use with supported versions of .NET and .NET Framework . To learn more, see Develop .NET isolated worker process functions .		
v4.x		
Expand table		
Supported version	Support level	Expected community EOL date
.NET 8	GA	November 10, 2026 ↗
.NET 6	GA	November 12, 2024 ↗
.NET Framework 4.8	GA	See policy ↗

.NET 7 was previously supported on the isolated worker model but reached the end of official support on [May 14, 2024 ↗](#).

For more information, see [Guide for running C# Azure Functions in an isolated worker process](#).

For information about planned changes to language support, see [Azure roadmap ↗](#).

For information about the language versions of previously supported versions of the Functions runtime, see [Retired runtime versions](#).

Run on a specific version

The version of the Functions runtime used by published apps in Azure is dictated by the [FUNCTIONS_EXTENSION_VERSION](#) application setting. In some cases and for certain languages, other settings can apply.

By default, function apps created in the Azure portal, by the Azure CLI, or from Visual Studio tools are set to version 4.x. You can modify this version if needed. You can only downgrade the runtime version to 1.x after you create your function app but before you add any functions. Updating to a later major version is allowed even with apps that have existing functions.

Migrating existing function apps

When your app has existing functions, you must take precautions before moving to a later major runtime version. The following articles detail breaking changes between major versions, including language-specific breaking changes. They also provide you with step-by-step instructions for a successful migration of your existing function app.

- [Migrate from runtime version 3.x to version 4.x](#)
- [Migrate from runtime version 1.x to version 4.x](#)

Changing version of apps in Azure

The following major runtime version values are used:

[\[+\] Expand table](#)

Value	Runtime target
~4	4.x
~1	1.x

Important

Don't arbitrarily change this app setting, because other app setting changes and changes to your function code might be required. For existing function apps, [follow the migration instructions](#).

Pinning to a specific minor version

To resolve issues your function app could have when running on the latest major version, you have to temporarily pin your app to a specific minor version. Pinning gives you time to get your app running correctly on the latest major version. The way that you pin to a minor version differs between Windows and Linux. To learn more, see [How to target Azure Functions runtime versions](#).

Older minor versions are periodically removed from Functions. For the latest news about Azure Functions releases, including the removal of specific older minor versions, monitor [Azure App Service announcements](#).

Minimum extension versions

There's technically not a correlation between binding extension versions and the Functions runtime version. However, starting with version 4.x the Functions runtime enforces a minimum version for all trigger and binding extensions.

If you receive a warning about a package not meeting a minimum required version, you should update that NuGet package to the minimum version as you normally would. The minimum version requirements for extensions used in Functions v4.x can be found in [the linked configuration file](#).

For C# script, update the extension bundle reference in the host.json as follows:

JSON

```
{  
    "version": "2.0",  
    "extensionBundle": {  
        "id": "Microsoft.Azure.Functions.ExtensionBundle",  
        "version": "[4.0.0, 5.0.0)"  
    }  
}
```

Retired versions

 **Important**

[Support will end for version 1.x of the Azure Functions runtime on September 14, 2026](#). We highly recommend that you [migrate your apps to version 4.x](#) for full support.

These versions of the Functions runtime reached the end of extended support on December 13, 2022.

[Expand table](#)

Version	Current support level	Previous support level
3.x	Out-of-support	GA
2.x	Out-of-support	GA

As soon as possible, you should migrate your apps to version 4.x to obtain full support. For a complete set of language-specific migration instructions, see [Migrate apps to Azure Functions version 4.x](#).

Apps using versions 2.x and 3.x can still be created and deployed from your CI/CD DevOps pipeline, and all existing apps continue to run without breaking changes. However, your apps aren't eligible for new features, security patches, and performance optimizations. You can only get related service support after you upgrade your apps to version 4.x.

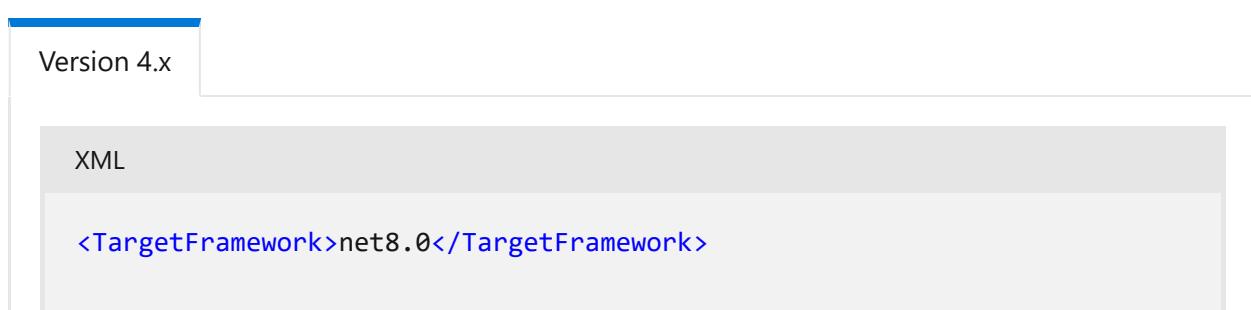

End of support for versions 2.x and 3.x is due to the end of support for .NET Core 3.1, which they had as a core dependency. This requirement affects all [languages supported by Azure Functions](#).

Locally developed application versions

You can make the following updates to function apps to locally change the targeted versions.

Visual Studio runtime versions

In Visual Studio, you select the runtime version when you create a project. Azure Functions tools for Visual Studio supports the two major runtime versions. The correct version is used when debugging and publishing based on project settings. The version settings are defined in the `.csproj` file in the following properties:

You can choose `net8.0`, `net6.0`, or `net48` as the target framework if you are using the [isolated worker model](#). If you are using the [in-process model](#), you can only choose `net6.0`, and you must include the `Microsoft.NET.Sdk.Functions` extension set to at least `4.0.0`.

.NET 7 was previously supported on the isolated worker model but reached the end of official support on [May 14, 2024](#).

Visual Studio Code and Azure Functions Core Tools

Azure Functions Core Tools is used for command-line development and also by the [Azure Functions extension](#) for Visual Studio Code. For more information, see [Install the Azure Functions Core Tools](#).

For Visual Studio Code development, you could also need to update the user setting for the `azureFunctions.projectRuntime` to match the version of the tools installed. This setting also updates the templates and languages used during function app creation.

Bindings

Starting with version 2.x, the runtime uses a new [binding extensibility model](#) that offers these advantages:

- Support for third-party binding extensions.
- Decoupling of runtime and bindings. This change allows binding extensions to be versioned and released independently. You can, for example, opt to upgrade to a version of an extension that relies on a newer version of an underlying SDK.
- A lighter execution environment, where only the bindings in use are known and loaded by the runtime.

Except for HTTP and timer triggers, all bindings must be explicitly added to the function app project, or registered in the portal. For more information, see [Register binding extensions](#).

The following table shows which bindings are supported in each runtime version.

This table shows the bindings that are supported in the major versions of the Azure Functions runtime:

[\[\]](#) Expand table

Type	1.x ¹	2.x and higher ²	Trigger	Input	Output
Blob storage	✓	✓	✓	✓	✓
Azure Cosmos DB	✓	✓	✓	✓	✓
Azure Data Explorer		✓		✓	✓
Azure SQL		✓	✓	✓	✓
Dapr ⁴		✓	✓	✓	✓
Event Grid	✓	✓	✓		✓
Event Hubs	✓	✓	✓		✓
HTTP & webhooks	✓	✓	✓		✓
IoT Hub	✓	✓	✓		
Kafka ³		✓	✓		✓
Mobile Apps	✓			✓	✓
Notification Hubs	✓				✓
Queue storage	✓	✓	✓		✓
Redis		✓	✓		
RabbitMQ ³		✓	✓		✓
SendGrid	✓	✓			✓
Service Bus	✓	✓	✓		✓
SignalR		✓	✓	✓	✓
Table storage	✓	✓		✓	✓
Timer	✓	✓	✓		
Twilio	✓	✓			✓

¹ Support will end for version 1.x of the Azure Functions runtime on September 14, 2026 [↗](#). We highly recommend that you [migrate your apps to version 4.x](#) for full support.

² Starting with the version 2.x runtime, all bindings except HTTP and Timer must be registered. See [Register binding extensions](#).

³ Triggers aren't supported in the Consumption plan. Requires [runtime-driven triggers](#).

⁴ Supported only in Kubernetes, IoT Edge, and other self-hosted modes only.

Function app timeout duration

The timeout duration for functions in a function app is defined by the `functionTimeout` property in the [host.json](#) project file. This property applies specifically to function executions. After the trigger starts function execution, the function needs to return/respond within the timeout duration. For more information, see [Improve Azure Functions performance and reliability](#).

The following table shows the default and maximum values (in minutes) for specific plans:

[+] [Expand table](#)

Plan	Default	Maximum ¹
Consumption plan	5	10
Flex Consumption plan	30	Unlimited ³
Premium plan	30 ²	Unlimited ³
Dedicated plan	30 ²	Unlimited ³

¹ Regardless of the function app timeout setting, 230 seconds is the maximum amount of time that an HTTP triggered function can take to respond to a request. This is because of the [default idle timeout of Azure Load Balancer](#). For longer processing times, consider using the [Durable Functions](#) async pattern or [defer the actual work and return an immediate response](#).

² The default timeout for version 1.x of the Functions runtime is *unlimited*.

³ Guaranteed for up to 60 minutes. [OS and runtime patching](#), vulnerability patching, and [scale in behaviors](#) can still cancel function executions so [ensure to write robust functions](#). ⁴ In a Flex Consumption plan, the host doesn't enforce an execution time limit. However, there are currently no guarantees because the platform might need to terminate your instances during scale-in, deployments, or to apply updates.

Next steps

For more information, see the following resources:

- [Code and test Azure Functions locally](#)
- [How to target Azure Functions runtime versions](#)
- [Release notes ↗](#)

Azure Functions Consumption plan hosting

Article • 05/21/2024

When you're using the Consumption plan, instances of the Azure Functions host are dynamically added and removed based on the number of incoming events. The Consumption plan, along with the [Flex Consumption plan](#), is a fully *serverless* hosting option for Azure Functions.

Benefits

The Consumption plan scales automatically, even during periods of high load. When running functions in a Consumption plan, you're charged for compute resources only when your functions are running. On a Consumption plan, a function execution times out after a configurable period of time.

For a comparison of the Consumption plan against the other plan and hosting types, see [function scale and hosting options](#).

💡 Tip

If you want the benefits of dynamic scale and execution-only billing, but also need to integrate your app with virtual networks, you should instead consider hosting your app in the [Flex Consumption plan](#).

Billing

Billing is based on number of executions, execution time, and memory used. Usage is aggregated across all functions within a function app. For more information, see the [Azure Functions pricing page](#).

To learn more about how to estimate costs when running in a Consumption plan, see [Understanding Consumption plan costs](#).

Create a Consumption plan function app

When you create a function app in the Azure portal, the Consumption plan is the default. When using APIs to create your function app, you don't have to first create an

App Service plan as you do with Premium and Dedicated plans.

In Consumption plan hosting, each function app typically runs in its own plan. In the Azure portal or in code, you may also see the Consumption plan referred to as `Dynamic` or `Y1`.

Use the following links to learn how to create a serverless function app in a Consumption plan, either programmatically or in the Azure portal:

- [Azure CLI](#)
- [Azure portal](#)
- [Azure Resource Manager template](#)

You can also create function apps in a Consumption plan when you publish a Functions project from [Visual Studio Code](#) or [Visual Studio](#).

Multiple apps in the same plan

The general recommendation is for each function app to have its own Consumption plan. However, if needed, function apps in the same region can be assigned to the same Consumption plan. Keep in mind that there is a [limit to the number of function apps that can run in a Consumption plan](#). Function apps in the same plan still scale independently of each other.

Azure Functions Flex Consumption plan hosting

Article • 10/17/2024

Flex Consumption is a Linux-based Azure Functions hosting plan that builds on the Consumption *pay for what you use* serverless billing model. It gives you more flexibility and customizability by introducing private networking, instance memory size selection, and fast/large scale-out features still based on a *serverless* model.

Important

The Flex Consumption plan is currently in preview. For a list of current limitations when using this hosting plan, see [Considerations](#). For current information about billing during the preview, see [Billing](#).

You can review end-to-end samples that feature the Flex Consumption plan in the [Flex Consumption plan samples repository](#).

Benefits

The Flex Consumption plan builds on the strengths of the Consumption plan, which include dynamic scaling and execution-based billing. With Flex Consumption, you also get these extra features:

- [Always-ready instances](#)
- [Virtual network integration](#)
- Fast scaling based on concurrency for both HTTP and non-HTTP apps
- Multiple choices for instance memory sizes

This table helps you directly compare the features of Flex Consumption with the Consumption hosting plan:

 Expand table

Feature	Consumption	Flex Consumption
Scale to zero	 Yes	 Yes
Scale behavior	Event driven	Event driven (fast)
Virtual networks	 Not supported	 Supported

Feature	Consumption	Flex Consumption
Dedicated compute (mitigate cold starts)	✖ None	<input checked="" type="checkbox"/> Always ready instances (optional)
Billing	Execution-time only	Execution-time + always-ready instances
Scale-out instances (max)	200	1000

For a complete comparison of the Flex Consumption plan against the Consumption plan and all other plan and hosting types, see [function scale and hosting options](#).

Virtual network integration

Flex Consumption expands on the traditional benefits of Consumption plan by adding support for [virtual network integration](#). When your apps run in a Flex Consumption plan, they can connect to other Azure services secured inside a virtual network. All while still allowing you to take advantage of serverless billing and scale, together with the scale and throughput benefits of the Flex Consumption plan. For more information, see [Enable virtual network integration](#).

Instance memory

When you create your function app in a Flex Consumption plan, you can select the memory size of the instances on which your app runs. See [Billing](#) to learn how instance memory sizes affect the costs of your function app.

Currently, Flex Consumption offers instance memory size options of both 2,048 MB and 4,096 MB.

When deciding on which instance memory size to use with your apps, here are some things to consider:

- The 2,048-MB instance memory size is the default and should be used for most scenarios. Use the 4,096-MB instance memory size for scenarios where your app requires more concurrency or higher processing power. For more information, see [Configure instance memory](#).
- You can change the instance memory size at any time. For more information, see [Configure instance memory](#).
- Instance resources are shared between your function code and the Functions host.
- The larger the instance memory size, the more each instance can handle as far as concurrent executions or more intensive CPU or memory workloads. Specific scale

decisions are workload-specific.

- The default concurrency of HTTP triggers depends on the instance memory size. For more information, see [HTTP trigger concurrency](#).
- Available CPUs and network bandwidth are provided proportional to a specific instance size.

Per-function scaling

Concurrency is a key factor that determines how Flex Consumption function apps scale. To improve the scale performance of apps with various trigger types, the Flex Consumption plan provides a more deterministic way of scaling your app on a per-function basis.

This *per-function scaling* behavior is a part of the hosting platform, so you don't need to configure your app or change the code. For more information, see [Per-function scaling](#) in the Event-driven scaling article.

In per-function scaling, decisions are made for certain function triggers based on group aggregations. This table shows the defined set of function scale groups:

[+] [Expand table](#)

Scale groups	Triggers in group	Settings value
HTTP triggers	HTTP trigger SignalR trigger	<code>http</code>
Blob storage triggers (Event Grid-based)	Blob storage trigger	<code>blob</code>
Durable Functions	Orchestration trigger Activity trigger Entity trigger	<code>durable</code>

All other functions in the app are scaled individually in their own set of instances, which are referenced using the convention `function:<NAMED_FUNCTION>`.

Always ready instances

Flex Consumption includes an *always ready* feature that lets you choose instances that are always running and assigned to each of your per-function scale groups or functions. This is a great option for scenarios where you need to have a minimum number of

instances always ready to handle requests, for example, to reduce your application's cold start latency. The default is 0 (zero).

For example, if you set always ready to 2 for your HTTP group of functions, the platform keeps two instances always running and assigned to your app for your HTTP functions in the app. Those instances are processing your function executions, but depending on concurrency settings, the platform scales beyond those two instances with on-demand instances.

To learn how to configure always ready instances, see [Set always ready instance counts](#).

Concurrency

Concurrency refers to the number of parallel executions of a function on an instance of your app. You can set a maximum number of concurrent executions that each instance should handle at any given time. For more information, see [HTTP trigger concurrency](#).

Concurrency has a direct effect on how your app scales because at lower concurrency levels, you need more instances to handle the event-driven demand for a function. While you can control and fine tune the concurrency, we provide defaults that work for most cases. To learn how to set concurrency limits for HTTP trigger functions, see [Set HTTP concurrency limits](#).

Deployment

Deployments in the Flex Consumption plan follow a single path. After your project code is built and zipped into an application package, it is deployed to a blob storage container. On startup, your app gets the package and runs your function code from this package. By default, the same storage account used to store internal host metadata (AzureWebJobsStorage) is also used as the deployment container. However, you can use an alternative storage account or choose your preferred authentication method by [configuring your app's deployment settings](#). In streamlining the deployment path, there's no longer the need for app settings to influence deployment behavior.

Billing

There are two modes by which your costs are determined when running your apps in the Flex Consumption plan. Each mode is determined on a per-instance basis.

Billing mode	Description
On Demand	<p>When running in <i>on demand</i> mode, you are billed only for the amount of time your function code is executing on your available instances. In on demand mode, no minimum instance count is required. You're billed for:</p> <ul style="list-style-type: none"> The total amount of memory provisioned while each on demand instance is <i>actively</i> executing functions (in GB-seconds), minus a free grant of GB-s per month. The total number of executions, minus a free grant (number) of executions per month.
Always ready	<p>You can configure one or more instances, assigned to specific trigger types (HTTP/Durable/Blob) and individual functions, that are always available to be able handle requests. When you have any always ready instances enabled, you're billed for:</p> <ul style="list-style-type: none"> The total amount of memory provisioned across all of your always ready instances, known as the <i>baseline</i> (in GB-seconds). The total amount of memory provisioned during the time each always ready instance is <i>actively</i> executing functions (in GB-seconds). The total number of executions. <p>In always ready billing, there are no free grants.</p>

The minimum billable execution period for both execution modes is 1,000 ms. Past that, the billable activity period is rounded up to the nearest 100 ms. You can find details on the Flex Consumption plan billing meters in the [Monitoring reference](#).

For details about how costs are calculated when you run in a Flex Consumption plan, including examples, see [Consumption-based costs](#).

For the most up-to-date information on execution pricing, always ready baseline costs, and free grants for on demand executions, see the [Azure Functions pricing page](#).

Supported language stack versions

This table shows the language stack versions that are currently supported for Flex Consumption apps:

[Expand table](#)

Language stack	Required version
C# (isolated process mode) ¹	.NET 8 ²

Language stack	Required version
Java	Java 11, Java 17
Node.js	Node 20
PowerShell	PowerShell 7.4
Python	Python 3.10, Python 3.11

¹[C# in-process mode](#) isn't supported. You instead need to [migrate your .NET code project to run in the isolated worker model](#).

²Requires version [1.20.0](#) or later of [Microsoft.Azure.Functions.Worker](#) and version [1.16.2](#) or later of [Microsoft.Azure.Functions.Worker.Sdk](#).

Regional subscription memory quotas

Currently in preview each region in a given subscription has a memory limit of [512,000 MB](#) for all instances of apps running on Flex Consumption plans. This means that, in a given subscription and region, you could have any combination of instance memory sizes and counts, as long as they stay under the quota limit. For example, each the following examples would mean the quota has been reached and the apps would stop scaling:

- You have one 2,048 MB app scaled to 100 and a second 2,048 MB app scaled to 150 instances
- You have one 2,048 MB app that scaled out to 250 instances
- You have one 4,096 MB app that scaled out to 125 instances
- You have one 4,096 MB app scaled to 100 and one 2,048 MB app scaled to 50 instances

This quota can be increased to allow your Flex Consumption apps to scale further, depending on your requirements. If your apps require a larger quota please create a support ticket.

Deprecated properties and settings

In Flex Consumption, many of the standard application settings and site configuration properties used in Bicep, ARM templates, and overall control plane are deprecated or have moved and shouldn't be used when automating function app resource creation. For more information, see [Flex Consumption plan deprecations](#).

Considerations

Keep these other considerations in mind when using Flex Consumption plan during the current preview:

- **Host:** There is a 30 seconds timeout for the app initialization. If your function app takes longer than 30 seconds to start you will see gRPC related System.TimeoutException entries. This timeout will be configurable and a more clear exception will be implemented as part of [this host work item](#).
- **Durable Functions:** Due to the per function scaling nature of Flex Consumption, to ensure the best performance for Durable Functions we recommend setting the [Always Ready instance count](#) for the `durable` group to `1`. Also, with the Azure Storage provider, consider reducing the [queue polling interval](#) to 10 seconds or less. Only Azure Storage is supported as a backend storage providers for Flex Consumption hosted durable functions.
- **VNet Integration** Ensure that the `Microsoft.App` Azure resource provider is enabled for your subscription by [following these instructions](#). The subnet delegation required by Flex Consumption apps is `Microsoft.App/environments`.
- **Triggers:** All triggers are fully supported except for Kafka and Azure SQL triggers. The Blob storage trigger only supports the [Event Grid source](#). Non-C# function apps must use version `[4.0.0, 5.0.0)` of the [extension bundle](#), or a later version.
- **Regions:** Not all regions are currently supported. To learn more, see [View currently supported regions](#).
- **Deployments:** Deployment slots are not currently supported.
- **Scale:** The lowest maximum scale in preview is `40`. The highest currently supported value is `1000`.
- **Managed dependencies:** [Managed dependencies in PowerShell](#) aren't supported by Flex Consumption. You must instead [define your own custom modules](#).
- **Diagnostic settings:** Diagnostic settings are not currently supported.
- **Certificates:** Loading certificates with the WEBSITE_LOAD_CERTIFICATES app setting is currently not supported.
- **Key Vault References:** Key Vault references in app settings do not work when Key Vault is network access restricted, even if the function app has Virtual Network integration. The current workaround is to directly reference the Key Vault in code and read the required secrets.

Azure Functions Premium plan

Article • 04/07/2024

The Azure Functions Elastic Premium plan is a dynamic scale hosting option for function apps. For other hosting plan options, see the [hosting plan article](#).

Important

Azure Functions can run on the Azure App Service platform. In the App Service platform, plans that host Premium plan function apps are referred to as *Elastic* Premium plans, with SKU names like `EP1`. If you choose to run your function app on a Premium plan, make sure to create a plan with an SKU name that starts with "E", such as `EP1`. App Service plan SKU names that start with "P", such as `P1V2` (Premium V2 Small plan), are actually [Dedicated hosting plans](#). Because they are Dedicated and not Elastic Premium, plans with SKU names starting with "P" won't scale dynamically and may increase your costs.

Premium plan hosting provides the following benefits to your functions:

- Avoid cold starts with warm instances.
- Virtual network connectivity.
- Supports [longer runtime durations](#).
- [Choice of Premium instance sizes](#).
- More predictable pricing, compared with the Consumption plan.
- High-density app allocation for plans with multiple function apps.
- Supports [Linux container deployments](#).

When you're using the Premium plan, instances of the Azure Functions host are added and removed based on the number of incoming events, just like the [Consumption plan](#). Multiple function apps can be deployed to the same Premium plan, and the plan allows you to configure compute instance size, base plan size, and maximum plan size.

Billing

Billing for the Premium plan is based on the number of core seconds and memory allocated across instances. This billing differs from the Consumption plan, which is billed based on per-second resource consumption and executions. There's no execution charge with the Premium plan. This billing results in a minimum monthly cost per active plan, regardless if the function is active or idle. Keep in mind that all function apps in a

Premium plan share allocated instances. To learn more, see the [Azure Functions pricing page](#).

 **Note**

Every premium plan has at least one active (billed) instance at all times.

Create a Premium plan

When you create a function app in the Azure portal, the Consumption plan is the default. To create a function app that runs in a Premium plan, you must explicitly create or choose an Azure Functions Premium hosting plan using one of the *Elastic Premium* SKUs. The function app you create is then hosted in this plan. The Azure portal makes it easy to create both the Premium plan and the function app at the same time. You can run more than one function app in the same Premium plan, but they must both run on the same operating system (Windows or Linux).

The following articles show you how to programmatically create a function app with a Premium plan:

- [Azure CLI](#)
- [Azure Resource Manager template](#)

Eliminate cold starts

When events or executions don't occur in the Consumption plan, your app might scale to zero instances. When new events come in, a new instance with your app running on it must be specialized. Specializing new instances takes time, depending on the app. This extra latency on the first call is often called app *cold start*.

Premium plan provides two features that work together to effectively eliminate cold starts in your functions: *always ready instances* and *prewarmed instances*. Always ready instances are a category of preallocated instances unaffected by scaling, and the prewarmed ones are a buffer as you scale due to HTTP events.

When events begin to trigger the app, they're first routed to the always ready instances. As the function becomes active due to HTTP events, other instances are warmed as a buffer. These buffered instances are called prewarmed instances. This buffer reduces cold start for new instances required during scale.

Always ready instances

In the Premium plan, you can have your app always ready on a specified number of instances. Your app runs continuously on those instances, regardless of load. If load exceeds what your always ready instances can handle, more instances are added as necessary, up to your specified maximum.

This app-level setting also controls your plan's minimum instances. For example, consider having three function apps in the same Premium plan. When two of your apps have always ready instance count set to one and in a third instance it's set to five, the minimum number for your whole plan is five. This also reflects the minimum number of instances for which your plan is billed. The maximum number of always ready instances we support per app is 20.

Portal

You can configure the number of always ready instances in the Azure portal by selected your **Function App**, going to the **Platform Features** tab, and selecting the **Scale Out** options. In the function app edit window, always ready instances are specific to that app.

The screenshot shows the 'Elastic Scale out' section of the Azure portal. It includes a note about controlling scale bounds, a 'Plan Scale out' section with 'Maximum Burst' set to 20 and 'Minimum Instances' set to 1, and an 'App Scale out' section with 'Always Ready Instances' set to 2 and 'Enforce Scale Out Limit' set to 'No'. A tooltip for minimum instances explains that explicitly configuring instances is recommended for advanced scenarios.

App Scale out

Always Ready Instances [?](#) 2

Enforce Scale Out Limit [?](#) No Yes

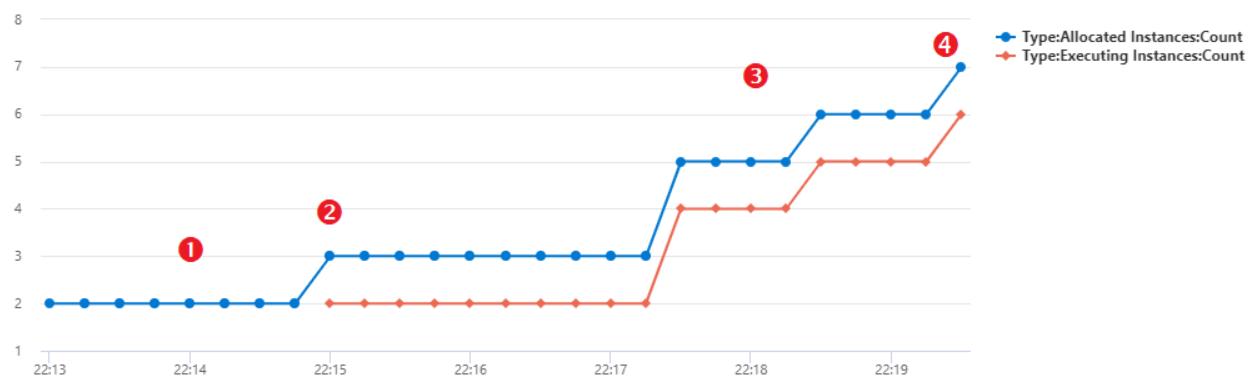

Prewarmed instances

The prewarmed instance count setting provides warmed instances as a buffer during HTTP scale and activation events. Prewarmed instances continue to buffer until the maximum scale-out limit is reached. The default prewarmed instance count is 1 and, for most scenarios, this value should remain as 1.

Consider a less-common scenario, such as an app running in a custom container. Because custom containers have a long warm-up, you could consider increasing this buffer of prewarmed instances. A prewarmed instance becomes active only after all active instances are in use.

You can also define a warmup trigger that is run during the prewarming process. You can use a warmup trigger to preload custom dependencies during the prewarming process so your functions are ready to start processing requests immediately. To learn more, see [Azure Functions warmup trigger](#).

Consider this example of how always-ready instances and prewarmed instances work together. A premium function app has two always ready instances configured, and the default of one prewarmed instance.

1. When the app is idle and no events are triggering, the app is provisioned and running with two instances. At this time, you're billed for the two always ready instances but aren't billed for a prewarmed instance as no prewarmed instance is allocated.
2. As your application starts receiving HTTP traffic, requests are load balanced across the two always-ready instances. As soon as those two instances start processing events, an instance gets added to fill the prewarmed buffer. The app is now running with three provisioned instances: the two always ready instances, and the third prewarmed and inactive buffer. You're billed for the three instances.
3. As load increases and your app needs more instances to handle HTTP traffic, that prewarmed instance is swapped to an active instance. HTTP load is now routed to all three instances, and a fourth instance is instantly provisioned to fill the prewarmed buffer.
4. This sequence of scaling and prewarming continues until the maximum instance count for the app is reached or load decreases causing the platform to scale back in after a period. No instances are prewarmed or activated beyond the maximum.

You can't change the prewarmed instance count setting in the portal, you must instead use the Azure CLI or Azure PowerShell.

Maximum function app instances

In addition to the [plan maximum burst count](#), you can configure a per-app maximum. The app maximum can be configured using the [app scale limit](#). The maximum app scale out limit cannot exceed the maximum burst instances of the plan.

Private network connectivity

Function apps deployed to a Premium plan can take advantage of [virtual network integration for web apps](#). When configured, your app can communicate with resources within your virtual network or secured via service endpoints. IP restrictions are also available on the app to restrict incoming traffic.

When assigning a subnet to your function app in a Premium plan, you need a subnet with enough IP addresses for each potential instance. We require an IP block with at least 100 available addresses.

For more information, see [integrate your function app with a virtual network](#).

Rapid elastic scale

More compute instances are automatically added for your app using the same rapid scaling logic as the Consumption plan. Apps in the same App Service Plan scale independently from one another based on the needs of an individual app. However, Functions apps in the same App Service Plan share VM resources to help reduce costs, when possible. The number of apps associated with a VM depends on the footprint of each app and the size of the VM.

To learn more about how scaling works, see [Event-driven scaling in Azure Functions](#).

Longer run duration

Functions in a Consumption plan are limited to 10 minutes for a single execution. In the Premium plan, the run duration defaults to 30 minutes to prevent runaway executions. However, you can [modify the host.json configuration](#) to make the duration unbounded for Premium plan apps, with the following limitations:

- Platform upgrades can trigger a managed shutdown and halt the function execution.
- Platform outages can cause an unhandled shutdown and halt the function execution.
- There's an idle timer that stops the worker after 60 minutes with no new executions.
- [Scale-in behavior](#) can cause worker shutdown after 60 minutes.
- [Slot swaps](#) can terminate executions on the source and target slots during the swap.

Migration

If you have an existing function app, you can use Azure CLI commands to migrate your app between a Consumption plan and a Premium plan on Windows. The specific commands depend on the direction of the migration. To learn more, see [Plan migration](#).

This migration isn't supported on Linux.

Premium plan settings

When you create the plan, there are two plan size settings: the minimum number of instances (or plan size) and the maximum burst limit.

If your app requires instances beyond the always-ready instances, it can continue to scale out until the number of instances hits the plan maximum burst limit, or the app maximum scale out limit if configured. You're billed for instances only while they're running and allocated to you, on a per-second basis. The platform makes its best effort at scaling your app out to the defined maximum limits.

Portal

You can configure the plan size and maximums in the Azure portal by selecting the **Scale Out** options under **Settings** of a function app deployed to that plan.

Elastic Scale out

This allows you to control the bounds that your Premium plan can scale within. [Learn more](#)

Plan Scale out

Maximum Burst [\(i\)](#)

Minimum Instances [\(i\)](#)

Explicitly configuring the number of instances for your plan is only recommended for advanced scenarios, and the configured value will only be honored if it is greater than the always ready instance maximum for apps in your plan. [Learn more](#)

App Scale out

Always Ready Instances [\(i\)](#)

Enforce Scale Out Limit [\(i\)](#)

No Yes

The minimum for every Premium plan is at least one instance. The actual minimum number of instances is determined for you based on the always ready instances requested by apps in the plan. For example, if app A requests five always ready instances, and app B requests two always ready instances in the same plan, the minimum plan size is determined as five. App A is running on all five, and app B is only running on 2.

Important

You are charged for each instance allocated in the minimum instance count regardless if functions are executing or not.

In most circumstances, this autocalculated minimum is sufficient. However, scaling beyond the minimum occurs at a best effort. It's possible, though unlikely, that at a specific time scale-out could be delayed if other instances are unavailable. By setting a minimum higher than the autocalculated minimum, you reserve instances in advance of scale-out.

Portal

You can configure the minimum instances in the Azure portal by selecting the **Scale Out** options under **Settings** of a function app deployed to that plan.

Elastic Scale out

This allows you to control the bounds that your Premium plan can scale within. [Learn more](#)

Plan Scale out

Maximum Burst 20

Minimum Instances 1

Explicitly configuring the number of instances for your plan is only recommended for advanced scenarios, and the configured value will only be honored if it is greater than the always ready instance maximum for apps in your plan. [Learn more](#)

App Scale out

Always Ready Instances 2

Enforce Scale Out Limit No Yes

Available instance SKUs

When creating or scaling your plan, you can choose between three instance sizes. You're billed for the total number of cores and memory provisioned, per second that each instance is allocated to you. Your app can automatically scale out to multiple instances as needed.

[Expand table](#)

SKU	Cores	Memory	Storage
EP1	1	3.5GB	250GB
EP2	2	7GB	250GB
EP3	4	14GB	250GB

Memory usage considerations

Running on a machine with more memory doesn't always mean that your function app uses all available memory.

For example, a JavaScript function app is constrained by the default memory limit in Node.js. To increase this fixed memory limit, add the app setting

`languageWorkers:node:arguments` with a value of `--max-old-space-size=<max memory in MB>`.

And for plans with more than 4 GB of memory, ensure the Bitness Platform Setting is set to `64 Bit` under [General Settings](#).

Region max scale-out

These are the currently supported maximum scale-out values for a single plan in each region and OS configuration:

[Expand table](#)

Region	Windows	Linux

Dedicated hosting plans for Azure Functions

Article • 01/30/2023

This article is about hosting your function app with dedicated resources in an App Service plan, including in an App Service Environment (ASE). For other hosting options, see the [hosting plan article](#).

An App Service plan defines a set of dedicated compute resources for an app to run. These dedicated compute resources are analogous to the [server farm](#) in conventional hosting. One or more function apps can be configured to run on the same computing resources (App Service plan) as other App Service apps, such as web apps. The dedicated App Service plans supported for function app hosting include Basic, Standard, Premium, and Isolated SKUs. For details about how the App Service plan works, see the [Azure App Service plans in-depth overview](#).

ⓘ Important

Free and Shared tier App Service plans aren't supported by Azure Functions. For a lower-cost option hosting your function executions, you should instead consider the [Consumption plan](#), where you are billed based on function executions.

Consider a dedicated App Service plan in the following situations:

- You have existing, underutilized VMs that are already running other App Service instances.
- You want to provide a custom image on which to run your functions.

Billing

You pay for function apps in an App Service Plan as you would for other App Service resources. This differs from Azure Functions [Consumption plan](#) or [Premium plan](#) hosting, which have consumption-based cost components. You are billed only for the plan, regardless of how many function apps or web apps run in the plan. To learn more, see the [App Service pricing page](#).

Always On

If you run on an App Service plan, you should enable the **Always on** setting so that your function app runs correctly. On an App Service plan, the functions runtime goes idle after a few minutes of inactivity, so only HTTP triggers will "wake up" your functions. The **Always on** setting is available only on an App Service plan. On a Consumption plan, the platform activates function apps automatically.

Even with Always On enabled, the execution timeout for individual functions is controlled by the `functionTimeout` setting in the [host.json](#) project file.

Scaling

Using an App Service plan, you can manually scale out by adding more VM instances. You can also enable autoscale, though autoscale will be slower than the elastic scale of the Premium plan. For more information, see [Scale instance count manually or automatically](#). You can also scale up by choosing a different App Service plan. For more information, see [Scale up an app in Azure](#).

ⓘ Note

When running JavaScript (Node.js) functions on an App Service plan, you should choose a plan that has fewer vCPUs. For more information, see [Choose single-core App Service plans](#).

App Service Environments

Running in an App Service Environment (ASE) lets you fully isolate your functions and take advantage of higher numbers of instances than an App Service Plan. To get started, see [Introduction to the App Service Environments](#).

If you just want to run your function app in a virtual network, you can do this using the [Premium plan](#). To learn more, see [Establish Azure Functions private site access](#).

Next steps

- [Azure Functions hosting options](#)
- [Azure App Service plan overview](#)

Linux container support in Azure Functions

Article • 05/21/2024

When you plan and develop your individual functions to run in Azure Functions, you are typically focused on the code itself. Azure Functions makes it easy to deploy just your code project to a function app in Azure. When you deploy your code project to a function app that runs on Linux, the project runs in a container that is created for you automatically. This container is managed by Functions.

Functions also supports containerized function app deployments. In a containerized deployment, you create your own function app instance in a local Docker container from a supported based image. You can then deploy this *containerized* function app to a hosting environment in Azure. Creating your own function app container lets you customize or otherwise control the immediate runtime environment of your function code.

Container hosting options

There are several options for hosting your containerized function apps in Azure:

[+] Expand table

Hosting option	Benefits
Azure Container Apps	Azure Functions provides integrated support for developing, deploying, and managing containerized function apps on Azure Container Apps . Use Azure Container Apps to host your function app containers when you need to run your event-driven functions in Azure in the same environment as other microservices, APIs, websites, workflows, or any container hosted programs. Container Apps hosting lets you run your functions in a managed Kubernetes-based environment with built-in support for open-source monitoring, mTLS, Dapr, and KEDA. Container Apps uses the power of the underlying Azure Kubernetes Service (AKS) while removing the complexity of having to work with Kubernetes APIs.
Azure Arc-enabled Kubernetes clusters (preview)	You can host your function apps on Azure Arc-enabled Kubernetes clusters as either a code-only deployment or in a custom Linux container . Azure Arc lets you attach Kubernetes clusters so that you can manage and configure them in Azure. <i>Hosting Azure Functions containers on Azure Arc-enabled Kubernetes clusters is currently in preview.</i>

Hosting option	Benefits
Azure Functions	You can deploy your containerized function apps to run in either an Elastic Premium plan or a Dedicated plan . Premium plan hosting provides you with the benefits of dynamic scaling. You might want to use Dedicated plan hosting to take advantage of existing unused App Service plan resources.
Kubernetes	Because the Azure Functions runtime provides flexibility in hosting where and how you want, you can host and manage your function app containers directly in Kubernetes clusters. KEDA (Kubernetes-based Event Driven Autoscaling) pairs seamlessly with the Azure Functions runtime and tooling to provide event driven scale in Kubernetes. Just keep in mind that running your containerized function apps on Kubernetes, either by using KEDA or by direct deployment, is an open-source effort that you can use free of cost, with best-effort support provided by contributors and from the community.

Getting started

Azure Container Apps hosting of Azure Functions

Article • 07/04/2024

Azure Functions provides integrated support for developing, deploying, and managing containerized function apps on [Azure Container Apps](#). Use Azure Container Apps to host your function app containers when you need to run your event-driven functions in Azure in the same environment as other microservices, APIs, websites, workflows, or any container hosted programs. Container Apps hosting lets you run your functions in a fully managed, Kubernetes-based environment with built-in support for open-source monitoring, mTLS, Dapr, and Kubernetes Event-driven Autoscaling (KEDA).

You can write your function code in any [language stack supported by Functions](#). You can use the same Functions triggers and bindings with event-driven scaling. You can also use existing Functions client tools and the Azure portal to create containers, deploy function app containers to Container Apps, and configure continuous deployment.

Container Apps integration also means that network and observability configurations, which are defined at the Container App environment level, apply to your function app as they do to all microservices running in a Container Apps environment. You also get the other cloud-native capabilities of Container Apps, including KEDA, Dapr, Envoy. You can still use Application Insights to monitor your functions executions, and your function app can access the same virtual networking resources provided by the environment.

For a general overview of container hosting options for Azure Functions, see [Linux container support in Azure Functions](#).

Hosting and workload profiles

There are two primary hosting plans for Container Apps, a serverless [Consumption plan](#) and a [Dedicated plan](#), which uses workload profiles to better control your deployment resources. A workload profile determines the amount of compute and memory resources available to container apps deployed in an environment. These profiles are configured to fit the different needs of your applications.

The Consumption workload profile is the default profile added to every Workload profiles environment type. You can add Dedicated workload profiles to your environment as you create an environment or after it's created. To learn more about workload profiles, see [Workload profiles in Azure Container Apps](#).

Container Apps hosting of containerized function apps is supported in all [regions that support Container Apps](#).

If your app doesn't have specific hardware requirements, you can run your environment either in a Consumption plan or in a Dedicated plan using the default Consumption workload profile. When running functions on Container Apps, you're charged only for the Container Apps usage. For more information, see the [Azure Container Apps pricing page](#).

Azure Functions on Azure Container Apps supports GPU-enabled hosting in the Dedicated plan with workload profiles.

To learn how to create and deploy a function app container to Container Apps in the default Consumption plan, see [Create your first containerized functions on Azure Container Apps](#).

To learn how to create a Container Apps environment with workload profiles and deploy a function app container to a specific workload, see [Container Apps workload profiles](#).

Functions in containers

To use Container Apps hosting, your code must run on a function app in a Linux container that you create and maintain. Functions maintains a set of [language-specific base images](#) that you can use to generate your containerized function apps.

When you create a code project using [Azure Functions Core Tools](#) and include the `--docker option`, Core Tools generates the Dockerfile with the correct base image, which you can use as a starting point when creating your container.

Important

When creating your own containers, you are required to keep the base image of your container updated to the latest supported base image. Supported base images for Azure Functions are language-specific and are found in the [Azure Functions base image repos](#).

The Functions team is committed to publishing monthly updates for these base images. Regular updates include the latest minor version updates and security fixes for both the Functions runtime and languages. You should regularly update your container from the latest base image and redeploy the updated version of your container.

When you make changes to your functions code, you must rebuild and republish your container image. For more information, see [Update an image in the registry](#).

Deployment options

Azure Functions currently supports the following methods of deploying a containerized function app to Azure Container Apps:

- [Apache Maven ↗](#)
- [ARM templates](#)
- [Azure CLI](#)
- [Azure Developer CLI \(azd\) ↗](#)
- [Azure Functions Core Tools](#)
- [Azure Pipeline tasks ↗](#)
- [Azure portal ↗](#)
- [Bicep files ↗](#)
- [GitHub Actions ↗](#)
- [Visual Studio Code ↗](#)

Virtual network integration

When you host your function apps in a Container Apps environment, your functions are able to take advantage of both internally and externally accessible virtual networks. To learn more about environment networks, see [Networking in Azure Container Apps environment](#).

Configure scale rules

Azure Functions on Container Apps is designed to configure the scale parameters and rules as per the event target. You don't need to worry about configuring the KEDA scaled objects. You can still set minimum and maximum replica count when creating or modifying your function app. The following Azure CLI command sets the minimum and maximum replica count when creating a new function app in a Container Apps environment from an Azure Container Registry:

Azure CLI

```
az functionapp create --name <APP_NAME> --resource-group <MY_RESOURCE_GROUP>
--max-replicas 15 --min-replicas 1 --storage-account <STORAGE_NAME> --
environment MyContainerappEnvironment --image
```

```
<LOGIN_SERVER>/azurefunctionsimage:v1 --registry-username <USERNAME> --  
registry-password <SECURE_PASSWORD> --registry-server <LOGIN_SERVER>
```

The following command sets the same minimum and maximum replica count on an existing function app:

Azure CLI

```
az functionapp config container set --name <APP_NAME> --resource-group  
<MY_RESOURCE_GROUP> --max-replicas 15 --min-replicas 1
```

Managed resource groups

Azure Functions on Container Apps runs your containerized function app resources in specially managed resource groups. These managed resource groups help protect the consistency of your apps by preventing unintended or unauthorized modification or deletion of resources in the managed group, even by service principals.

A managed resource group is created for you the first time you create function app resources in a Container Apps environment. Container Apps resources required by your containerized function app run in this managed resource group. Any other function apps that you create in the same environment use this existing group.

A managed resource group gets removed automatically after all function app container resources are removed from the environment. While the managed resource group is visible, any attempts to modify or remove the managed resource group result in an error. To remove a managed resource group from an environment, remove all of the function app container resources and it gets removed for you.

If you run into any issues with these managed resource groups, you should contact support.

Considerations for Container Apps hosting

Keep in mind the following considerations when deploying your function app containers to Container Apps:

- While all triggers can be used, only the following triggers can dynamically scale (from zero instances) when running in a Container Apps environment:
 - HTTP
 - Azure Queue Storage
 - Azure Service Bus

- Azure Event Hubs
- Kafka
- Timer
- These limitations apply to Kafka triggers:
 - The protocol value of `ssl` isn't supported when hosted on Container Apps. Use a [different protocol value](#).
 - For a Kafka trigger to dynamically scale when connected to Event Hubs, the `username` property must resolve to an application setting that contains the actual username value. When the default `$ConnectionString` value is used, the Kafka trigger won't be able to cause the app to scale dynamically.
- For the built-in Container Apps [policy definitions](#), currently only environment-level policies apply to Azure Functions containers.
- You can use managed identities both for [trigger and binding connections](#) and for [deployments from an Azure Container Registry](#).
- When either your function app and Azure Container Registry-based deployment use managed identity-based connections, you can't modify the CPU and memory allocation settings in the portal. You must instead [use the Azure CLI](#).
- You currently can't move a Container Apps hosted function app deployment between resource groups or between subscriptions. Instead, you would have to recreate the existing containerized app deployment in a new resource group, subscription, or region.
- When using Container Apps, you don't have direct access to the lower-level Kubernetes APIs.
- The `containerapp` extension conflicts with the `appservice-kube` extension in Azure CLI. If you have previously published apps to Azure Arc, run `az extension list` and make sure that `appservice-kube` isn't installed. If it is, you can remove it by running `az extension remove -n appservice-kube`.

Deployment technologies in Azure Functions

Article • 04/02/2024

You can use a few different technologies to deploy your Azure Functions project code to Azure. This article provides an overview of the deployment methods available to you and recommendations for the best method to use in various scenarios. It also provides an exhaustive list of and key details about the underlying deployment technologies.

Deployment methods

The deployment technology you use to publish code to your function app in Azure depends on your specific needs and the point in the development cycle. For example, during development and testing you may deploy directly from your development tool, such as Visual Studio Code. When your app is in production, you're more likely to publish continuously from source control or by using an automated publishing pipeline, which can include validation and testing.

The following table describes the available deployment methods for your code project.

[+] Expand table

Deployment type	Methods	Best for...
Tools-based	<ul style="list-style-type: none">Visual Studio Code publishVisual Studio publishCore Tools publish	Deployments during development and other improvised deployments. Deploying your code on-demand using local development tools .
App Service-managed	<ul style="list-style-type: none">Deployment Center (CI/CD)Container deployments	Continuous deployment (CI/CD) from source control or from a container registry. Deployments are managed by the App Service platform (Kudu).
External pipelines	<ul style="list-style-type: none">Azure PipelinesGitHub Actions	Production pipelines that include validation, testing, and other actions that must be run as part of an automated deployment. Deployments are managed by the pipeline.

Specific deployments should use the best technology based on the specific scenario. Many of the deployment methods are based on [zip deployment](#), which is recommended for deployment.

Deployment technology availability

The deployment method also depends on the hosting plan and operating system on which you run your function app.

Currently, Functions offers three hosting plans:

- Consumption
- Premium
- Dedicated (App Service)

Each plan has different behaviors. Not all deployment technologies are available for each hosting plan and operating system. This chart provides information on the supported deployment technologies:

[\[+\] Expand table](#)

Deployment technology	Windows Consumption	Windows Premium	Windows Dedicated	Linux Consumption	Linux Premium	Linux Dedicated
External package URL ¹	✓	✓	✓	✓	✓	✓
Zip deploy	✓	✓	✓	✓	✓	✓
Docker container					✓	✓
Source control	✓	✓	✓		✓	✓
Local Git ¹	✓	✓	✓		✓	✓
FTPS ¹	✓	✓	✓		✓	✓
In-portal editing ²	✓	✓	✓	✓	✓	✓

¹ Deployment technologies that require you to [manually sync triggers](#) aren't recommended.

² In-portal editing is disabled when code is deployed to your function app from outside the portal. For more information, including language support details for in-portal editing, see [Language support details](#).

Key concepts

Some key concepts are critical to understanding how deployments work in Azure Functions.

Trigger syncing

When you change any of your triggers, the Functions infrastructure must be aware of the changes. Synchronization happens automatically for many deployment technologies. However, in some cases, you must manually sync your triggers.

You must manually sync triggers when using these deployment options:

- [External package URL](#)
- [Local Git](#)
- [FTPS](#)

You can sync triggers in one of three ways:

- Restart your function app in the Azure portal.
- Send an HTTP POST request to

```
https://<functionappname>.azurewebsites.net/admin/host/synctriggers?code=<API_KEY>
```

using the [master key](#).

- Send an HTTP POST request to

```
https://management.azure.com/subscriptions/<SUBSCRIPTION_ID>/resourceGroups/<RESOURCE_GROUP_NAME>/providers/Microsoft.Web/sites/<FUNCTION_APP_NAME>/syncfunctiontriggers?api-version=2016-08-01
```

. Replace the placeholders with your subscription ID, resource group name, and the name of your function app. This request requires an [access token](#) in the [Authorization request header](#).

When you deploy using an external package URL, you need to manually restart your function app to fully sync your deployment when the package changes without changing the URL, which includes initial deployment.

When your function app is secured by inbound network restrictions, the sync triggers endpoint can only be called from a client inside the virtual network.

Remote build

Azure Functions can automatically perform builds on the code it receives after zip deployments. These builds differ depending on whether your app is running on Windows or Linux.

Windows

All function apps running on Windows have a small management app, the `scm` site provided by [Kudu](#). This site handles much of the deployment and build logic for Azure Functions.

When an app is deployed to Windows, language-specific commands, like `dotnet restore` (C#) or `npm install` (JavaScript) are run.

The following considerations apply when using remote builds during deployment:

- Remote builds are supported for function apps running on Linux in the Consumption plan. However, deployment options are limited for these apps because they don't have an `scm` (Kudu) site.
- Function apps running on Linux a [Premium plan](#) or in a [Dedicated \(App Service\) plan](#) do have an `scm` (Kudu) site, but it's limited compared to Windows.
- Remote builds aren't performed when an app is using [run-from-package](#). To learn how to use remote build in these cases, see [Zip deploy](#).
- You may have issues with remote build when your app was created before the feature was made available (August 1, 2019). For older apps, either create a new function app or run `az functionapp update --resource-group <RESOURCE_GROUP_NAME> --name <APP_NAME>` to update your function app. This command might take two tries to succeed.

App content storage

Several deployment methods store the deployed or built application payload on the storage account associated with the function app. Functions tries to use the Azure Files content share when configured, but some methods instead store the payload in the blob storage instance associated with the `AzureWebJobsStorage` connection. See the details in the *Where app content is stored* paragraphs of each deployment technology covered in the next section.

Important

The storage account is used to store important app data, sometimes including the application code itself. You should limit access from other apps and users to the storage account.

Deployment technology details

The following deployment methods are available in Azure Functions.

External package URL

You can use an external package URL to reference a remote package (.zip) file that contains your function app. The file is downloaded from the provided URL, and the app runs in [Run From Package](#) mode.

How to use it: Add [WEBSITE_RUN_FROM_PACKAGE](#) to your application settings. The value of this setting should be a URL (the location of the specific package file you want to run). You can add settings either [in the portal](#) or [by using the Azure CLI](#).

If you use Azure Blob storage, use a private container with a [shared access signature \(SAS\)](#) to give Functions access to the package. Any time the application restarts, it fetches a copy of the content. Your reference must be valid for the lifetime of the application.

When to use it: External package URL is the only supported deployment method for Azure Functions running on Linux in the Consumption plan, if the user doesn't want a [remote build](#) to occur. Whenever you deploy the package file that a function app references, you must [manually sync triggers](#), including the initial deployment. When you change the contents of the package file and not the URL itself, you must also restart your function app to sync triggers.

Where app content is stored: App content is stored at the URL specified. This could be on Azure Blobs, possibly in the storage account specified by the `AzureWebJobsStorage` connection. Some client tools may default to deploying to a blob in this account. For example, for Linux Consumption apps, the Azure CLI will attempt to deploy through a package stored in a blob on the account specified by `AzureWebJobsStorage`.

Zip deploy

Use zip deploy to push a .zip file that contains your function app to Azure. Optionally, you can set your app to start [running from package](#), or specify that a [remote build](#) occurs.

How to use it: Deploy by using your favorite client tool: [Visual Studio Code](#), [Visual Studio](#), or from the command line using the [Azure Functions Core Tools](#). By default, these tools use zip deployment and [run from package](#). Core Tools and the Visual

Studio Code extension both enable [remote build](#) when deploying to Linux. To manually deploy a .zip file to your function app, follow the instructions in [Deploy from a .zip file or URL](#).

When you deploy by using zip deploy, you can set your app to [run from package](#). To run from package, set the `WEBSITE_RUN_FROM_PACKAGE` application setting value to `1`. We recommend zip deployment. It yields faster loading times for your applications, and it's the default for VS Code, Visual Studio, and the Azure CLI.

When to use it: Zip deploy is the recommended deployment technology for Azure Functions.

Where app content is stored: App content from a zip deploy by default is stored on the file system, which may be backed by Azure Files from the storage account specified when the function app was created. In Linux Consumption, the app content instead is persisted on a blob in the storage account specified by the `AzureWebJobsStorage` connection.

Docker container

You can deploy a function app running in a Linux container.

How to use it: [Create your functions in a Linux container](#) then deploy the container to a Premium or Dedicated plan in Azure Functions or another container host. Use the [Azure Functions Core Tools](#) to create a customized Dockerfile for your project that you use to build a containerized function app. You can use the container in the following deployments:

- Deploy to Azure Functions resources you create in the Azure portal. For more information, see [Azure portal create using containers](#).
- Deploy to Azure Functions resources you create from the command line. Requires either a Premium or Dedicated (App Service) plan. To learn how, see [Create your first containerized Azure Functions](#).
- Deploy to Azure Container Apps (preview). To learn how, see [Create your first containerized Azure Functions on Azure Container Apps](#).
- Deploy to Azure Arc (preview). To learn how, see [Create your first containerized Azure Functions on Azure Arc \(preview\)](#).
- Deploy to a Kubernetes cluster. You can deploy to a cluster using [Azure Functions Core Tools](#). Use the `func kubernetes deploy` command.

When to use it: Use the Docker container option when you need more control over the Linux environment where your function app runs and where the container is hosted. This deployment mechanism is available only for functions running on Linux.

Where app content is stored: App content is stored in the specified container registry as a part of the image.

Source control

You can enable continuous integration between your function app and a source code repository. With source control enabled, an update to code in the connected source repository triggers deployment of the latest code from the repository. For more information, see the [Continuous deployment for Azure Functions](#).

How to use it: The easiest way to set up publishing from source control is from the Deployment Center in the Functions area of the portal. For more information, see [Continuous deployment for Azure Functions](#).

When to use it: Using source control is the best practice for teams that collaborate on their function apps. Source control is a good deployment option that enables more sophisticated deployment pipelines. Source control is usually enabled on a staging slot, which can be swapped into production after validation of updates from the repository. For more information, see [Azure Functions deployment slots](#).

Where app content is stored: The app content is in the source control system, but a locally cloned and built app content from is stored on the app file system, which may be backed by Azure Files from the storage account specified when the function app was created.

Local Git

You can use local Git to push code from your local machine to Azure Functions by using Git.

How to use it: Follow the instructions in [Local Git deployment to Azure App Service](#).

When to use it: To reduce the chance of errors, you should avoid using deployment methods that require the additional step of [manually syncing triggers](#). Use [zip deployment](#) when possible.

Where app content is stored: App content is stored on the file system, which may be backed by Azure Files from the storage account specified when the function app was created.

FTP/S

You can use FTP/S to directly transfer files to Azure Functions, although this deployment method isn't recommended. When you're not planning on using FTP, you should disable it. If you do choose to use FTP, you should enforce FTPS. To learn how in the Azure portal, see [Enforce FTPS](#).

How to use it: Follow the instructions in [FTPS deployment settings](#) to get the URL and credentials you can use to deploy to your function app using FTPS.

When to use it: To reduce the chance of errors, you should avoid using deployment methods that require the additional step of [manually syncing triggers](#). Use [zip deployment](#) when possible.

Where app content is stored: App content is stored on the file system, which may be backed by Azure Files from the storage account specified when the function app was created.

Portal editing

In the portal-based editor, you can directly edit the files that are in your function app (essentially deploying every time you save your changes).

How to use it: To be able to edit your functions in the [Azure portal](#), you must have [created your functions in the portal](#). To preserve a single source of truth, using any other deployment method makes your function read-only and prevents continued portal editing. To return to a state in which you can edit your files in the Azure portal, you can manually turn the edit mode back to `Read/Write` and remove any deployment-related application settings (like `WEBSITE_RUN_FROM_PACKAGE`).

When to use it: The portal is a good way to get started with Azure Functions. For more advanced development work, we recommend that you use one of the following client tools:

- [Visual Studio Code](#)
- [Azure Functions Core Tools \(command line\)](#)

- [Visual Studio](#)

Where app content is stored: App content is stored on the file system, which may be backed by Azure Files from the storage account specified when the function app was created.

The following table shows the operating systems and languages that support in-portal editing:

[\[+\] Expand table](#)

Language	Windows Consumption	Windows Premium	Windows Dedicated	Linux Consumption	Linux Premium	Linux Dedicated
C# ¹						
Java						
JavaScript (Node.js)	✓	✓	✓		✓	✓
Python ²				✓	✓	✓
PowerShell	✓	✓	✓			
TypeScript (Node.js)						

¹ In-portal editing is only supported for C# script files, which run in-process with the host. For more information, see the [Azure Functions C# script \(.csx\) developer reference](#).

² In-portal editing is only supported for the v1 Python programming model.

Deployment behaviors

When you deploy updates to your function app code, currently executing functions are terminated. After deployment completes, the new code is loaded to begin processing requests. Review [Improve the performance and reliability of Azure Functions](#) to learn how to write stateless and defensive functions.

If you need more control over this transition, you should use deployment slots.

Deployment slots

When you deploy your function app to Azure, you can deploy to a separate deployment slot instead of directly to production. Deploying to a deployment slot and then swapping into production after verification is the recommended way to configure [continuous deployment](#).

The way that you deploy to a slot depends on the specific deployment tool you use. For example, when using Azure Functions Core Tools, you include the `--slot` option to indicate the name of a specific slot for the `func azure functionapp publish` command.

For more information on deployment slots, see the [Azure Functions Deployment Slots](#) documentation for details.

Connect to eventing and messaging services from Azure Functions

Article • 11/11/2022

As a cloud computing service, Azure Functions is frequently used to move data between various Azure services. To make it easier for you to connect your code to other services, Functions implements a set of binding extensions to connect to these services. To learn more, see [Azure Functions triggers and bindings concepts](#).

By definition, Azure Functions executions are stateless. If you need to connect your code to services in a more stateful way, consider instead using [Durable Functions](#) or [Azure Logic Apps](#).

Triggers and bindings are provided to consuming and emitting data easier. There may be cases where you need more control over the service connection, or you just feel more comfortable using a client library provided by a service SDK. In those cases, you can use a client instance from the SDK in your function execution to access the service as you normally would. When using a client directly, you need to pay attention to the effect of scale and performance on client connections. To learn more, see the [guidance on using static clients](#).

You can't obtain the client instance used by a service binding from your function execution.

The rest of this article provides specific guidance for integrating your code with the specific Azure services supported by Functions.

Event Grid

Event Grid is an Azure service that sends HTTP requests to notify you about events that happen in publishers. A *publisher* is the service or resource that originates the event. For example, an Azure blob storage account is a publisher, and a [blob upload or deletion is an event](#). Some [Azure services have built-in support for publishing events to Event Grid](#).

Event *handlers* receive and process events. Azure Functions is one of several [Azure services that have built-in support for handling Event Grid events](#). Functions provides an Event Grid trigger, which invokes a function when an event is received from Event Grid. A similar output binding can be used to send events from your function to an [Event Grid custom topic](#).

You can also use an HTTP trigger to handle Event Grid Events. To learn more, see [Receive events to an HTTP endpoint](#). We recommend using the Event Grid trigger over HTTP trigger.

Azure Functions provides built-in integration with Azure Event Grid by using [triggers and bindings](#).

To learn how to configure and locally evaluate your Event Grid trigger and bindings, see [How to work with Event Grid triggers and bindings in Azure Functions](#)

For more information about Event Grid trigger and output binding definitions and examples, see one of the following reference articles:

- [Azure Event Grid bindings for Azure Functions](#)
- [Azure Event Grid trigger for Azure Functions](#)
- [Azure Event Grid output binding for Azure Functions](#)

Next steps

To learn more about Event Grid with Functions, see the following articles:

- [Azure Event Grid bindings for Azure Functions](#)
- [Tutorial: Automate resizing uploaded images using Event Grid](#)

Event-driven scaling in Azure Functions

Article • 08/01/2024

In the Consumption, Flex Consumption, and Premium plans, Azure Functions scales resources by adding more instances based on the number of events that trigger a function.

ⓘ Important

The [Flex Consumption plan](#) is currently in preview.

The way in which your function app scales depends on the hosting plan:

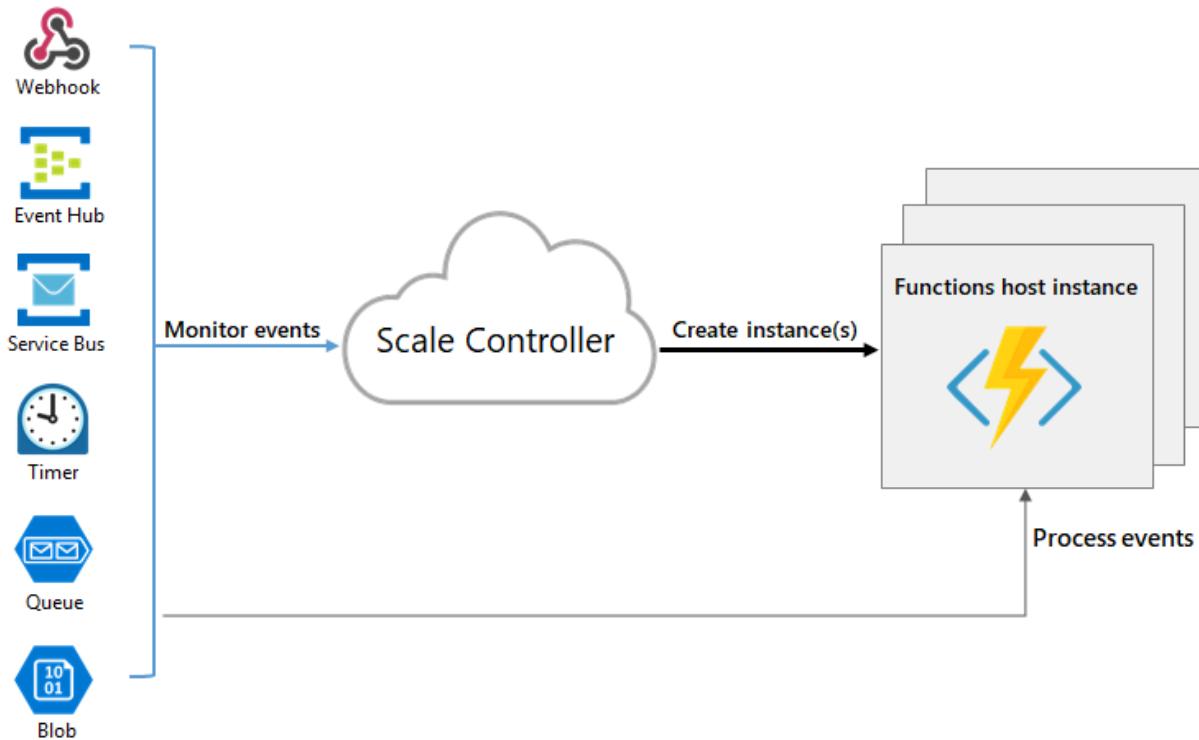

- **Consumption plan:** Each instance of the Functions host in the Consumption plan is limited, typically to 1.5 GB of memory and one CPU. An instance of the host supports the entire function app. As such, all functions within a function app share resource in an instance are scaled at the same time. When function apps share the same Consumption plan, they're still scaled independently.
- **Flex Consumption plan:** The plan uses a deterministic per-function scaling strategy, where each function is scaled independently, except for HTTP, Blob, and Durable Functions triggered functions which scale in their own groups. For more information, see [Per-function scaling](#). These instances are then scaled based on the concurrency of your requests.
- **Premium plan:** The specific size of the Premium plan determines the available memory and CPU for all apps in that plan on that instance. The plan scales out its instances based on the scaling needs of the apps in the plan, and the apps scale within the plan as needed.

Function code files are stored on Azure Files shares on the function's main storage account. When you delete the main storage account of the function app, the function code files are deleted and can't be recovered.

Runtime scaling

Azure Functions uses a component called the *scale controller* to monitor the rate of events and determine whether to scale out or scale in. The scale controller uses heuristics for each trigger type. For example, when you're using an Azure Queue storage trigger, it uses [target-based scaling](#).

The unit of scale for Azure Functions is the function app. When the function app is scaled out, more resources are allocated to run multiple instances of the Azure Functions host. Conversely, as compute demand is reduced, the scale controller removes function host instances. The number of instances is eventually "scaled in" when no functions are running within a function app.

Cold Start

Should your function app become idle for a few minutes, the platform might decide to scale the number of instances on which your app runs down to zero. The next request has the added latency of scaling from zero to one. This latency is referred to as a *cold start*. The number of dependencies required by your function app can affect the cold start time. Cold start is more of an issue for synchronous operations, such as HTTP triggers that must return a response. If cold starts are impacting your functions, consider using a plan other than the Consumption. The other plans offer these strategies to mitigate or eliminate cold starts:

- **Premium plan:** supports both prewarmed instances and always ready instances, with a minimum of one instance.
- **Flex Consumption plan:** supports an optional number of always ready instances, which can be defined on a per instance scaling basis.
- **Dedicated plan:** the plan itself doesn't scale dynamically, but you can run your app continuously with the **Always on** setting is enabled.

Understanding scaling behaviors

Scaling can vary based on several factors, and apps scale differently based on the triggers and language selected. There are a few intricacies of scaling behaviors to be aware of:

- **Maximum instances:** A single function app only scales out to a [maximum allowed by the plan](#). However, a single instance [can process more than one message or request at a time](#). You can [specify a lower maximum](#) to throttle scale as required.
- **New instance rate:** For HTTP triggers, new instances are allocated, at most, once per second. For non-HTTP triggers, new instances are allocated, at most, once every 30 seconds. Scaling is faster when running in a [Premium plan](#).
- **Target-based scaling:** Target-based scaling provides a fast and intuitive scaling model for customers and is currently supported for Service Bus queues and topics, Storage queues, Event Hubs, Apache Kafka, and Azure Cosmos DB extensions. Make sure to review [target-based scaling](#) to understand their scaling behavior.
- **Per-function scaling:** With some notable exceptions, functions running in the Flex Consumption plan scale on independent instances. The exceptions include HTTP triggers and Blob storage (Event Grid) triggers. Each of these trigger types scale together as a group on the same instances. Likewise, all Durable Functions triggers also share instances and scale together. For more information, see [per-function scaling](#).
- **Maximum monitored triggers:** Currently, the scale controller can only monitor up to 100 triggers to make scaling decisions. When your app has more than 100 event-based triggers, scale decisions are made based on only the first 100 triggers that execute. For more information, see [Best practices and patterns for scalable apps](#).

Limit scale-out

You might decide to restrict the maximum number of instances an app can use for scale-out. This is most common for cases where a downstream component like a database has limited throughput. For the maximum scale limits when running the various hosting plans, see [Scale limits](#).

Flex Consumption plan

By default, apps running in a Flex Consumption plan have a limit of `100` overall instances. Currently the lowest maximum instance count value is `40`, and the highest supported maximum instance count value is `1000`. When you use the `az functionapp create`

command to create a function app in the Flex Consumption plan, use the `--maximum-instance-count` parameter to set this maximum instance count for of your app.

Note that while you can change the maximum instance count of Flex Consumption apps up to 1000, your apps will reach a quota limit before reaching that number. Review [Regional subscription memory quotas](#) for more details.

This example creates an app with a maximum instance count of `200`:

Azure CLI

```
az functionapp create --resource-group <RESOURCE_GROUP> --name <APP_NAME> --storage <STORAGE_ACCOUNT_NAME> --runtime <LANGUAGE_RUNTIME> --runtime-version <RUNTIME_VERSION> --flexconsumption-location <REGION> --maximum-instance-count 200
```

This example uses the `az functionapp scale config set` command to change the maximum instance count for an existing app to `150`:

Azure CLI

```
az functionapp scale config set --resource-group <RESOURCE_GROUP> --name <APP_NAME> --maximum-instance-count 150
```

Consumption/Premium plans

In a Consumption or Elastic Premium plan, you can specify a lower maximum limit for your app by modifying the value of the `functionAppScaleLimit` site configuration setting. The `functionAppScaleLimit` can be set to `0` or `null` for unrestricted, or a valid value between `1` and the app maximum.

Azure CLI

Azure CLI

```
az resource update --resource-type Microsoft.Web/sites -g <RESOURCE_GROUP> -n <FUNCTION_APP-NAME>/config/web --set properties.functionAppScaleLimit=<SCALE_LIMIT>
```

Scale-in behaviors

Event-driven scaling automatically reduces capacity when demand for your functions is reduced. It does this by draining instances of their current function executions and then removes those instances. This behavior is logged as drain mode. The grace period for functions that are currently executing can extend up to 10 minutes for Consumption plan apps and up to 60 minutes for Premium plan apps. Event-driven scaling and this behavior don't apply to Dedicated plan apps.

The following considerations apply for scale-in behaviors:

- For app running on Windows in a Consumption plan, only apps created after May 2021 have drain mode behaviors enabled by default.
- To enable graceful shutdown for functions using the Service Bus trigger, use version 4.2.0 or a later version of the [Service Bus Extension](#).

Per-function scaling

Applies only to the Flex Consumption plan (preview).

The [Flex Consumption plan](#) is unique in that it implements a *per-function scaling* behavior. In per-function scaling, except for HTTP triggers, Blob (Event Grid) triggers, and Durable Functions, all other function trigger types in your app scale on independent instances. HTTP triggers in your app all scale together as a group on the same instances, as do all Blob (Event Grid), and all Durable Functions triggers, which have their own shared instances.

Consider a function app hosted a Flex Consumption plan that has these function:

[+] [Expand table](#)

function1	function2	function3	function4	function5	function6	function7
HTTP trigger	HTTP trigger	Orchestration trigger (Durable)	Activity trigger (Durable)	Service Bus trigger	Service Bus trigger	Event Hubs trigger

In this example:

- The two HTTP triggered functions (`function1` and `function2`) both run together on their own instances and scale together according to [HTTP concurrency settings](#).
- The two Durable functions (`function3` and `function4`) both run together on their own instances and scale together based on [configured concurrency throttles](#).
- The Service bus triggered function `function5` runs in its own and is scaled independently according to the [target-based scaling rules for Service Bus queues](#)

and topics.

- The Service bus triggered function `function6` runs in its own and is scaled independently according to the [target-based scaling rules for Service Bus queues and topics](#).
- The Event Hubs trigger (`function7`) runs in its own instances and is scaled independently according to the [target-based scaling rules for Event Hubs](#).

Best practices and patterns for scalable apps

There are many aspects of a function app that impacts how it scales, including host configuration, runtime footprint, and resource efficiency. For more information, see the [scalability section of the performance considerations article](#). You should also be aware of how connections behave as your function app scales. For more information, see [How to manage connections in Azure Functions](#).

If your app has more than 100 functions that use event-based triggers, consider breaking the app into one or more apps, where each app has less than 100 event-based functions.

For more information on scaling in Python and Node.js, see [Azure Functions Python developer guide - Scaling and concurrency](#) and [Azure Functions Node.js developer guide - Scaling and concurrency](#).

Target-based scaling

Article • 05/05/2024

Target-based scaling provides a fast and intuitive scaling model for customers and is currently supported for these binding extensions:

- [Apache Kafka](#)
- [Azure Cosmos DB](#)
- [Azure Event Hubs](#)
- [Azure Queue Storage](#)
- [Azure Service Bus \(queue and topics\)](#)

Target-based scaling replaces the previous Azure Functions incremental scaling model as the default for these extension types. Incremental scaling added or removed a maximum of one worker at [each new instance rate](#), with complex decisions for when to scale. In contrast, target-based scaling allows scale up of four instances at a time, and the scaling decision is based on a simple target-based equation:

$$\text{Desired instances} = \frac{\text{Event source length}}{\text{Target executions per instance}}$$

In this equation, *event source length* refers to the number of events that must be processed. The default *target executions per instance* values come from the SDKs used by the Azure Functions extensions. You don't need to make any changes for target-based scaling to work.

Considerations

The following considerations apply when using target-based scaling:

- Target-based scaling is enabled by default for function apps on the [Consumption plan](#), [Flex Consumption plan](#), and [Elastic Premium plans](#). Event-driven scaling isn't supported when running on [Dedicated \(App Service\) plans](#).
- Target-based scaling is enabled by default starting with version 4.19.0 of the Functions runtime.
- When you use target-based scaling, scale limits are still honored. For more information, see [Limit scale out](#).

- To achieve the most accurate scaling based on metrics, use only one target-based triggered function per function app. You should also consider running in a Flex Consumption plan, which offers [per-function scaling](#).
- When multiple functions in the same function app are all requesting to scale out at the same time, a sum across those functions is used to determine the change in desired instances. Functions requesting to scale out override functions requesting to scale in.
- When there are scale-in requests without any scale-out requests, the max scale in value is used.

Opting out

Target-based scaling is enabled by default for function apps hosted on a Consumption plan or on a Premium plans. To disable target-based scaling and fall back to incremental scaling, add the following app setting to your function app:

[\[+\] Expand table](#)

App Setting	Value
TARGET_BASED_SCALING_ENABLED	0

Customizing target-based scaling

You can make the scaling behavior more or less aggressive based on your app's workload by adjusting *target executions per instance*. Each extension has different settings that you can use to set *target executions per instance*.

This table summarizes the `host.json` values that are used for the *target executions per instance* values and the defaults:

[\[+\] Expand table](#)

Extension	host.json values	Default Value
Event Hubs (Extension v5.x+)	<code>extensions.eventHubs.maxEventBatchSize</code>	100*
Event Hubs (Extension v3.x+)	<code>extensions.eventHubs.eventProcessorOptions.maxBatchSize</code>	10

Extension	host.json values	Default Value
Event Hubs (if defined)	extensions.eventHubs.targetUnprocessedEventThreshold	n/a
Service Bus (Extension v5.x+, Single Dispatch)	extensions.serviceBus.maxConcurrentCalls	16
Service Bus (Extension v5.x+, Single Dispatch Sessions Based)	extensions.serviceBus.maxConcurrentSessions	8
Service Bus (Extension v5.x+, Batch Processing)	extensions.serviceBus.maxMessageBatchSize	1000
Service Bus (Functions v2.x+, Single Dispatch)	extensions.serviceBus.messageHandlerOptions.maxConcurrentCalls	16
Service Bus (Functions v2.x+, Single Dispatch Sessions Based)	extensions.serviceBus.sessionHandlerOptions.maxConcurrentSessions	2000
Service Bus (Functions v2.x+, Batch Processing)	extensions.serviceBus.batchOptions.maxMessageCount	1000
Storage Queue	extensions.queues.batchSize	16

* The default `maxEventBatchSize` changed in [v6.0.0](#) of the `Microsoft.Azure.WebJobs.Extensions.EventHubs` package. In earlier versions, this value was 10.

For some binding extensions, *target executions per instance* is set using a function attribute:

[\[+\] Expand table](#)

Extension	Function trigger setting	Default Value
Apache Kafka	<code>lagThreshold</code>	1000
Azure Cosmos DB	<code>maxItemsPerInvocation</code>	100

To learn more, see the [example configurations for the supported extensions](#).

Premium plan with runtime scale monitoring enabled

When [runtime scale monitoring](#) is enabled, the extensions themselves handle dynamic scaling. This is because the [scale controller](#) doesn't have access to services secured by a virtual network. After you enable runtime scale monitoring, you'll need to upgrade your extension packages to these minimum versions to unlock the extra target-based scaling functionality:

[\[+\] Expand table](#)

Extension Name	Minimum Version Needed
Apache Kafka	3.9.0
Azure Cosmos DB	4.1.0
Event Hubs	5.2.0
Service Bus	5.9.0
Storage Queue	5.1.0

Dynamic concurrency support

Target-based scaling introduces faster scaling, and uses defaults for *target executions per instance*. When using Service Bus, Storage queues, or Kafka, you can also enable [dynamic concurrency](#). In this configuration, the *target executions per instance* value is determined automatically by the dynamic concurrency feature. It starts with limited concurrency and identifies the best setting over time.

Supported extensions

The way in which you configure target-based scaling in your host.json file depends on the specific extension type. This section provides the configuration details for the extensions that currently support target-based scaling.

Service Bus queues and topics

The Service Bus extension support three execution models, determined by the `IsBatched` and `IsSessionsEnabled` attributes of your Service Bus trigger. The default value for `IsBatched` and `IsSessionsEnabled` is `false`.

[+] Expand table

Execution Model	<code>IsBatched</code>	<code>IsSessionsEnabled</code>	Setting Used for <i>target executions per instance</i>
Single dispatch processing	false	false	<code>maxConcurrentCalls</code>
Single dispatch processing (session-based)	false	true	<code>maxConcurrentSessions</code>
Batch processing	true	false	<code>maxMessageBatchSize</code> or <code>maxMessageCount</code>

ⓘ Note

Scale efficiency: For the Service Bus extension, use *Manage* rights on resources for the most efficient scaling. With *Listen* rights scaling reverts to incremental scale because the queue or topic length can't be used to inform scaling decisions. To learn more about setting rights in Service Bus access policies, see [Shared Access Authorization Policy](#).

Single dispatch processing

In this model, each invocation of your function processes a single message. The `maxConcurrentCalls` setting governs *target executions per instance*. The specific setting depends on the version of the Service Bus extension.

v5.x+

Modify the `host.json` setting `maxConcurrentCalls`, as in the following example:

JSON

```
{  
    "version": "2.0",  
    "extensions": {  
        "serviceBus": {  
            "maxConcurrentCalls": 16  
        }  
    }  
}
```

Single dispatch processing (session-based)

In this model, each invocation of your function processes a single message. However, depending on the number of active sessions for your Service Bus topic or queue, each instance leases one or more sessions. The specific setting depends on the version of the Service Bus extension.

v5.x+

Modify the `host.json` setting `maxConcurrentSessions` to set *target executions per instance*, as in the following example:

JSON

```
{  
    "version": "2.0",  
    "extensions": {  
        "serviceBus": {  
            "maxConcurrentSessions": 8  
        }  
    }  
}
```

Batch processing

In this model, each invocation of your function processes a batch of messages. The specific setting depends on the version of the Service Bus extension.

v5.x+

Modify the `host.json` setting `maxMessageBatchSize` to set *target executions per instance*, as in the following example:

JSON

```
{  
    "version": "2.0",  
    "extensions": {  
        "serviceBus": {  
            "maxMessageBatchSize": 1000  
        }  
    }  
}
```

Event Hubs

For Azure Event Hubs, Azure Functions scales based on the number of unprocessed events distributed across all the partitions in the event hub. By default, the `host.json` attributes used for *target executions per instance* are `maxEventBatchSize` and `maxBatchSize`. However, if you choose to fine-tune target-based scaling, you can define a separate parameter `targetUnprocessedEventThreshold` that overrides to set *target executions per instance* without changing the batch settings. If `targetUnprocessedEventThreshold` is set, the total unprocessed event count is divided by this value to determine the number of instances, which is then be rounded up to a worker instance count that creates a balanced partition distribution.

ⓘ Note

Since Event Hubs is a partitioned workload, the target instance count for Event Hubs is capped by the number of partitions in your event hub.

The specific setting depends on the version of the Event Hubs extension.

v5.x+

Modify the `host.json` setting `maxEventBatchSize` to set *target executions per instance*, as in the following example:

JSON

```
{  
    "version": "2.0",  
    "extensions": {  
        "eventHubs": {  
            "maxEventBatchSize" : 100  
        }  
    }  
}
```

```
    }  
}
```

When defined in `host.json`, `targetUnprocessedEventThreshold` is used as *target executions per instance* instead of `maxEventBatchSize`, as in the following example:

JSON

```
{  
  "version": "2.0",  
  "extensions": {  
    "eventHubs": {  
      "targetUnprocessedEventThreshold": 153  
    }  
  }  
}
```

Storage Queues

For v2.x+ of the Storage extension, modify the `host.json` setting `batchSize` to set *target executions per instance*:

JSON

```
{  
  "version": "2.0",  
  "extensions": {  
    "queues": {  
      "batchSize": 16  
    }  
  }  
}
```

ⓘ Note

Scale efficiency: For the storage queue extension, messages with `visibilityTimeout` are still counted in *event source length* by the Storage Queue APIs. This can cause overscaling of your function app. Consider using Service Bus queues que scheduled messages, `limiting scale out`, or not using `visibilityTimeout` for your solution.

Azure Cosmos DB

Azure Cosmos DB uses a function-level attribute, `MaxItemsPerInvocation`. The way you set this function-level attribute depends on your function language.

C#

For a compiled C# function, set `MaxItemsPerInvocation` in your trigger definition, as shown in the following examples for an in-process C# function:

C#

```
namespace CosmosDBSamplesV2
{
    public static class CosmosTrigger
    {
        [FunctionName("CosmosTrigger")]
        public static void Run([CosmosDBTrigger(
            databaseName: "ToDoItems",
            collectionName: "Items",
            MaxItemsPerInvocation: 100,
            ConnectionStringSetting = "CosmosDBConnection",
            LeaseCollectionName = "leases",
            CreateLeaseCollectionIfNotExists =
true)]IReadOnlyList<Document> documents,
            ILogger log)
        {
            if (documents != null && documents.Count > 0)
            {
                log.LogInformation($"Documents modified:
{documents.Count}");
                log.LogInformation($"First document Id:
{documents[0].Id}");
            }
        }
    }
}
```

ⓘ Note

Since Azure Cosmos DB is a partitioned workload, the target instance count for the database is capped by the number of physical partitions in your container. To learn more about Azure Cosmos DB scaling, see [physical partitions](#) and [lease ownership](#).

Apache Kafka

The Apache Kafka extension uses a function-level attribute, `LagThreshold`. For Kafka, the number of *desired instances* is calculated based on the total consumer lag divided by the `LagThreshold` setting. For a given lag, reducing the lag threshold increases the number of desired instances.

The way you set this function-level attribute depends on your function language. This example sets the threshold to `100`.

C#

For a compiled C# function, set `LagThreshold` in your trigger definition, as shown in the following examples for an in-process C# function for a Kafka Event Hubs trigger:

```
C#  
  
[FunctionName("KafkaTrigger")]
public static void Run(
    [KafkaTrigger("BrokerList",
        "topic",
        Username = "$ConnectionString",
        Password = "%EventHubConnectionString%",
        Protocol = BrokerProtocol.SaslSsl,
        AuthenticationMode = BrokerAuthenticationMode.Plain,
        ConsumerGroup = "$Default",
        LagThreshold = 100)] KafkaEventData<string> kevent,
    ILogger log)
{
    log.LogInformation($"C# Kafka trigger function processed a message:
{kevent.Value}");
}
```

Azure Functions reliable event processing

Article • 06/28/2022

Event processing is one of the most common scenarios associated with serverless architecture. This article describes how to create a reliable message processor with Azure Functions to avoid losing messages.

Challenges of event streams in distributed systems

Consider a system that sends events at a constant rate of 100 events per second. At this rate, within minutes multiple parallel Functions instances can consume the incoming 100 events every second.

However, any of the following less-optimal conditions are possible:

- What if the event publisher sends a corrupt event?
- What if your Functions instance encounters unhandled exceptions?
- What if a downstream system goes offline?

How do you handle these situations while preserving the throughput of your application?

With queues, reliable messaging comes naturally. When paired with a Functions trigger, the function creates a lock on the queue message. If processing fails, the lock is released to allow another instance to retry processing. Processing then continues until either the message is evaluated successfully, or it is added to a poison queue.

Even while a single queue message may remain in a retry cycle, other parallel executions continue to keep to dequeuing remaining messages. The result is that the overall throughput remains largely unaffected by one bad message. However, storage queues don't guarantee ordering and aren't optimized for the high throughput demands required by Event Hubs.

By contrast, Azure Event Hubs doesn't include a locking concept. To allow for features like high-throughput, multiple consumer groups, and replay-ability, Event Hubs events behave more like a video player. Events are read from a single point in the stream per partition. From the pointer you can read forwards or backwards from that location, but you have to choose to move the pointer for events to process.

When errors occur in a stream, if you decide to keep the pointer in the same spot, event processing is blocked until the pointer is advanced. In other words, if the pointer is stopped to deal with problems processing a single event, the unprocessed events begin piling up.

Azure Functions avoids deadlocks by advancing the stream's pointer regardless of success or failure. Since the pointer keeps advancing, your functions need to deal with failures appropriately.

How Azure Functions consumes Event Hubs events

Azure Functions consumes Event Hub events while cycling through the following steps:

1. A pointer is created and persisted in Azure Storage for each partition of the event hub.
2. When new messages are received (in a batch by default), the host attempts to trigger the function with the batch of messages.
3. If the function completes execution (with or without exception) the pointer advances and a checkpoint is saved to the storage account.
4. If conditions prevent the function execution from completing, the host fails to progress the pointer. If the pointer isn't advanced, then later checks end up processing the same messages.
5. Repeat steps 2–4

This behavior reveals a few important points:

- *Unhandled exceptions may cause you to lose messages.* Executions that result in an exception will continue to progress the pointer. Setting a [retry policy](#) will delay progressing the pointer until the entire retry policy has been evaluated.
- *Functions guarantees at-least-once delivery.* Your code and dependent systems may need to [account for the fact that the same message could be received twice](#).

Handling exceptions

As a general rule, every function should include a [try/catch block](#) at the highest level of code. Specifically, all functions that consume Event Hubs events should have a [catch](#) block. That way, when an exception is raised, the catch block handles the error before the pointer progresses.

Retry mechanisms and policies

Some exceptions are transient in nature and don't reappear when an operation is attempted again moments later. This is why the first step is always to retry the operation. You can leverage the function app [retry policies](#) or author retry logic within the function execution.

Introducing fault-handling behaviors to your functions allow you to define both basic and advanced retry policies. For instance, you could implement a policy that follows a workflow illustrated by the following rules:

- Try to insert a message three times (potentially with a delay between retries).
- If the eventual outcome of all retries is a failure, then add a message to a queue so processing can continue on the stream.
- Corrupt or unprocessed messages are then handled later.

ⓘ Note

[Polly](#) is an example of a resilience and transient-fault-handling library for C# applications.

Non-exception errors

Some issues arise even when an error is not present. For example, consider a failure that occurs in the middle of an execution. In this case, if a function doesn't complete execution, the offset pointer is never progressed. If the pointer doesn't advance, then any instance that runs after a failed execution continues to read the same messages. This situation provides an "at-least-once" guarantee.

The assurance that every message is processed at least one time implies that some messages may be processed more than once. Your function apps need to be aware of this possibility and must be built around the [principles of idempotency](#).

Stop and restart execution

While a few errors may be acceptable, what if your app experiences significant failures? You may want to stop triggering on events until the system reaches a healthy state. Having the opportunity to pause processing is often achieved with a circuit breaker pattern. The circuit breaker pattern allows your app to "break the circuit" of the event process and resume at a later time.

There are two pieces required to implement a circuit breaker in an event process:

- Shared state across all instances to track and monitor health of the circuit
- Master process that can manage the circuit state (open or closed)

Implementation details may vary, but to share state among instances you need a storage mechanism. You may choose to store state in Azure Storage, a Redis cache, or any other account that is accessible by a collection of functions.

[Azure Logic Apps](#) or [durable functions](#) are a natural fit to manage the workflow and circuit state. Other services may work just as well, but logic apps are used for this example. Using logic apps, you can pause and restart a function's execution giving you the control required to implement the circuit breaker pattern.

Define a failure threshold across instances

To account for multiple instances processing events simultaneously, persisting shared external state is needed to monitor the health of the circuit.

A rule you may choose to implement might enforce that:

- If there are more than 100 eventual failures within 30 seconds across all instances, then break the circuit and stop triggering on new messages.

The implementation details will vary given your needs, but in general you can create a system that:

1. Log failures to a storage account (Azure Storage, Redis, etc.)
2. When new failure is logged, inspect the rolling count to see if the threshold is met (for example, more than 100 in last 30 seconds).
3. If the threshold is met, emit an event to Azure Event Grid telling the system to break the circuit.

Managing circuit state with Azure Logic Apps

The following description highlights one way you could create an Azure Logic App to halt a Functions app from processing.

Azure Logic Apps comes with built-in connectors to different services, features stateful orchestrations, and is a natural choice to manage circuit state. After detecting the circuit needs to break, you can build a logic app to implement the following workflow:

1. Trigger an Event Grid workflow and stop the Azure Function (with the Azure Resource connector)

2. Send a notification email that includes an option to restart the workflow

The email recipient can investigate the health of the circuit and, when appropriate, restart the circuit via a link in the notification email. As the workflow restarts the function, messages are processed from the last Event Hub checkpoint.

Using this approach, no messages are lost, all messages are processed in order, and you can break the circuit as long as necessary.

Concurrency in Azure Functions

Article • 05/21/2024

This article describes the concurrency behaviors of event-driven triggers in Azure Functions. It also compares the static and dynamic concurrency models.

ⓘ Important

The [Flex Consumption plan](#) is currently in preview.

In Functions, you can have multiple executing processes of a given function running concurrently on a single compute instance. For example, consider a case where you have three different functions in your function app that is scaled-out to multiple instances to handle an increased load. In this scenario, each function is executing in response to individual invocations across all three instances, and a given instance can handle multiple invocations of the same type. Keep in mind that the function executions on a single instance share the same memory, CPU, and connection resources. Because multiple function executions can run on each instance concurrently, each function needs to have a way to manage the number of concurrent executions.

When your app is hosted in a dynamic scale plan (Consumption, Flex Consumption, or Premium), the host scales the number of function app instances up or down based on the number of incoming events. To learn more, see [Event Driven Scaling](#). When you host your functions in a Dedicated (App Service) plan, you must manually configure your instances or [set up an autoscale scheme](#).

These scale decisions also are directly impacted by the concurrency of executions on a given instance. When an app in a dynamic scale plan hits a concurrency limit, it might need to scale to keep up with incoming demand.

Functions provides two main ways of managing concurrency:

- **Static concurrency:** You can configure host-level limits on concurrency, which are specific to individual triggers. This is the default concurrency behavior for Functions.
- **Dynamic concurrency:** For certain trigger types, the Functions host can automatically determine the best level of concurrency for that trigger in your app. You must [opt in to this concurrency model](#).

Static concurrency

By default, most triggers support a host-level static configuration model. In this model, each trigger type has a per-instance concurrency limit. However, for most triggers you can also request a specific per-instance concurrency for that trigger type. For example, the [Service Bus trigger](#) provides both a `MaxConcurrentCalls` and a `MaxConcurrentSessions` setting in the [host.json file](#). These settings together control the maximum number of messages each function processes concurrently on each instance. Other trigger types have built-in mechanisms for load-balancing invocations across instances. For example, Event Hubs and Azure Cosmos DB both use a partition-based scheme.

For trigger types that support concurrency configuration, the settings you choose are applied to all running instances. This allows you to control the maximum concurrency for your functions on each instance. For example, when your function is CPU or resource-intensive, you may choose to limit concurrency to keep instances healthy and rely on scaling to handle increased loads. Similarly, when your function is making requests to a downstream service that is being throttled, you should also consider limiting concurrency to avoid overloading the downstream service.

HTTP trigger concurrency

Applies only to the Flex Consumption plan (preview)

The Flex Consumption plan scales all HTTP trigger functions together as a group. For more information, see [Per-function scaling](#). The following table indicates the default concurrency setting for HTTP triggers on a given instance, based on the configured [instance memory size](#).

[] [Expand table](#)

Instance size (MB)	Default concurrency*
2048	16
4096	32

*For Python apps, the default HTTP trigger concurrency for all instances sizes is 1.

These defaults should work well for most cases, and you start with them. Consider that at a given number of HTTP requests, increasing the HTTP concurrency value reduces the number of instances required to handle HTTP requests. Likewise decreasing the HTTP concurrency value requires more instances to handle the same load.

If you need to fine tune the HTTP concurrency, you can do this by using the Azure CLI. For more information, see [Set HTTP concurrency limits](#).

The default concurrency values in the previous table only apply when you haven't set your own HTTP concurrency setting. When you haven't explicitly set an HTTP concurrency setting, the default concurrency increases as shown in the table when you change the instance size. After you specifically set an HTTP concurrency value, that value is maintained despite changes in the instance size.

Determine optimal static concurrency

While static concurrency configurations give you control of certain trigger behaviors, such as throttling your functions, it can be difficult to determine the optimal values for these settings. Generally, you have to arrive at acceptable values by an iterative process of load testing. Even after you determine a set of values that are working for a particular load profile, the number of events arriving from your connected services may change from day to day. This variability means your app often may run with suboptimal values. For example, your function app may process particularly demanding message payloads on the last day of the week, which requires you to throttle concurrency down. However, during the rest of the week the message payloads are simpler, which means you could use a higher concurrency level the rest of the week.

Ideally, we want the system to allow instances to process as much work as they can while keeping each instance healthy and latencies low, which is what dynamic concurrency is designed to do.

Dynamic concurrency

Functions now provides a dynamic concurrency model that simplifies configuring concurrency for all function apps running in the same plan.

Note

Dynamic concurrency is currently only supported for the Azure Blob, Azure Queue, and Service Bus triggers and requires you to use the versions listed in the [extension support section below](#).

Benefits

Using dynamic concurrency provides the following benefits:

- **Simplified configuration:** You no longer have to manually determine per-trigger concurrency settings. The system learns the optimal values for your workload over time.
- **Dynamic adjustments:** Concurrency is adjusted up or down dynamically in real time, which allows the system to adapt to changing load patterns over time.
- **Instance health protection:** The runtime limits concurrency to levels a function app instance can comfortably handle. This protects the app from overloading itself by taking on more work than it should.
- **Improved throughput:** Overall throughput is improved because individual instances aren't pulling more work than they can quickly process. This allows work to be load-balanced more effectively across instances. For functions that can handle higher loads, higher throughput can be obtained by increasing concurrency to values above the default configuration.

Dynamic concurrency configuration

Dynamic concurrency can be enabled at the host level in the host.json file. When enabled, the concurrency levels of any binding extensions that support this feature are adjusted automatically as needed. In these cases, dynamic concurrency settings override any manually configured concurrency settings.

By default, dynamic concurrency is disabled. With dynamic concurrency enabled, concurrency starts at 1 for each function, and is adjusted up to an optimal value, which is determined by the host.

You can enable dynamic concurrency in your function app by adding the following settings in your host.json file:

```
JSON

{
  "version": "2.0",
  "concurrency": {
    "dynamicConcurrencyEnabled": true,
    "snapshotPersistenceEnabled": true
  }
}
```

When `SnapshotPersistenceEnabled` is `true`, which is the default, the learned concurrency values are periodically persisted to storage so new instances start from those values instead of starting from 1 and having to redo the learning.

Concurrency manager

Behind the scenes, when dynamic concurrency is enabled there's a concurrency manager process running in the background. This manager constantly monitors instance health metrics, like CPU and thread utilization, and changes throttles as needed. When one or more throttles are enabled, function concurrency is adjusted down until the host is healthy again. When throttles are disabled, concurrency is allowed to increase. Various heuristics are used to intelligently adjust concurrency up or down as needed based on these throttles. Over time, concurrency for each function stabilizes to a particular level.

Concurrency levels are managed for each individual function. As such, the system balances between resource-intensive functions that require a low level of concurrency and more lightweight functions that can handle higher concurrency. The balance of concurrency for each function helps to maintain overall health of the function app instance.

When dynamic concurrency is enabled, you'll see dynamic concurrency decisions in your logs. For example, you'll see logs when various throttles are enabled, and whenever concurrency is adjusted up or down for each function. These logs are written under the **Host.Concurrency** log category in the traces table.

Extension support

Dynamic concurrency is enabled for a function app at the host level, and any extensions that support dynamic concurrency run in that mode. Dynamic concurrency requires collaboration between the host and individual trigger extensions. Only the listed versions of the following extensions support dynamic concurrency.

[] [Expand table](#)

Extension	Version	Description
Queue storage	version 5.x	The Azure Queue storage trigger has its own message polling loop. When using static config, concurrency is governed by the <code>BatchSize</code> / <code>NewBatchThreshold</code> config options. When using dynamic concurrency, those configuration values are ignored. Dynamic concurrency is integrated into the message loop, so the number of messages fetched per iteration are dynamically adjusted. When throttles are enabled (host is overloaded), message processing will be paused until throttles are disabled. When throttles are disabled, concurrency will increase.
Blob storage	version 5.x	Internally, the Azure Blob storage trigger uses the same infrastructure that the Azure Queue Trigger uses. When new/updated blobs need to be processed, messages are written to a platform managed control queue, and that queue is processed using the same logic used for

Extension	Version	Description
Service Bus	version 5.x	<p>QueueTrigger. When dynamic concurrency is enabled, concurrency for the processing of that control queue will be dynamically managed.</p> <p>The Service Bus trigger currently supports three execution models. Dynamic concurrency affects these execution models as follows:</p> <ul style="list-style-type: none"> • Single dispatch topic/queue processing: Each invocation of your function processes a single message. When using static config, concurrency is governed by the <code>MaxConcurrentCalls</code> config option. When using dynamic concurrency, that config value is ignored, and concurrency is adjusted dynamically. • Session based single dispatch topic/queue processing: Each invocation of your function processes a single message. Depending on the number of active sessions for your topic/queue, each instance leases one or more sessions. Messages in each session are processed serially, to guarantee ordering in a session. When dynamic concurrency isn't used, concurrency is governed by the <code>MaxConcurrentSessions</code> setting. With dynamic concurrency enabled, <code>MaxConcurrentSessions</code> is ignored and the number of sessions each instance is processing is dynamically adjusted. • Batch processing: Each invocation of your function processes a batch of messages, governed by the <code>MaxMessageCount</code> setting. Because batch invocations are serial, concurrency for your batch-triggered function is always one and dynamic concurrency doesn't apply.

Designing Azure Functions for identical input

Article • 06/28/2022

The reality of event-driven and message-based architecture dictates the need to accept identical requests while preserving data integrity and system stability.

To illustrate, consider an elevator call button. As you press the button, it lights up and an elevator is sent to your floor. A few moments later, someone else joins you in the lobby. This person smiles at you and presses the illuminated button a second time. You smile back and chuckle to yourself as you're reminded that the command to call an elevator is idempotent.

Pressing an elevator call button a second, third, or fourth time has no bearing on the final result. When you press the button, regardless of the number of times, the elevator is sent to your floor. Idempotent systems, like the elevator, result in the same outcome no matter how many times identical commands are issued.

When it comes to building applications, consider the following scenarios:

- What happens if your inventory control application tries to delete the same product more than once?
- How does your human resource application behave if there is more than one request to create an employee record for the same person?
- Where does the money go if your banking app gets 100 requests to make the same withdrawal?

There are many contexts where requests to a function may receive identical commands. Some situations include:

- Retry policies sending the same request many times.
- Cached commands replayed to the application.
- Application errors sending multiple identical requests.

To protect data integrity and system health, an idempotent application contains logic that may contain the following behaviors:

- Verifying of the existence of data before trying to execute a delete.
- Checking to see if data already exists before trying to execute a create action.
- Reconciling logic that creates eventual consistency in data.
- Concurrency controls.
- Duplication detection.

- Data freshness validation.
- Guard logic to verify input data.

Ultimately idempotency is achieved by ensuring a given action is possible and is only executed once.

Azure Functions triggers and bindings concepts

Article • 09/10/2024

In this article, you learn the high-level concepts surrounding functions triggers and bindings.

Triggers cause a function to run. A trigger defines how a function is invoked and a function must have exactly one trigger. Triggers can also pass data into your function, as you would with method calls.

Binding to a function is a way of declaratively connecting your functions to other resources; bindings either pass data into your function (an *input binding*) or enable you to write data out from your function (an *output binding*) using *binding parameters*. Your function trigger is essentially a special type of input binding.

You can mix and match different bindings to suit your function's specific scenario. Bindings are optional and a function might have one or multiple input and/or output bindings.

Triggers and bindings let you avoid hardcoding access to other services. Your function receives data (for example, the content of a queue message) in function parameters. You send data (for example, to create a queue message) by using the return value of the function.

Consider the following examples of how you could implement different functions.

[] Expand table

Example scenario	Trigger	Input binding	Output binding
A new queue message arrives which runs a function to write to another queue.	Queue*	None	Queue*
A scheduled job reads Blob Storage contents and creates a new Azure Cosmos DB document.	Timer	Blob Storage	Azure Cosmos DB
The Event Grid is used to read an image from Blob Storage and a document from Azure Cosmos DB to send an email.	Event Grid	Blob Storage and Azure Cosmos DB	SendGrid

* Represents different queues

These examples aren't meant to be exhaustive, but are provided to illustrate how you can use triggers and bindings together. For a more comprehensive set of scenarios, see [Azure Functions scenarios](#).

Tip

Functions doesn't require you to use input and output bindings to connect to Azure services. You can always create an Azure SDK client in your code and use it instead for your data transfers. For more information, see [Connect to services](#).

Trigger and binding definitions

Triggers and bindings are defined differently depending on the development language. Make sure to select your language at the [top](#) of the article.

Bindings can be either input or output bindings. Not all services support both input and output bindings. See your specific binding extension for [specific bindings code examples](#).

This example shows an HTTP triggered function with an output binding that writes a message to an Azure Storage queue.

For C# class library functions, triggers and bindings are configured by decorating methods and parameters with C# attributes, where the specific attribute applied might depend on the C# runtime model:

Isolated worker model

The HTTP trigger (`HttpTrigger`) is defined on the `Run` method for a function named `HttpExample` that returns a `MultiResponse` object:

```
C#  
  
[Function("HttpExample")]
public static MultiResponse
Run([HttpTrigger(AuthorizationLevel.Function, "get", "post")]
HttpRequestData req,
    FunctionContext executionContext)
{
```

This example shows the `MultiResponse` object definition which both returns an `HttpResponse` to the HTTP request and also writes a message to a storage queue

using a `QueueOutput` binding:

C#

```
public class MultiResponse
{
    [QueueOutput("outqueue", Connection = "AzureWebJobsStorage")]
    public string[] Messages { get; set; }
    public HttpResponseMessage HttpResponseMessage { get; set; }
}
```

For more information, see the [C# isolated worker model guide](#).

Legacy C# Script functions use a `function.json` definition file. For more information, see the [Azure Functions C# script \(.csx\) developer reference](#).

This example is an HTTP triggered function that creates a queue item for each HTTP request received.

Add bindings to a function

You can connect your function to other services by using input or output bindings. Add a binding by adding its specific definitions to your function. To learn how, see [Add bindings to an existing function in Azure Functions](#).

Supported bindings

This table shows the bindings that are supported in the major versions of the Azure Functions runtime:

[] [Expand table](#)

Type	1.x ¹	2.x and higher ²	Trigger	Input	Output
Blob storage	✓	✓	✓	✓	✓
Azure Cosmos DB	✓	✓	✓	✓	✓
Azure Data Explorer		✓		✓	✓
Azure SQL		✓	✓	✓	✓
Dapr ⁴		✓	✓	✓	✓
Event Grid	✓	✓	✓		✓

Type	1.x ¹	2.x and higher ²	Trigger	Input	Output
Event Hubs	✓	✓	✓		✓
HTTP & webhooks	✓	✓	✓		✓
IoT Hub	✓	✓	✓		
Kafka ³		✓	✓		✓
Mobile Apps	✓			✓	✓
Notification Hubs	✓				✓
Queue storage	✓	✓	✓		✓
Redis		✓	✓		
RabbitMQ ³		✓	✓		✓
SendGrid	✓	✓			✓
Service Bus	✓	✓	✓		✓
SignalR		✓	✓	✓	✓
Table storage	✓	✓		✓	✓
Timer	✓	✓	✓		
Twilio	✓	✓			✓

Notes:

- Support will end for version 1.x of the Azure Functions runtime on September 14, 2026 [↗](#). We highly recommend that you [migrate your apps to version 4.x](#) for full support.
- Starting with the version 2.x runtime, all bindings except HTTP and Timer must be registered. See [Register binding extensions](#).
- Triggers aren't supported in the Consumption plan. Requires [runtime-driven triggers](#).
- Supported in Kubernetes, IoT Edge, and other self-hosted modes only.

For information about which bindings are in preview or are approved for production use, see [Supported languages](#).

Specific binding extension versions are only supported while the underlying service SDK is supported. Changes to support in the underlying service SDK version affect the support for the consuming extension.

Bindings code examples

Use the following table to find more examples of specific binding types that show you how to work with bindings in your functions. First, choose the language tab that corresponds to your project.

Binding code for C# depends on the [specific process model](#).

Isolated process

Register Azure Functions binding extensions

Article • 06/26/2024

Starting with Azure Functions version 2.x, the functions runtime only includes HTTP and timer triggers by default. Other [triggers and bindings](#) are available as separate packages.

.NET class library functions apps use bindings that are installed in the project as NuGet packages. Extension bundles allow non-.NET functions apps to use the same bindings without having to deal with the .NET infrastructure.

The following table indicates when and how you register bindings.

[+] Expand table

Development environment	Registration in Functions 1.x	Registration in Functions 2.x or later
Azure portal	Automatic	Automatic*
Non-.NET languages	Automatic	Use extension bundles (recommended) or explicitly install extensions
C# class library using Visual Studio	Use NuGet tools	Use NuGet tools
C# class library using Visual Studio Code	N/A	Use .NET Core CLI

* Portal uses extension bundles, including C# script.

Extension bundles

By default, extension bundles provide binding support for functions in these languages:

- Java
- JavaScript
- PowerShell
- Python
- C# script
- Other (custom handlers)

In rare cases where extension bundles can't be used, you can explicitly install binding extensions with your function app project. Extension bundles are supported for version 2.x and later version of the Functions runtime.

Extension bundles are a way to add a pre-defined set of compatible binding extensions to your function app. Extension bundles are versioned. Each version contains a specific set of binding extensions that are verified to work together. Select a bundle version based on the extensions that you need in your app.

When you create a non-.NET Functions project from tooling or in the portal, extension bundles are already enabled in the app's `host.json` file.

An extension bundle reference is defined by the `extensionBundle` section in a `host.json` as follows:

```
JSON
{
    "version": "2.0",
    "extensionBundle": {
        "id": "Microsoft.Azure.Functions.ExtensionBundle",
        "version": "[4.0.0, 5.0.0)"
    }
}
```

The following properties are available in `extensionBundle`:

[+] Expand table

Property	Description
<code>id</code>	The namespace for Microsoft Azure Functions extension bundles.
<code>version</code>	The version range of the bundle to install. The Functions runtime always picks the maximum permissible version defined by the version range or interval. For example, a <code>version</code> value range of <code>[4.0.0, 5.0.0)</code> allows all bundle versions from 4.0.0 up to but not including 5.0.0. For more information, see the interval notation for specifying version ranges .

The following table lists the currently available version ranges of the default `Microsoft.Azure.Functions.ExtensionBundle` bundles and links to the extensions they include.

[+] Expand table

Bundle version	Version in host.json	Included extensions
1.x	[1.* , 2.0.0)	See extensions.json ↗ used to generate the bundle.
2.x	[2.* , 3.0.0)	See extensions.json ↗ used to generate the bundle.
3.x	[3.3.0, 4.0.0)	See extensions.json ↗ used to generate the bundle.
4.x	[4.0.0, 5.0.0)	See extensions.json ↗ used to generate the bundle.

ⓘ Note

Even though host.json supports custom ranges for `version`, you should use a version range value from this table, such as [4.0.0, 5.0.0). For a complete list of extension bundle releases and extension versions in each release, see the [extension bundles release page](#) ↗.

Explicitly install extensions

For compiled C# class library projects ([in-process](#) and [isolated worker process](#)), you install the NuGet packages for the extensions that you need as you normally would. For examples see either the [Visual Studio Code developer guide](#) or the [Visual Studio developer guide](#). See the [extension bundles release page](#) ↗ to review combinations of extension versions that are verified compatible.

For non-.NET languages and C# script, when you can't use extension bundles you need to manually install required binding extensions in your local project. The easiest way is to use Azure Functions Core Tools. For more information, see [func extensions install](#).

For portal-only development, you need to manually create an extensions.csproj file in the root of your function app. To learn more, see [Manually install extensions](#).

Azure Functions binding expression patterns

Article • 08/31/2023

One of the most powerful features of [triggers and bindings](#) is *binding expressions*. In the `function.json` file and in function parameters and code, you can use expressions that resolve to values from various sources.

Most expressions are identified by wrapping them in curly braces. For example, in a queue trigger function, `{queueTrigger}` resolves to the queue message text. If the `path` property for a blob output binding is `container/{queueTrigger}` and the function is triggered by a queue message `HelloWorld`, a blob named `HelloWorld` is created.

Types of binding expressions

- [App settings](#)
- [Trigger file name](#)
- [Trigger metadata](#)
- [JSON payloads](#)
- [New GUID](#)
- [Current date and time](#)

Binding expressions - app settings

As a best practice, secrets and connection strings should be managed using app settings, rather than configuration files. This limits access to these secrets and makes it safe to store files such as `function.json` in public source control repositories.

App settings are also useful whenever you want to change configuration based on the environment. For example, in a test environment, you may want to monitor a different queue or blob storage container.

App setting binding expressions are identified differently from other binding expressions: they are wrapped in percent signs rather than curly braces. For example if the blob output binding path is `%Environment%/newblob.txt` and the `Environment` app setting value is `Development`, a blob will be created in the `Development` container.

When a function is running locally, app setting values come from the `local.settings.json` file.

ⓘ Note

The `connection` property of triggers and bindings is a special case and automatically resolves values as app settings, without percent signs.

The following example is an Azure Queue Storage trigger that uses an app setting `%input_queue_name%` to define the queue to trigger on.

JSON

```
{  
  "bindings": [  
    {  
      "name": "order",  
      "type": "queueTrigger",  
      "direction": "in",  
      "queueName": "%input_queue_name%",  
      "connection": "MY_STORAGE_ACCT_APP_SETTING"  
    }  
  ]  
}
```

You can use the same approach in class libraries:

C#

```
[FunctionName("QueueTrigger")]
public static void Run(
    [QueueTrigger("%input_queue_name%")]string myQueueItem,
    ILogger log)
{
    log.LogInformation($"C# Queue trigger function processed:
{myQueueItem}");
}
```

Trigger file name

The `path` for a Blob trigger can be a pattern that lets you refer to the name of the triggering blob in other bindings and function code. The pattern can also include filtering criteria that specify which blobs can trigger a function invocation.

For example, in the following Blob trigger binding, the `path` pattern is `sample-images/{filename}`, which creates a binding expression named `filename`:

JSON

```
{  
  "bindings": [  
    {  
      "name": "image",  
      "type": "blobTrigger",  
      "path": "sample-images/{filename}",  
      "direction": "in",  
      "connection": "MyStorageConnection"  
    },  
    ...  
  ]
```

The expression `filename` can then be used in an output binding to specify the name of the blob being created:

JSON

```
...  
{  
  "name": "imageSmall",  
  "type": "blob",  
  "path": "sample-images-sm/{filename}",  
  "direction": "out",  
  "connection": "MyStorageConnection"  
}  
],  
}
```

Function code has access to this same value by using `filename` as a parameter name:

C#

```
// C# example of binding to {filename}  
public static void Run(Stream image, string filename, Stream imageSmall,  
ILogger log)  
{  
    log.LogInformation($"Blob trigger processing: {filename}");  
    // ...  
}
```

The same ability to use binding expressions and patterns applies to attributes in class libraries. In the following example, the attribute constructor parameters are the same `path` values as the preceding `function.json` examples:

C#

```
[FunctionName("ResizeImage")]  
public static void Run(  
    [BlobTrigger("sample-images/{filename}")] Stream image,
```

```
[Blob("sample-images-sm/{filename}", FileAccess.Write)] Stream
imageSmall,
    string filename,
    ILogger log)
{
    log.LogInformation($"Blob trigger processing: {filename}");
    // ...
}
```

You can also create expressions for parts of the file name. In the following example, function is triggered only on file names that match a pattern: `anyname-anyfile.csv`

JSON

```
{
    "name": "myBlob",
    "type": "blobTrigger",
    "direction": "in",
    "path": "testContainerName/{date}-{filetype}.csv",
    "connection": "OrderStorageConnection"
}
```

For more information on how to use expressions and patterns in the Blob path string, see the [Storage blob binding reference](#).

Trigger metadata

In addition to the data payload provided by a trigger (such as the content of the queue message that triggered a function), many triggers provide additional metadata values. These values can be used as input parameters in C# and F# or properties on the `context.bindings` object in JavaScript.

For example, an Azure Queue storage trigger supports the following properties:

- QueueTrigger - triggering message content if a valid string
- DequeueCount
- ExpirationTime
- Id
- InsertionTime
- NextVisibleTime
- PopReceipt

These metadata values are accessible in `function.json` file properties. For example, suppose you use a queue trigger and the queue message contains the name of a blob

you want to read. In the `function.json` file, you can use `queueTrigger` metadata property in the blob `path` property, as shown in the following example:

```
JSON

{
  "bindings": [
    {
      "name": "myQueueItem",
      "type": "queueTrigger",
      "queueName": "myqueue-items",
      "connection": "MyStorageConnection",
    },
    {
      "name": "myInputBlob",
      "type": "blob",
      "path": "samples-workitems/{queueTrigger}",
      "direction": "in",
      "connection": "MyStorageConnection"
    }
  ]
}
```

Details of metadata properties for each trigger are described in the corresponding reference article. For an example, see [queue trigger metadata](#). Documentation is also available in the **Integrate** tab of the portal, in the **Documentation** section below the binding configuration area.

JSON payloads

In some scenarios, you can refer to the trigger payload's properties in configuration for other bindings in the same function and in function code. This requires that the trigger payload is JSON and is smaller than a threshold specific to each trigger. Typically, the payload size needs to be less than 100MB, but you should check the reference content for each trigger. Using trigger payload properties may impact the performance of your application, and it forces the trigger parameter type to be simple types like strings or a custom object type representing JSON data. It cannot be used with streams, clients, or other SDK types.

The following example shows the `function.json` file for a webhook function that receives a blob name in JSON: `{"BlobName": "HelloWorld.txt"}`. A Blob input binding reads the blob, and the HTTP output binding returns the blob contents in the HTTP response. Notice that the Blob input binding gets the blob name by referring directly to the `BlobName` property (`"path": "strings/{BlobName}"`)

JSON

```
{  
  "bindings": [  
    {  
      "name": "info",  
      "type": "httpTrigger",  
      "direction": "in",  
      "webHookType": "genericJson"  
    },  
    {  
      "name": "blobContents",  
      "type": "blob",  
      "direction": "in",  
      "path": "strings/{BlobName}",  
      "connection": "AzureWebJobsStorage"  
    },  
    {  
      "name": "res",  
      "type": "http",  
      "direction": "out"  
    }  
  ]  
}
```

For this to work in C# and F#, you need a class that defines the fields to be deserialized, as in the following example:

C#

```
using System.Net;  
using Microsoft.Extensions.Logging;  
  
public class BlobInfo  
{  
    public string BlobName { get; set; }  
}  
  
public static HttpResponseMessage Run(HttpRequestMessage req, BlobInfo info,  
string blobContents, ILogger log)  
{  
    if (blobContents == null) {  
        return req.CreateResponse(HttpStatusCode.NotFound);  
    }  
  
    log.LogInformation($"Processing: {info.BlobName}");  
  
    return req.CreateResponse(HttpStatusCode.OK, new {  
        data = $"{blobContents}"  
    });  
}
```

In JavaScript, JSON deserialization is automatically performed.

JavaScript

```
module.exports = async function (context, info) {
    if ('BlobName' in info) {
        context.res = {
            body: { 'data': context.bindings.blobContents }
        }
    } else {
        context.res = {
            status: 404
        };
    }
}
```

Dot notation

If some of the properties in your JSON payload are objects with properties, you can refer to those directly by using dot (.) notation. This notation doesn't work for [Azure Cosmos DB](#) or [Table storage](#) bindings.

For example, suppose your JSON looks like this:

JSON

```
{
    "BlobName": {
        "FileName": "HelloWorld",
        "Extension": "txt"
    }
}
```

You can refer directly to `FileName` as `BlobName.FileName`. With this JSON format, here's what the `path` property in the preceding example would look like:

JSON

```
"path": "strings/{BlobName.FileName}.{BlobName.Extension}",
```

In C#, you would need two classes:

C#

```
public class BlobInfo
{
    public BlobName BlobName { get; set; }
}
public class BlobName
{
    public string FileName { get; set; }
    public string Extension { get; set; }
}
```

Create GUIDs

The `{rand-guid}` binding expression creates a GUID. The following blob path in a `function.json` file creates a blob with a name like `50710cb5-84b9-4d87-9d83-a03d6976a682.txt`.

JSON

```
{
    "type": "blob",
    "name": "blobOutput",
    "direction": "out",
    "path": "my-output-container/{rand-guid}.txt"
}
```

Current time

The binding expression `DateTime` resolves to `DateTime.UtcNow`. The following blob path in a `function.json` file creates a blob with a name like `2018-02-16T17-59-55Z.txt`.

JSON

```
{
    "type": "blob",
    "name": "blobOutput",
    "direction": "out",
    "path": "my-output-container/{DateTime}.txt"
}
```

Binding at runtime

In C# and other .NET languages, you can use an imperative binding pattern, as opposed to the declarative bindings in `function.json` and attributes. Imperative binding is useful

when binding parameters need to be computed at runtime rather than design time. To learn more, see the [C# developer reference](#) or the [C# script developer reference](#).

Azure Functions error handling and retries

Article • 04/26/2024

Handling errors in Azure Functions is important to help you avoid lost data, avoid missed events, and monitor the health of your application. It's also an important way to help you understand the retry behaviors of event-based triggers.

This article describes general strategies for error handling and the available retry strategies.

ⓘ Important

Preview retry policy support for certain triggers was removed in December 2022.

Retry policies for supported triggers are now generally available (GA). For a list of extensions that currently support retry policies, see the [Retries](#) section.

Handling errors

Errors that occur in an Azure function can come from:

- Use of built-in Functions [triggers and bindings](#).
- Calls to APIs of underlying Azure services.
- Calls to REST endpoints.
- Calls to client libraries, packages, or third-party APIs.

To avoid loss of data or missed messages, it's important to practice good error handling. This table describes some recommended error-handling practices and provides links to more information.

[] [Expand table](#)

Recommendation	Details
Enable Application Insights	Azure Functions integrates with Application Insights to collect error data, performance data, and runtime logs. You should use Application Insights to discover and better understand errors that occur in your function executions. To learn more, see Monitor Azure Functions .
Use structured error handling	Capturing and logging errors is critical to monitoring the health of your application. The top-most level of any function code should include a

Recommendation	Details
	try/catch block. In the catch block, you can capture and log errors. For information about what errors might be raised by bindings, see Binding error codes . Depending on your specific retry strategy, you might also raise a new exception to run the function again.
Plan your retry strategy	Several Functions bindings extensions provide built-in support for retries and others let you define retry policies, which are implemented by the Functions runtime. For triggers that don't provide retry behaviors, you should consider implementing your own retry scheme. For more information, see Retries .
Design for idempotency	The occurrence of errors when you're processing data can be a problem for your functions, especially when you're processing messages. It's important to consider what happens when the error occurs and how to avoid duplicate processing. To learn more, see Designing Azure Functions for identical input .

Retries

There are two kinds of retries available for your functions:

- Built-in retry behaviors of individual trigger extensions
- Retry policies provided by the Functions runtime

The following table indicates which triggers support retries and where the retry behavior is configured. It also links to more information about errors that come from the underlying services.

[] [Expand table](#)

Trigger/binding	Retry source	Configuration
Azure Cosmos DB	Retry policies	Function-level
Blob Storage	Binding extension	host.json
Event Grid	Binding extension	Event subscription
Event Hubs	Retry policies	Function-level
Kafka	Retry policies	Function-level
Queue Storage	Binding extension	host.json
RabbitMQ	Binding extension	Dead letter queue ↗

Trigger/binding	Retry source	Configuration
Service Bus	Binding extension	host.json*
Timer	Retry policies	Function-level

*Requires version 5.x of the Azure Service Bus extension. In older extension versions, retry behaviors are implemented by the [Service Bus dead letter queue](#).

Retry policies

Azure Functions lets you define retry policies for specific trigger types, which are enforced by the runtime. These trigger types currently support retry policies:

- [Azure Cosmos DB](#)
- [Event Hubs](#)
- [Kafka](#)
- [Timer](#)

Retry policies aren't supported in version 1.x of the Functions runtime.

The retry policy tells the runtime to rerun a failed execution until either successful completion occurs or the maximum number of retries is reached.

A retry policy is evaluated when a function executed by a supported trigger type raises an uncaught exception. As a best practice, you should catch all exceptions in your code and raise new exceptions for any errors that you want to result in a retry.

Important

Event Hubs checkpoints aren't written until after the retry policy for the execution has completed. Because of this behavior, progress on the specific partition is paused until the current batch is done processing.

The version 5.x of the Event Hubs extension supports additional retry capabilities for interactions between the Functions host and the event hub. For more information, see `clientRetryOptions` in the [Event Hubs host.json reference](#).

Retry strategies

You can configure two retry strategies that are supported by policy:

Fixed delay

A specified amount of time is allowed to elapse between each retry.

When running in a Consumption plan, you are only billed for time your function code is executing. You aren't billed for the wait time between executions in either of these retry strategies.

Max retry counts

You can configure the maximum number of times that a function execution is retried before eventual failure. The current retry count is stored in memory of the instance.

It's possible for an instance to have a failure between retry attempts. When an instance fails during a retry policy, the retry count is lost. When there are instance failures, the Event Hubs trigger is able to resume processing and retry the batch on a new instance, with the retry count reset to zero. The timer trigger doesn't resume on a new instance.

This behavior means that the maximum retry count is a best effort. In some rare cases, an execution could be retried more than the requested maximum number of times. For Timer triggers, the retries can be less than the maximum number requested.

Retry examples

Examples are provided for both fixed delay and exponential backoff strategies. To see examples for a specific strategy, you must first select that strategy in the previous tab.

Isolated worker model

Function-level retries are supported with the following NuGet packages:

- [Microsoft.Azure.Functions.Worker.Sdk](#) >= 1.9.0
- [Microsoft.Azure.Functions.Worker.Extensions.EventHubs](#) >= 5.2.0
- [Microsoft.Azure.Functions.Worker.Extensions.Kafka](#) >= 3.8.0
- [Microsoft.Azure.Functions.Worker.Extensions.Timer](#) >= 4.2.0

C#

```
[Function(nameof(TimerFunction))]
[FixedDelayRetry(5, "00:00:10")]
public static void Run([TimerTrigger("0 */5 * * *")] TimerInfo
timerInfo,
    FunctionContext context)
```

```
{  
    var logger = context.GetLogger(nameof(TimerFunction));  
    logger.LogInformation($"Function Ran. Next timer schedule =  
{timerInfo.ScheduleStatus.Next}");  
}
```

[+] [Expand table](#)

Property	Description
MaxRetryCount	Required. The maximum number of retries allowed per function execution. -1 means to retry indefinitely.
DelayInterval	The delay used between retries. Specify it as a string with the format HH:mm:ss.

Binding error codes

When you're integrating with Azure services, errors might originate from the APIs of the underlying services. Information that relates to binding-specific errors is available in the "Exceptions and return codes" sections of the following articles:

- [Azure Cosmos DB](#)
- [Blob Storage](#)
- [Event Grid](#)
- [Event Hubs](#)
- [IoT Hub](#)
- [Notification Hubs](#)
- [Queue Storage](#)
- [Service Bus](#)
- [Table Storage](#)

- [Best practices for reliable Azure functions](#)

Shifting from Express.js to Azure Functions

Article • 09/20/2022

Express.js is one of the most popular Node.js frameworks for web developers and remains an excellent choice for building apps that serve API endpoints.

When migrating code to a serverless architecture, refactoring Express.js endpoints affects the following areas:

- **Middleware:** Express.js features a robust collection of middleware. Many middleware modules are no longer required in light of Azure Functions and [Azure API Management](#) capabilities. Ensure you can replicate or replace any logic handled by essential middleware before migrating endpoints.
- **Differing APIs:** The API used to process both requests and responses differs among Azure Functions and Express.js. The following example details the required changes.
- **Default route:** By default, Azure Functions endpoints are exposed under the `api` route. Routing rules are configurable via [routePrefix in the host.json file](#).
- **Configuration and conventions:** A Functions app uses the `function.json` file to define HTTP verbs, define security policies, and can configure the function's [input and output](#). By default, the folder name that which contains the function files defines the endpoint name, but you can change the name via the `route` property in the [function.json](#) file.

💡 Tip

Learn more through the interactive tutorial [Refactor Node.js and Express APIs to Serverless APIs with Azure Functions](#).

Example

Express.js

The following example shows a typical Express.js `GET` endpoint.

JavaScript

```
// server.js
app.get('/hello', (req, res) => {
  try {
    res.send("Success!");
  } catch(error) {
    const err = JSON.stringify(error);
    res.status(500).send(`Request error. ${err}`);
  }
});
```

When a `GET` request is sent to `/hello`, an `HTTP 200` response containing `Success` is returned. If the endpoint encounters an error, the response is an `HTTP 500` with the error details.

Azure Functions

Azure Functions organizes configuration and code files into a single folder for each function. By default, the name of the folder dictates the function name.

For instance, a function named `hello` has a folder with the following files.

files

```
| - hello
|   - function.json
|   - index.js
```

The following example implements the same result as the above Express.js endpoint, but with Azure Functions.

JavaScript

```
JavaScript

// hello/index.js
module.exports = async function (context, req) {
  try {
    context.res = { body: "Success!" };
  } catch(error) {
    const err = JSON.stringify(error);
    context.res = {
      status: 500,
      body: `Request error. ${err}`
    };
}
```

```
    }  
};
```

When moving to Functions, the following changes are made:

- **Module:** The function code is implemented as a JavaScript module.
- **Context and response object:** The [context](#) allows you to communicate with the Function's runtime. From the context, you can read request data and set the function's response. Synchronous code requires you to call 1.x `context.done()` to complete execution, while 2.x+ `async` functions resolve the request implicitly.
- **Naming convention:** The folder name used to contain the Azure Functions files is used as the endpoint name by default (this can be overridden in the [function.json](#)).
- **Configuration:** You define the HTTP verbs in the [function.json](#) file such as `POST` or `PUT`.

The following *function.json* file holds configuration information for the function.

JSON

```
{  
  "bindings": [  
    {  
      "authLevel": "function",  
      "type": "httpTrigger",  
      "direction": "in",  
      "name": "req",  
      "methods": ["get"]  
    },  
    {  
      "type": "http",  
      "direction": "out",  
      "name": "res"  
    }  
  ]  
}
```

By defining `get` in the `methods` array, the function is available to HTTP `GET` requests. If you want to your API to accept support `POST` requests, you can add `post` to the array as well.

Securing Azure Functions

Article • 07/18/2024

In many ways, planning for secure development, deployment, and operation of serverless functions is much the same as for any web-based or cloud-hosted application. [Azure App Service](#) provides the hosting infrastructure for your function apps. This article provides security strategies for running your function code, and how App Service can help you secure your functions.

The platform components of App Service, including Azure VMs, storage, network connections, web frameworks, management and integration features, are actively secured and hardened. App Service goes through vigorous compliance checks on a continuous basis to make sure that:

- Your app resources are [secured ↗](#) from the other customers' Azure resources.
- [VM instances and runtime software are regularly updated](#) to address newly discovered vulnerabilities.
- Communication of secrets (such as connection strings) between your app and other Azure resources (such as [SQL Database ↗](#)) stays within Azure and doesn't cross any network boundaries. Secrets are always encrypted when stored.
- All communication over the App Service connectivity features, such as [hybrid connection](#), is encrypted.
- Connections with remote management tools like Azure PowerShell, Azure CLI, Azure SDKs, REST APIs, are all encrypted.
- 24-hour threat management protects the infrastructure and platform against malware, distributed denial-of-service (DDoS), man-in-the-middle (MITM), and other threats.

For more information on infrastructure and platform security in Azure, see [Azure Trust Center ↗](#).

For a set of security recommendations that follow the [Microsoft cloud security benchmark](#), see [Azure Security Baseline for Azure Functions](#).

Secure operation

This section guides you on configuring and running your function app as securely as possible.

Defender for Cloud

Defender for Cloud integrates with your function app in the portal. It provides, for free, a quick assessment of potential configuration-related security vulnerabilities. Function apps running in a dedicated plan can also use Defender for Cloud's enhanced security features for an extra cost. To learn more, see [Protect your Azure App Service web apps and APIs](#).

Log and monitor

One way to detect attacks is through activity monitoring and logging analytics. Functions integrates with Application Insights to collect log, performance, and error data for your function app. Application Insights automatically detects performance anomalies and includes powerful analytics tools to help you diagnose issues and to understand how your functions are used. To learn more, see [Monitor Azure Functions](#).

Functions also integrates with Azure Monitor Logs to enable you to consolidate function app logs with system events for easier analysis. You can use diagnostic settings to configure streaming export of platform logs and metrics for your functions to the destination of your choice, such as a Logs Analytics workspace. To learn more, see [Monitoring Azure Functions with Azure Monitor Logs](#).

For enterprise-level threat detection and response automation, stream your logs and events to a Logs Analytics workspace. You can then connect Microsoft Sentinel to this workspace. To learn more, see [What is Microsoft Sentinel](#).

For more security recommendations for observability, see the [Azure security baseline for Azure Functions](#).

Secure HTTP endpoints

HTTP endpoints that are exposed publicly provide a vector of attack for malicious actors. When securing your HTTP endpoints, you should use a layered security approach. These techniques can be used to reduce the vulnerability of publicly exposed HTTP endpoints, ordered from most basic to most secure and restrictive:

- [Require HTTPS](#)
- [Require access keys](#)
- [Enable App Service Authentication/Authorization](#)
- [Use Azure API Management \(APIM\) to authenticate requests](#)
- [Deploy your function app to a virtual network](#)
- [Deploy your function app in isolation](#)

Require HTTPS

By default, clients can connect to function endpoints by using both HTTP or HTTPS. You should redirect HTTP to HTTPS because HTTPS uses the SSL/TLS protocol to provide a secure connection, which is both encrypted and authenticated. To learn how, see [Enforce HTTPS](#).

When you require HTTPS, you should also require the latest TLS version. To learn how, see [Enforce TLS versions](#).

For more information, see [Secure connections \(TLS\)](#).

Function access keys

Functions lets you use keys to make it harder to access your function endpoints. Unless the HTTP access level on an HTTP triggered function is set to `anonymous`, requests must include an access key in the request. For more information, see [Work with access keys in Azure Functions](#).

While access keys can provide some mitigation for unwanted access, the only way to truly secure your function endpoints is by implementing positive authentication of clients accessing your functions. You can then make authorization decisions based on identity.

For the highest level of security, you can also secure the entire application architecture inside a virtual network [using private endpoints](#) or by [running in isolation](#).

Enable App Service Authentication/Authorization

The App Service platform lets you use Microsoft Entra ID and several third-party identity providers to authenticate clients. You can use this strategy to implement custom authorization rules for your functions, and you can work with user information from your function code. To learn more, see [Authentication and authorization in Azure App Service](#) and [Working with client identities](#).

Use Azure API Management (APIM) to authenticate requests

APIM provides various API security options for incoming requests. To learn more, see [API Management authentication policies](#). With APIM in place, you can configure your function app to accept requests only from the IP address of your APIM instance. To learn more, see [IP address restrictions](#).

Permissions

As with any application or service, the goal is run your function app with the lowest possible permissions.

User management permissions

Functions supports built-in Azure role-based access control ([Azure RBAC](#)). Azure roles supported by Functions are [Contributor](#), [Owner](#), and [Reader](#).

Permissions are effective at the function app level. The Contributor role is required to perform most function app-level tasks. You also need the Contributor role along with the [Monitoring Reader permission](#) to be able to view log data in Application Insights. Only the Owner role can delete a function app.

Organize functions by privilege

Connection strings and other credentials stored in application settings gives all of the functions in the function app the same set of permissions in the associated resource. Consider minimizing the number of functions with access to specific credentials by moving functions that don't use those credentials to a separate function app. You can always use techniques such as [function chaining](#) to pass data between functions in different function apps.

Managed identities

A managed identity from Microsoft Entra ID allows your app to easily access other Microsoft Entra protected resources such as Azure Key Vault. The identity is managed by the Azure platform and does not require you to provision or rotate any secrets. For more about managed identities in Microsoft Entra ID, see [Managed identities for Azure resources](#).

Your application can be granted two types of identities:

- A **system-assigned identity** is tied to the app and is deleted if the app is deleted. An app can only have one system-assigned identity.
- A **user-assigned identity** is a standalone Azure resource that can be assigned to your app. An app can have multiple user-assigned identities, and one user-assigned identity can be assigned to multiple Azure resources, such as two App Service apps.

Managed identities can be used in place of secrets for connections from some triggers and bindings. See [Identity-based connections](#).

For more information, see [How to use managed identities for App Service and Azure Functions](#).

Restrict CORS access

[Cross-origin resource sharing \(CORS\)](#) is a way to allow web apps running in another domain to make requests to your HTTP trigger endpoints. App Service provides built-in support for handing the required CORS headers in HTTP requests. CORS rules are defined on a function app level.

While it's tempting to use a wildcard that allows all sites to access your endpoint, this defeats the purpose of CORS, which is to help prevent cross-site scripting attacks. Instead, add a separate CORS entry for the domain of each web app that must access your endpoint.

Managing secrets

To be able to connect to the various services and resources need to run your code, function apps need to be able to access secrets, such as connection strings and service keys. This section describes how to store secrets required by your functions.

Never store secrets in your function code.

Application settings

By default, you store connection strings and secrets used by your function app and bindings as application settings. This makes these credentials available to both your function code and the various bindings used by the function. The application setting (key) name is used to retrieve the actual value, which is the secret.

For example, every function app requires an associated storage account, which is used by the runtime. By default, the connection to this storage account is stored in an application setting named `AzureWebJobsStorage`.

App settings and connection strings are stored encrypted in Azure. They're decrypted only before being injected into your app's process memory when the app starts. The encryption keys are rotated regularly. If you prefer to instead manage the secure storage of your secrets, the app setting should instead be references to Azure Key Vault.

You can also encrypt settings by default in the local.settings.json file when developing functions on your local computer. For more information, see [Encrypt the local settings file](#).

Key Vault references

While application settings are sufficient for most many functions, you may want to share the same secrets across multiple services. In this case, redundant storage of secrets results in more potential vulnerabilities. A more secure approach is to a central secret storage service and use references to this service instead of the secrets themselves.

[Azure Key Vault](#) is a service that provides centralized secrets management, with full control over access policies and audit history. You can use a Key Vault reference in the place of a connection string or key in your application settings. To learn more, see [Use Key Vault references for App Service and Azure Functions](#).

Identity-based connections

Identities may be used in place of secrets for connecting to some resources. This has the advantage of not requiring the management of a secret, and it provides more fine-grained access control and auditing.

When you're writing code that creates the connection to [Azure services that support Microsoft Entra authentication](#), you can choose to use an identity instead of a secret or connection string. Details for both connection methods are covered in the documentation for each service.

Some Azure Functions binding extensions can be configured to access services using identity-based connections. For more information, see [Configure an identity-based connection](#).

Set usage quotas

Consider setting a usage quota on functions running in a Consumption plan. When you set a daily GB-sec limit on the sum total execution of functions in your function app, execution is stopped when the limit is reached. This could potentially help mitigate against malicious code executing your functions. To learn how to estimate consumption for your functions, see [Estimating Consumption plan costs](#).

Data validation

The triggers and bindings used by your functions don't provide any additional data validation. Your code must validate any data received from a trigger or input binding. If an upstream service is compromised, you don't want unvalidated inputs flowing through your functions. For example, if your function stores data from an Azure Storage queue in a relational database, you must validate the data and parameterize your commands to avoid SQL injection attacks.

Don't assume that the data coming into your function has already been validated or sanitized. It's also a good idea to verify that the data being written to output bindings is valid.

Handle errors

While it seems basic, it's important to write good error handling in your functions. Unhandled errors bubble-up to the host and are handled by the runtime. Different bindings handle processing of errors differently. To learn more, see [Azure Functions error handling](#).

Disable remote debugging

Make sure that remote debugging is disabled, except when you are actively debugging your functions. You can disable remote debugging in the **General Settings** tab of your function app **Configuration** in the portal.

Restrict CORS access

Azure Functions supports cross-origin resource sharing (CORS). CORS is configured [in the portal](#) and through the [Azure CLI](#). The CORS allowed origins list applies at the function app level. With CORS enabled, responses include the `Access-Control-Allow-Origin` header. For more information, see [Cross-origin resource sharing](#).

Don't use wildcards in your allowed origins list. Instead, list the specific domains from which you expect to get requests.

Store data encrypted

Azure Storage encrypts all data in a storage account at rest. For more information, see [Azure Storage encryption for data at rest](#).

By default, data is encrypted with Microsoft-managed keys. For additional control over encryption keys, you can supply customer-managed keys to use for encryption of blob

and file data. These keys must be present in Azure Key Vault for Functions to be able to access the storage account. To learn more, see [Encryption at rest using customer-managed keys](#).

Secure related resources

A function app frequently depends on additional resources, so part of securing the app is securing these external resources. At a minimum, most function apps include a dependency on Application Insights and Azure Storage. Consult the [Azure security baseline for Azure Monitor](#) and the [Azure security baseline for Storage](#) for guidance on securing these resources.

Important

The storage account is used to store important app data, sometimes including the application code itself. You should limit access from other apps and users to the storage account.

You should also consult the guidance for any resource types your application logic depends on, both as triggers and bindings and from your function code.

Secure deployment

Azure Functions tooling and integration make it easy to publish local function project code to Azure. It's important to understand how deployment works when considering security for an Azure Functions topology.

Deployment credentials

App Service deployments require a set of deployment credentials. These deployment credentials are used to secure your function app deployments. Deployment credentials are managed by the App Service platform and are encrypted at rest.

There are two kinds of deployment credentials:

- **User-level credentials:** one set of credentials for the entire Azure account. It can be used to deploy to App Service for any app, in any subscription, that the Azure account has permission to access. It's the default set that's surfaced in the portal GUI (such as the [Overview](#) and [Properties](#) of the app's [resource page](#)). When a user is granted app access via Role-Based Access Control (RBAC) or coadmin

permissions, that user can use their own user-level credentials until the access is revoked. Do not share these credentials with other Azure users.

- **App-level credentials:** one set of credentials for each app. It can be used to deploy to that app only. The credentials for each app are generated automatically at app creation. They can't be configured manually, but can be reset anytime. For a user to be granted access to app-level credentials via (RBAC), that user must be contributor or higher on the app (including Website Contributor built-in role). Readers are not allowed to publish, and can't access those credentials.

At this time, Key Vault isn't supported for deployment credentials. To learn more about managing deployment credentials, see [Configure deployment credentials for Azure App Service](#).

Disable FTP

By default, each function app has an FTP endpoint enabled. The FTP endpoint is accessed using deployment credentials.

FTP isn't recommended for deploying your function code. FTP deployments are manual, and they require you to synchronize triggers. To learn more, see [FTP deployment](#).

When you're not planning on using FTP, you should disable it in the portal. If you do choose to use FTP, you should [enforce FTPS](#).

Secure the scm endpoint

Every function app has a corresponding `scm` service endpoint that is used by the Advanced Tools (Kudu) service for deployments and other App Service [site extensions](#). The scm endpoint for a function app is always a URL in the form `https://<FUNCTION_APP_NAME>.scm.azurewebsites.net`. When you use network isolation to secure your functions, you must also account for this endpoint.

By having a separate scm endpoint, you can control deployments and other advanced tools functionalities for function app that are isolated or running in a virtual network. The scm endpoint supports both basic authentication (using deployment credentials) and single sign-on with your Azure portal credentials. To learn more, see [Accessing the Kudu service](#).

Continuous security validation

Since security needs to be considered at every step in the development process, it makes sense to also implement security validations in a continuous deployment environment. This is sometimes called DevSecOps. Using Azure DevOps for your deployment pipeline lets you integrate validation into the deployment process. For more information, see [Learn how to add continuous security validation to your CI/CD pipeline](#).

Network security

Restricting network access to your function app lets you control who can access your functions endpoints. Functions leverages App Service infrastructure to enable your functions to access resources without using internet-routable addresses or to restrict internet access to a function endpoint. To learn more about these networking options, see [Azure Functions networking options](#).

Set access restrictions

Access restrictions allow you to define lists of allow/deny rules to control traffic to your app. Rules are evaluated in priority order. If there are no rules defined, then your app will accept traffic from any address. To learn more, see [Azure App Service Access Restrictions](#).

Secure the storage account

When you create a function app, you must create or link to a general-purpose Azure Storage account that supports Blob, Queue, and Table storage. You can replace this storage account with one that is secured by a virtual network with access enabled by service endpoints or private endpoints. For more information, see [Restrict your storage account to a virtual network](#).

Deploy your function app to a virtual network

[Azure Private Endpoint](#) is a network interface that connects you privately and securely to a service powered by Azure Private Link. Private Endpoint uses a private IP address from your virtual network, effectively bringing the service into your virtual network.

You can use Private Endpoint for your functions hosted in the [Premium](#) and [App Service](#) plans.

If you want to make calls to Private Endpoints, then you must make sure that your DNS lookups resolve to the private endpoint. You can enforce this behavior in one of the

following ways:

- Integrate with Azure DNS private zones. When your virtual network doesn't have a custom DNS server, this is done automatically.
- Manage the private endpoint in the DNS server used by your app. To do this you must know the private endpoint address and then point the endpoint you are trying to reach to that address using an A record.
- Configure your own DNS server to forward to [Azure DNS private zones](#).

To learn more, see [using Private Endpoints for Web Apps](#).

Deploy your function app in isolation

Azure App Service Environment provides a dedicated hosting environment in which to run your functions. These environments let you configure a single front-end gateway that you can use to authenticate all incoming requests. For more information, see [Configuring a Web Application Firewall \(WAF\) for App Service Environment](#).

Use a gateway service

Gateway services, such as [Azure Application Gateway](#) and [Azure Front Door](#) let you set up a Web Application Firewall (WAF). WAF rules are used to monitor or block detected attacks, which provide an extra layer of protection for your functions. To set up a WAF, your function app needs to be running in an ASE or using Private Endpoints (preview). To learn more, see [Using Private Endpoints](#).

Azure security baseline for Functions

Article • 12/26/2023

This security baseline applies guidance from the [Microsoft cloud security benchmark version 1.0](#) to Functions. The Microsoft cloud security benchmark provides recommendations on how you can secure your cloud solutions on Azure. The content is grouped by the security controls defined by the Microsoft cloud security benchmark and the related guidance applicable to Functions.

You can monitor this security baseline and its recommendations using Microsoft Defender for Cloud. Azure Policy definitions will be listed in the Regulatory Compliance section of the Microsoft Defender for Cloud portal page.

When a feature has relevant Azure Policy Definitions, they are listed in this baseline to help you measure compliance with the Microsoft cloud security benchmark controls and recommendations. Some recommendations may require a paid Microsoft Defender plan to enable certain security scenarios.

ⓘ Note

Features not applicable to Functions have been excluded. To see how Functions completely maps to the Microsoft cloud security benchmark, see the [full Functions security baseline mapping file ↗](#).

Security profile

The security profile summarizes high-impact behaviors of Functions, which may result in increased security considerations.

ⓘ [Expand table](#)

Service Behavior Attribute	Value
Product Category	Compute, Web
Customer can access HOST / OS	No Access
Service can be deployed into customer's virtual network	True
Stores customer content at rest	True

Virtual Network Integration

Description: Service supports deployment into customer's private Virtual Network (VNet). [Learn more](#).

[+] [Expand table](#)

Supported	Enabled By Default	Configuration Responsibility
True	False	Customer

Configuration Guidance: Deploy the service into a virtual network. Assign private IPs to the resource (where applicable) unless there is a strong reason to assign public IPs directly to the resource.

Note: Networking features are exposed by the service but need to be configured for the application. By default, public network access is allowed.

Reference: [Azure Functions networking options](#)

Network Security Group Support

Description: Service network traffic respects Network Security Groups rule assignment on its subnets. [Learn more](#).

[+] [Expand table](#)

Supported	Enabled By Default	Configuration Responsibility
True	False	Customer

Configuration Guidance: Use network security groups (NSG) to restrict or monitor traffic by port, protocol, source IP address, or destination IP address. Create NSG rules to restrict your service's open ports (such as preventing management ports from being

accessed from untrusted networks). Be aware that by default, NSGs deny all inbound traffic but allow traffic from virtual network and Azure Load Balancers.

Reference: [Azure Functions networking options](#)

NS-2: Secure cloud services with network controls

Features

Azure Private Link

Description: Service native IP filtering capability for filtering network traffic (not to be confused with NSG or Azure Firewall). [Learn more](#).

[+] Expand table

Supported	Enabled By Default	Configuration Responsibility
True	False	Customer

Configuration Guidance: Deploy private endpoints for all Azure resources that support the Private Link feature, to establish a private access point for the resources.

Reference: [Azure Functions networking options](#)

Disable Public Network Access

Description: Service supports disabling public network access either through using service-level IP ACL filtering rule (not NSG or Azure Firewall) or using a 'Disable Public Network Access' toggle switch. [Learn more](#).

[+] Expand table

Supported	Enabled By Default	Configuration Responsibility
True	False	Customer

Feature notes: Azure Functions can be configured with private endpoints, but there is not presently a single toggle for disabling public network access absent configuring private endpoints.

Configuration Guidance: Disable public network access either using the service-level IP ACL filtering rule or a toggling switch for public network access.

Identity management

For more information, see the [Microsoft cloud security benchmark: Identity management](#).

IM-1: Use centralized identity and authentication system

Features

Azure AD Authentication Required for Data Plane Access

Description: Service supports using Azure AD authentication for data plane access.

[Learn more.](#)

[] Expand table

Supported	Enabled By Default	Configuration Responsibility
True	False	Customer

Feature notes: Customer-owned endpoints may be configured to require Azure AD authentication requirements. System-provided endpoints for deployment operations and advanced developer tools support Azure AD but by default have the ability to alternatively use publishing credentials. These publishing credentials can be disabled. Some data plane endpoints on the app may be accessed by administrative keys configured in the Functions host, and these are not configurable with Azure AD requirements at this time.

Configuration Guidance: Use Azure Active Directory (Azure AD) as the default authentication method to control your data plane access.

Reference: [Configure deployment credentials - disable basic authentication](#)

Local Authentication Methods for Data Plane Access

Description: Local authentications methods supported for data plane access, such as a local username and password. [Learn more.](#)

[] Expand table

Supported	Enabled By Default	Configuration Responsibility
True	True	Microsoft

Feature notes: Deployment credentials are created by default, but they can be disabled. Some operations exposed by the application runtime may be performed using an administrative key, which cannot presently be disabled. This key can be stored in Azure Key Vault, and it can be regenerated at any time. Avoid the usage of local authentication methods or accounts, these should be disabled wherever possible. Instead use Azure AD to authenticate where possible.

Configuration Guidance: No additional configurations are required as this is enabled on a default deployment.

Reference: [Disable basic authentication](#)

IM-3: Manage application identities securely and automatically

Features

Managed Identities

Description: Data plane actions support authentication using managed identities. [Learn more.](#)

[+] Expand table

Supported	Enabled By Default	Configuration Responsibility
True	False	Customer

Configuration Guidance: Use Azure managed identities instead of service principals when possible, which can authenticate to Azure services and resources that support Azure Active Directory (Azure AD) authentication. Managed identity credentials are fully managed, rotated, and protected by the platform, avoiding hard-coded credentials in source code or configuration files.

Reference: [How to use managed identities for App Service and Azure Functions](#)

Service Principals

Description: Data plane supports authentication using service principals. [Learn more.](#)

[+] Expand table

Supported	Enabled By Default	Configuration Responsibility
True	False	Customer

Configuration Guidance: There is no current Microsoft guidance for this feature configuration. Please review and determine if your organization wants to configure this security feature.

Microsoft Defender for Cloud monitoring

Features

Azure RBAC for Data Plane

Description: Azure Role-Based Access Control (Azure RBAC) can be used to manage access to service's data plane actions. [Learn more](#).

[+] Expand table

Supported	Enabled By Default	Configuration Responsibility
True	False	Customer

Feature notes: The only data-plane actions which can leverage Azure RBAC are the Kudu/SCM/deployment endpoints. These require permission over the `Microsoft.Web/sites/publish/Action` operation. Endpoints exposed by the customer application itself are not covered by Azure RBAC.

Configuration Guidance: Use Azure role-based access control (Azure RBAC) to manage Azure resource access through built-in role assignments. Azure RBAC roles can be assigned to users, groups, service principals, and managed identities.

Reference: [RBAC permissions required to access Kudu](#)

PA-8: Determine access process for cloud provider support

Features

Customer Lockbox

Description: Customer Lockbox can be used for Microsoft support access. [Learn more](#).

[+] Expand table

Supported	Enabled By Default	Configuration Responsibility
True	False	Customer

Configuration Guidance: In support scenarios where Microsoft needs to access your data, use Customer Lockbox to review, then approve or reject each of Microsoft's data access requests.

Data protection

For more information, see the [Microsoft cloud security benchmark: Data protection](#).

DP-2: Monitor anomalies and threats targeting sensitive data

Features

Data Leakage/Loss Prevention

Description: Service supports DLP solution to monitor sensitive data movement (in customer's content). [Learn more](#).

[+] Expand table

Supported	Enabled By Default	Configuration Responsibility
False	Not Applicable	Not Applicable

Configuration Guidance: This feature is not supported to secure this service.

DP-3: Encrypt sensitive data in transit

Features

Data in Transit Encryption

Description: Service supports data in-transit encryption for data plane. [Learn more](#).

[+] Expand table

Supported	Enabled By Default	Configuration Responsibility
True	False	Customer

Feature notes: Function apps are created by default to support TLS 1.2 as a minimum version, but an app can be configured with a lower version through a configuration setting. HTTPS is not required of incoming requests by default, but this can also be set via a configuration setting, at which point any HTTP request will be automatically redirected to use HTTPS.

Configuration Guidance: Enable secure transfer in services where there is a native data in transit encryption feature built in. Enforce HTTPS on any web applications and services and ensure TLS v1.2 or later is used. Legacy versions such as SSL 3.0, TLS v1.0 should be disabled. For remote management of Virtual Machines, use SSH (for Linux) or RDP/TLS (for Windows) instead of an unencrypted protocol.

Reference: [Add and manage TLS/SSL certificates in Azure App Service](#)

Microsoft Defender for Cloud monitoring

Azure Policy built-in definitions - Microsoft.Web:

Name (Azure portal)	Description	Effect(s)	Version (GitHub)
App Service apps should only be accessible over HTTPS ↗	Use of HTTPS ensures server/service authentication and protects data in transit from network layer eavesdropping attacks.	Audit, Disabled, Deny	4.0.0 ↗

DP-4: Enable data at rest encryption by default

Features

Data at Rest Encryption Using Platform Keys

Description: Data at-rest encryption using platform keys is supported, any customer content at rest is encrypted with these Microsoft managed keys. [Learn more](#).

[+] Expand table

Supported	Enabled By Default	Configuration Responsibility
True	True	Microsoft

Configuration Guidance: No additional configurations are required as this is enabled on a default deployment.

DP-5: Use customer-managed key option in data at rest encryption when required

Features

Data at Rest Encryption Using CMK

Description: Data at-rest encryption using customer-managed keys is supported for customer content stored by the service. [Learn more](#).

[\[+\] Expand table](#)

Supported	Enabled By Default	Configuration Responsibility
True	False	Customer

Feature notes: Azure Functions does not directly support this feature, but an application can be configured to leverage services which do, in place of any possible data storage in Functions. Azure Files may be mounted as the file system, all App Settings, including secrets, may be stored in Azure Key Vault, and deployment options such as run-from-package may pull content from Azure Blob storage.

Configuration Guidance: If required for regulatory compliance, define the use case and service scope where encryption using customer-managed keys are needed. Enable and implement data at rest encryption using customer-managed key for those services.

Reference: [Encrypt your application data at rest using customer-managed keys](#)

DP-6: Use a secure key management process

Features

Key Management in Azure Key Vault

Description: The service supports Azure Key Vault integration for any customer keys, secrets, or certificates. [Learn more.](#)

[+] [Expand table](#)

Supported	Enabled By Default	Configuration Responsibility
True	False	Customer

Configuration Guidance: Use Azure Key Vault to create and control the life cycle of your encryption keys, including key generation, distribution, and storage. Rotate and revoke your keys in Azure Key Vault and your service based on a defined schedule or when there is a key retirement or compromise. When there is a need to use customer-managed key (CMK) in the workload, service, or application level, ensure you follow the best practices for key management: Use a key hierarchy to generate a separate data encryption key (DEK) with your key encryption key (KEK) in your key vault. Ensure keys are registered with Azure Key Vault and referenced via key IDs from the service or application. If you need to bring your own key (BYOK) to the service (such as importing HSM-protected keys from your on-premises HSMs into Azure Key Vault), follow recommended guidelines to perform initial key generation and key transfer.

Reference: [Use Key Vault references for App Service and Azure Functions](#)

DP-7: Use a secure certificate management process

Features

Certificate Management in Azure Key Vault

Description: The service supports Azure Key Vault integration for any customer certificates. [Learn more.](#)

[+] [Expand table](#)

Supported	Enabled By Default	Configuration Responsibility
True	False	Customer

Configuration Guidance: Use Azure Key Vault to create and control the certificate lifecycle, including creation, importing, rotation, revocation, storage, and purging of the certificate. Ensure the certificate generation follows defined standards without using any insecure properties, such as: insufficient key size, overly long validity period, insecure

cryptography. Setup automatic rotation of the certificate in Azure Key Vault and the Azure service (if supported) based on a defined schedule or when there is a certificate expiration. If automatic rotation is not supported in the application, ensure they are still rotated using manual methods in Azure Key Vault and the application.

Reference: [Add a TLS/SSL certificate in Azure App Service](#)

Asset management

For more information, see the [Microsoft cloud security benchmark: Asset management](#).

AM-2: Use only approved services

Features

Azure Policy Support

Description: Service configurations can be monitored and enforced via Azure Policy.
[Learn more.](#)

[+] Expand table

Supported	Enabled By Default	Configuration Responsibility
True	False	Customer

Configuration Guidance: Use Microsoft Defender for Cloud to configure Azure Policy to audit and enforce configurations of your Azure resources. Use Azure Monitor to create alerts when there is a configuration deviation detected on the resources. Use Azure Policy [deny] and [deploy if not exists] effects to enforce secure configuration across Azure resources.

Logging and threat detection

For more information, see the [Microsoft cloud security benchmark: Logging and threat detection](#).

LT-1: Enable threat detection capabilities

Features

Microsoft Defender for Service / Product Offering

Description: Service has an offering-specific Microsoft Defender solution to monitor and alert on security issues. [Learn more.](#)

[+] [Expand table](#)

Supported	Enabled By Default	Configuration Responsibility
True	False	Customer

Feature notes: Defender for App Service includes Azure Functions. If this solution is enabled, function apps under the enablement scope will be included.

Configuration Guidance: Use Azure Active Directory (Azure AD) as the default authentication method to control your management plane access. When you get an alert from Microsoft Defender for Key Vault, investigate and respond to the alert.

Reference: [Defender for App Service](#)

LT-4: Enable logging for security investigation

Features

Azure Resource Logs

Description: Service produces resource logs that can provide enhanced service-specific metrics and logging. The customer can configure these resource logs and send them to their own data sink like a storage account or log analytics workspace. [Learn more.](#)

[+] [Expand table](#)

Supported	Enabled By Default	Configuration Responsibility
True	False	Customer

Configuration Guidance: Enable resource logs for the service. For example, Key Vault supports additional resource logs for actions that get a secret from a key vault or and Azure SQL has resource logs that track requests to a database. The content of resource logs varies by the Azure service and resource type.

Backup and recovery

For more information, see the [Microsoft cloud security benchmark: Backup and recovery](#).

BR-1: Ensure regular automated backups

Features

Azure Backup

Description: The service can be backed up by the Azure Backup service. [Learn more](#).

[+] [Expand table](#)

Supported	Enabled By Default	Configuration Responsibility
False	Not Applicable	Not Applicable

Feature notes: A feature for backing up an application is available if hosted on a Standard, Premium, or Isolated App Service plan. This feature does not leverage Azure Backup and does not include event sources or externally linked storage. See [/azure/app-service/manage-backup](#) for more details.

Configuration Guidance: This feature is not supported to secure this service.

Service Native Backup Capability

Description: Service supports its own native backup capability (if not using Azure Backup). [Learn more](#).

[+] [Expand table](#)

Supported	Enabled By Default	Configuration Responsibility
True	False	Customer

Feature notes: A backup feature is available to apps running on Standard, Premium, and Isolated App Service plans. This does not include backing up event sources or externally provided storage.

Configuration Guidance: There is no current Microsoft guidance for this feature configuration. Please review and determine if your organization wants to configure this security feature.

Reliability in Azure Functions

Article • 09/11/2024

This article describes reliability support in [Azure Functions](#), and covers both intra-regional resiliency with [availability zones](#) and [cross-region recovery and business continuity](#). For a more detailed overview of reliability principles in Azure, see [Azure reliability](#).

Availability zone support for Azure Functions is available on both Premium (Elastic Premium) and Dedicated (App Service) plans. This article focuses on zone redundancy support for Premium plans. For zone redundancy on Dedicated plans, see [Migrate App Service to availability zone support](#).

Availability zone support

Azure availability zones are at least three physically separate groups of datacenters within each Azure region. Datacenters within each zone are equipped with independent power, cooling, and networking infrastructure. In the case of a local zone failure, availability zones are designed so that if the one zone is affected, regional services, capacity, and high availability are supported by the remaining two zones.

Failures can range from software and hardware failures to events such as earthquakes, floods, and fires. Tolerance to failures is achieved with redundancy and logical isolation of Azure services. For more detailed information on availability zones in Azure, see [Regions and availability zones](#).

Azure availability zones-enabled services are designed to provide the right level of reliability and flexibility. They can be configured in two ways. They can be either zone redundant, with automatic replication across zones, or zonal, with instances pinned to a specific zone. You can also combine these approaches. For more information on zonal vs. zone-redundant architecture, see [Recommendations for using availability zones and regions](#).

Azure Functions supports a [zone-redundant deployment](#).

When you configure Functions as zone redundant, the platform automatically spreads the function app instances across three zones in the selected region.

Instance spreading with a zone-redundant deployment is determined inside the following rules, even as the app scales in and out:

- The minimum function app instance count is three.

- When you specify a capacity larger than three, the instances are spread evenly only when the capacity is a multiple of 3.
- For a capacity value more than $3 \times N$, extra instances are spread across the remaining one or two zones.

Important

Azure Functions can run on the Azure App Service platform. In the App Service platform, plans that host Premium plan function apps are referred to as Elastic Premium plans, with SKU names like EP1. If you choose to run your function app on a Premium plan, make sure to create a plan with an SKU name that starts with "E", such as EP1. App Service plan SKU names that start with "P", such as P1V2 (Premium V2 Small plan), are actually [Dedicated hosting plans](#). Because they are Dedicated and not Elastic Premium, plans with SKU names starting with "P" won't scale dynamically and may increase your costs.

Regional availability

Zone-redundant Premium plans are available in the following regions:

[\[+\] Expand table](#)

Americas	Europe	Middle East	Africa	Asia Pacific
Brazil South	France Central	Israel Central	South Africa North	Australia East
Canada Central	Germany West Central	Qatar Central		Central India
Central US	Italy North	UAE North		China North 3
East US	North Europe			East Asia
East US 2	Norway East			Japan East
South Central US	Sweden Central			Southeast Asia
West US 2	Switzerland North			
West US 3	UK South			
	West Europe			

Prerequisites

Availability zone support is a property of the Premium plan. The following are the current requirements/limitations for enabling availability zones:

- You can only enable availability zones when creating a Premium plan for your function app. You can't convert an existing Premium plan to use availability zones.
- You must use a [zone redundant storage account \(ZRS\)](#) for your function app's [storage account](#). If you use a different type of storage account, Functions can show unexpected behavior during a zonal outage.
- Both Windows and Linux are supported.
- Must be hosted on an [Elastic Premium](#) or Dedicated hosting plan. To learn how to use zone redundancy with a Dedicated plan, see [Migrate App Service to availability zone support](#).
 - Availability zone support isn't currently available for function apps on [Consumption](#) plans.
- Function apps hosted on a Premium plan must have a minimum [always ready instances](#) count of three.
 - The platform enforces this minimum count behind the scenes if you specify an instance count fewer than three.
- If you aren't using Premium plan or a scale unit that supports availability zones, are in an unsupported region, or are unsure, see the [migration guidance](#).

Pricing

There's no extra cost associated with enabling availability zones. Pricing for a zone redundant Premium App Service plan is the same as a single zone Premium plan. For each App Service plan you use, you're charged based on the SKU you choose, the capacity you specify, and any instances you scale to based on your autoscale criteria. If you enable availability zones but specify a capacity less than three for an App Service plan, the platform enforces a minimum instance count of three for that App Service plan and charges you for those three instances.

Create a zone-redundant Premium plan and function app

There are currently two ways to deploy a zone-redundant Premium plan and function app. You can use either the [Azure portal](#) or an ARM template.

Azure portal

1. In the Azure portal, go to the [Create Function App](#) page. For more information about creating a function app in the portal, see [Create a function](#)

app.

2. Select **Functions Premium** and then select the **Select** button. This article describes how to create a zone redundant app in a Premium plan. Zone redundancy isn't currently available in Consumption plans. For information on zone redundancy on app service plans, see [Reliability in Azure App Service](#).
3. On the **Create Function App (Functions Premium)** page, on the **Basics** tab, enter the settings for your function app. Pay special attention to the settings in the following table (also highlighted in the following screenshot), which have specific requirements for zone redundancy.

 [Expand table](#)

Setting	Suggested value	Notes for zone redundancy
Region	Your preferred supported region	The region under which the new function app is created. You must pick a region that supports availability zones. See the region availability list .
Pricing plan	One of the Elastic Premium plans. For more information, see Available instance SKUs .	This article describes how to create a zone redundant app in a Premium plan. Zone redundancy isn't currently available in Consumption plans. For information on zone redundancy on App Service plans, see Reliability in Azure App Service .
Zone redundancy	Enabled	This setting specifies whether your app is zone redundant. You won't be able to select <code>Enabled</code> unless you have chosen a region that supports zone redundancy, as described previously.

Create a function app, which lets you group functions as a logical unit for easier management, deployment and sharing of resources. Functions lets you execute your code in a serverless environment without having to first create a VM or publish a web application.

Zone redundancy

An App Service plan can be deployed as a zone redundant service in the regions that support it. This is a deployment time only decision. You can't make an App Service plan zone redundant after it has been deployed [Learn more](#)

Zone redundancy

- Enabled:** Your App Service plan and the apps in it will be zone redundant. The minimum App Service plan instance count will be three.
- Disabled:** Your App Service Plan and the apps in it will not be zone redundant. The minimum App Service plan instance count will be one.

4. On the **Storage** tab, enter the settings for your function app storage account. Pay special attention to the setting in the following table, which has specific requirements for zone redundancy.

i Expand table

Setting	Suggested value	Notes for zone redundancy
Storage account	A zone-redundant storage account	As described in the prerequisites section, we strongly recommend using a zone-redundant storage account for your zone-redundant function app.

5. For the rest of the function app creation process, create your function app as normal. There are no settings in the rest of the creation process that affect zone redundancy.

After the zone-redundant plan is created and deployed, any function app hosted on your new plan is considered zone-redundant.

Availability zone migration

Azure Function Apps currently doesn't support in-place migration of existing function apps instances. For information on how to migrate the public multitenant Premium plan from non-availability zone to availability zone support, see [Migrate App Service to availability zone support](#).

Zone down experience

All available function app instances of zone-redundant function apps are enabled and processing events. When a zone goes down, Functions detect lost instances and automatically attempts to find new replacement instances if needed. Elastic scale behavior still applies. However, in a zone-down scenario there's no guarantee that requests for additional instances can succeed, since back-filling lost instances occurs on a best-effort basis. Applications that are deployed in an availability zone enabled Premium plan continue to run even when other zones in the same region suffer an outage. However, it's possible that non-runtime behaviors could still be impacted from an outage in other availability zones. These impacted behaviors can include Premium plan scaling, application creation, application configuration, and application publishing. Zone redundancy for Premium plans only guarantees continued uptime for deployed applications.

When Functions allocates instances to a zone redundant Premium plan, it uses best effort zone balancing offered by the underlying Azure Virtual Machine Scale Sets. A Premium plan is considered balanced when each zone has either the same number of VMs (± 1 VM) in all of the other zones used by the Premium plan.

Cross-region disaster recovery and business continuity

Disaster recovery (DR) is about recovering from high-impact events, such as natural disasters or failed deployments that result in downtime and data loss. Regardless of the

cause, the best remedy for a disaster is a well-defined and tested DR plan and an application design that actively supports DR. Before you begin to think about creating your disaster recovery plan, see [Recommendations for designing a disaster recovery strategy](#).

When it comes to DR, Microsoft uses the [shared responsibility model](#). In a shared responsibility model, Microsoft ensures that the baseline infrastructure and platform services are available. At the same time, many Azure services don't automatically replicate data or fall back from a failed region to cross-replicate to another enabled region. For those services, you are responsible for setting up a disaster recovery plan that works for your workload. Most services that run on Azure platform as a service (PaaS) offerings provide features and guidance to support DR and you can use [service-specific features to support fast recovery](#) to help develop your DR plan.

This section explains some of the strategies that you can use to deploy Functions to allow for disaster recovery.

For disaster recovery for Durable Functions, see [Disaster recovery and geo-distribution in Azure Durable Functions](#).

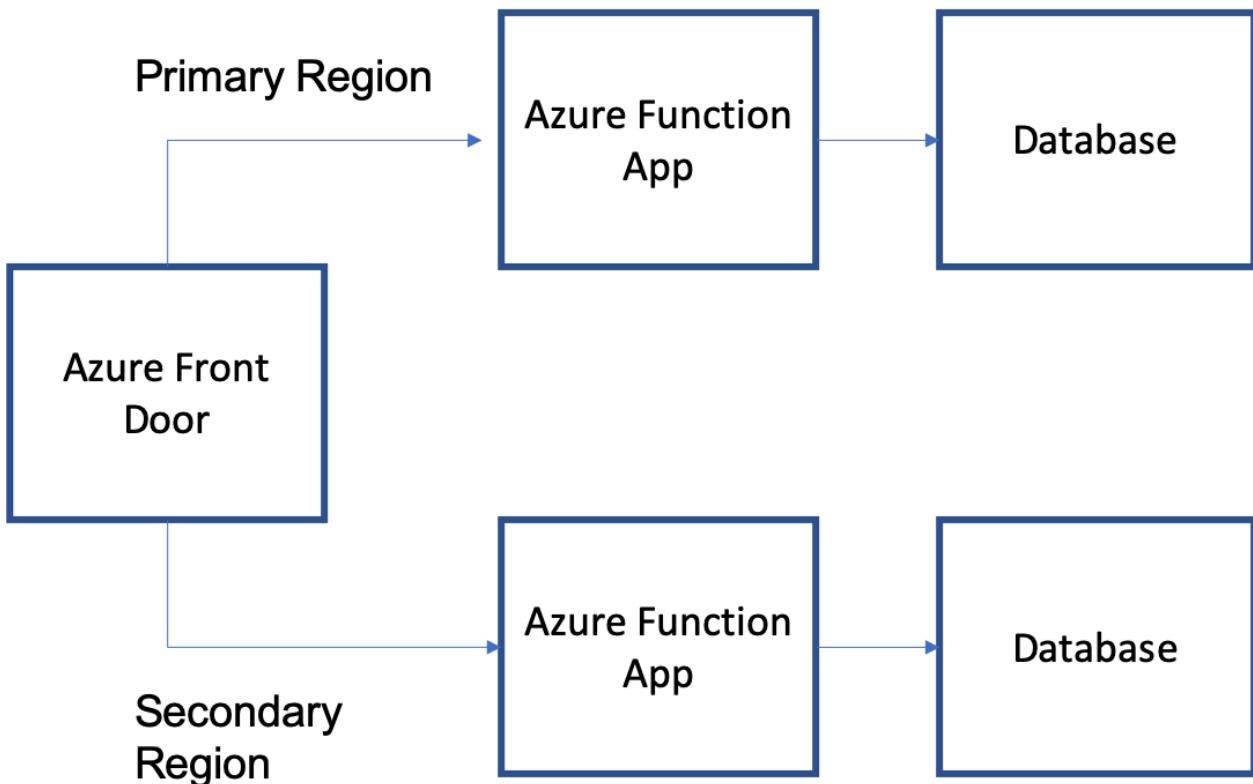

Multi-region disaster recovery

Because there is no built-in redundancy available, functions run in a function app in a specific Azure region. To avoid loss of execution during outages, you can redundantly deploy the same functions to function apps in multiple regions. To learn more about multi-region deployments, see the guidance in [Highly available multi-region web application](#).

When you run the same function code in multiple regions, there are two patterns to consider, [active-active](#) and [active-passive](#).

Active-active pattern for HTTP trigger functions

With an active-active pattern, functions in both regions are actively running and processing events, either in a duplicate manner or in rotation. It's recommended that you use an active-active pattern in combination with [Azure Front Door](#) for your critical HTTP triggered functions, which can route and round-robin HTTP requests between functions running in multiple regions. Front door can also periodically check the health of each endpoint. When a function in one region stops responding to health checks, Azure Front Door takes it out of rotation, and only forwards traffic to the remaining healthy functions.

ⓘ Important

Although, it's highly recommended that you use the [active-passive pattern](#) for non-HTTPS trigger functions. You can create active-active deployments for non-HTTP triggered functions. However, you need to consider how the two active regions interact or coordinate with one another. When you deploy the same function app to two regions with each triggering on the same Service Bus queue, they would act as competing consumers on de-queueing that queue. While this means each message is only being processed by either one of the instances, it also means there's still a single point of failure on the single Service Bus instance.

You could instead deploy two Service Bus queues, with one in a primary region, one in a secondary region. In this case, you could have two function apps, with each pointed to the Service Bus queue active in their region. The challenge with this topology is how the queue messages are distributed between the two regions. Often, this means that each publisher attempts to publish a message to *both* regions, and each message is processed by both active function apps. While this creates the desired active/active pattern, it also creates other challenges around duplication of compute and when or how data is consolidated.

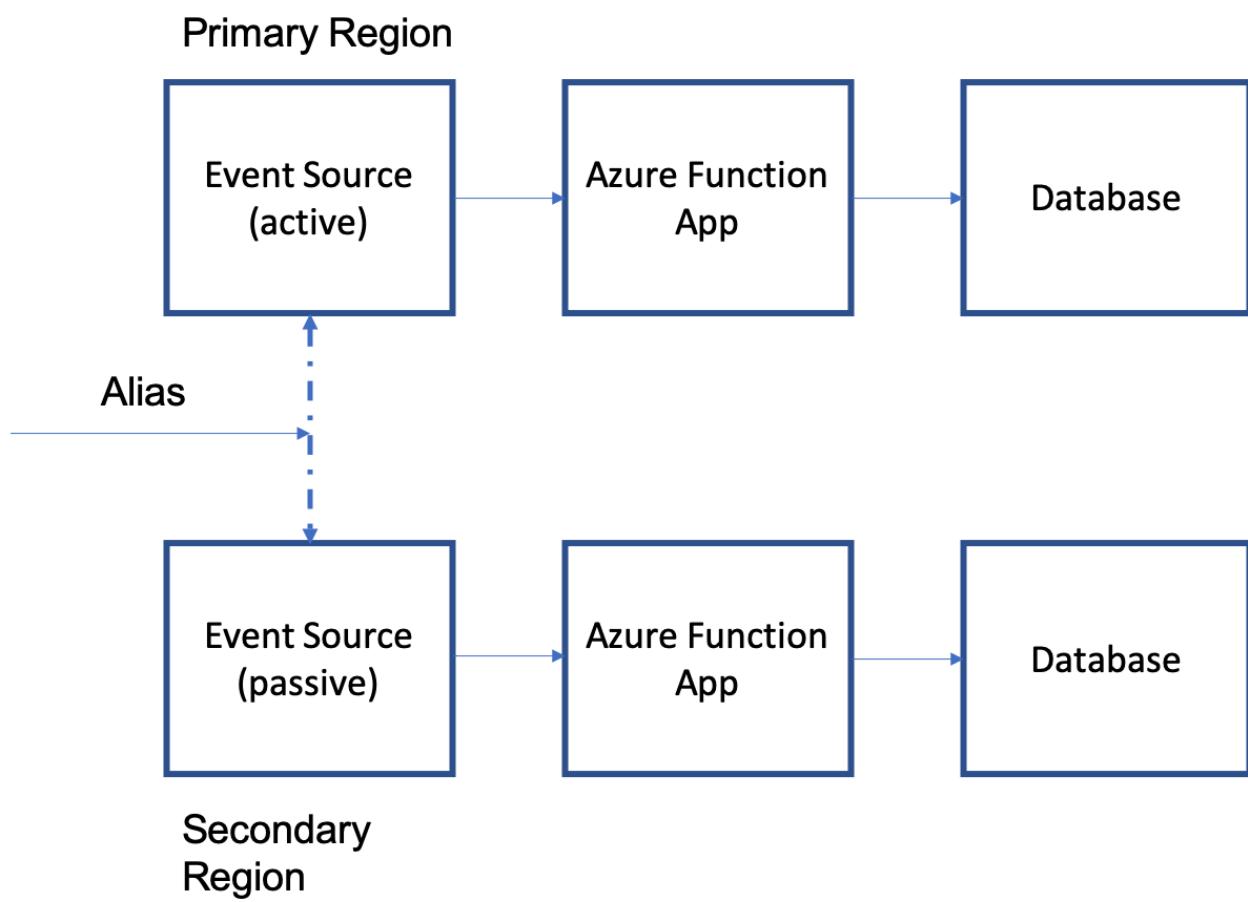

Active-passive pattern for non-HTTPS trigger functions

It's recommended that you use active-passive pattern for your event-driven, non-HTTP triggered functions, such as Service Bus and Event Hubs triggered functions.

To create redundancy for non-HTTP trigger functions, use an active-passive pattern. With an active-passive pattern, functions run actively in the region that's receiving events; while the same functions in a second region remain idle. The active-passive pattern provides a way for only a single function to process each message while providing a mechanism to fail over to the secondary region in a disaster. Function apps work with the failover behaviors of the partner services, such as [Azure Service Bus geo-recovery](#) and [Azure Event Hubs geo-recovery](#).

Consider an example topology using an Azure Event Hubs trigger. In this case, the active/passive pattern requires involve the following components:

- Azure Event Hubs deployed to both a primary and secondary region.
- [Geo-disaster enabled](#) to pair the primary and secondary event hubs. This also creates an *alias* you can use to connect to event hubs and switch from primary to secondary without changing the connection info.
- Function apps are deployed to both the primary and secondary (failover) region, with the app in the secondary region essentially being idle because messages aren't being sent there.
- Function app triggers on the *direct* (non-alias) connection string for its respective event hub.
- Publishers to the event hub should publish to the alias connection string.

Before failover, publishers sending to the shared alias route to the primary event hub. The primary function app is listening exclusively to the primary event hub. The secondary function app is passive and idle. As soon as failover is initiated, publishers sending to the shared alias are routed to the secondary event hub. The secondary function app now becomes active and starts triggering automatically. Effective failover to a secondary region can be driven entirely from the event hub, with the functions becoming active only when the respective event hub is active.

Read more on information and considerations for failover with [Service Bus](#) and [Event Hubs](#).

Migrate your function app to a zone-redundant plan

Article • 01/18/2023

Availability zones support for Azure Functions is available on [Premium \(Elastic Premium\)](#) and [Dedicated \(App Service\)](#) plans. A zone-redundant function app plan automatically balances its instances between availability zones for higher availability. This article describes how to migrate to the public multi-tenant Premium plan with availability zone support. For migration to zone redundancy on Dedicated plans, refer [here](#).

Downtime requirements

Downtime will be dependent on how you decide to carry out the migration. Since you can't convert pre-existing Premium plans to use availability zones, migration will consist of a side-by-side deployment where you'll create new Premium plans. Downtime will depend on how you choose to redirect traffic from your old to your new availability zone enabled function app. For example, for HTTP based functions if you're using an [Application Gateway](#), a [custom domain](#), or [Azure Front Door](#), downtime will be dependent on the time it takes to update those respective services with your new app's information. Alternatively, you can route traffic to multiple apps at the same time using a service such as [Azure Traffic Manager](#) and only fully cutover to your new availability zone enabled apps when everything is deployed and fully tested. You can also [write defensive functions](#) to ensure messages are not lost during the migration for non-HTTP functions.

Migration guidance: Redeployment

If you want your function app to use availability zones, redeploy your app into a newly created availability zone enabled Premium function app plan.

How to redeploy

The following steps describe how to enable availability zones.

1. If you're already using the Premium SKU and are in one of the [supported regions](#), you can move on to the next step. Otherwise, you should create a new resource group in one of the supported regions.

2. Create a Premium plan in one of the supported regions and the resource group.
Ensure the [new Premium plan has zone redundancy enabled](#).
3. Create and deploy your function apps into the new Premium plan using your desired [deployment method](#).
4. After testing and enabling the new function apps, you can optionally disable or delete your previous non-availability zone apps.

Azure Functions diagnostics overview

Article • 11/03/2021

When you're running a function app, you want to be prepared for any issues that may arise, from 4xx errors to trigger failures. Azure Functions diagnostics is an intelligent and interactive experience to help you troubleshoot your function app with no configuration or extra cost. When you do run into issues with your function app, Azure Functions diagnostics points out what's wrong. It guides you to the right information to more easily and quickly troubleshoot and resolve the issue. This article shows you the basics of how to use Azure Functions diagnostics to more quickly diagnose and solve common function app issues.

Start Azure Functions diagnostics

To start Azure Functions diagnostics:

1. Navigate to your function app in the [Azure portal](#).
2. Select **Diagnose and solve problems** to open Azure Functions diagnostics.
3. Choose a category that best describes the issue of your function app by using the keywords in the homepage tile. You can also type a keyword that best describes your issue in the search bar. For example, you could type `execution` to see a list of diagnostic reports related to your function app execution and open them directly from the homepage.

The screenshot shows the Azure Functions Diagnostics interface for a function app named 'myFunctionApp-dma'. The left sidebar has a red box around the 'Diagnose and solve problems' section. The main area has a search bar with 'execution' typed in, and a list of five results:

- Function App Health Check
- Function Compilation Error (.csx)
- Function Execution Performance
- Function Executions and Errors
- Timer Trigger Issue Analysis

Below this is a section titled 'Azure Functions Diagnostics' with a purple header 'Availability and Performance'. It contains a brief description and a list of keywords: Downtime, 5xx Errors, 4xx Errors, CPU.

Use the Interactive interface

Once you select a homepage category that best aligns with your function app's problem, Azure Functions diagnostics' interactive interface, named Genie, can guide you through diagnosing and solving problem of your app. You can use the tile shortcuts provided by Genie to view the full diagnostic report of the problem category that you're interested in. The tile shortcuts provide you a direct way of accessing your diagnostic metrics.

The screenshot shows the 'Availability and Performance' section of the Genie interface. It includes a welcome message: 'Hello! Welcome to Azure Functions Diagnostics! My name is Genie and I'm here to help you diagnose and solve problems.' Below this is a message: 'Here are some issues related to Availability and Performance that I can help with. Please select the tile that best describes your issue.' A grid of tiles provides links to various diagnostic tools:

AlwaysOn Check	Application Crashes	Application Insights Logging Sampling Check	Check RunFromPackage Logs	Function App Down or Reporting Errors	Function App Settings Check
Function Cold Start	Function Configuration Checks	Function Execution Performance	High CPU Analysis	HTTP 4xx Errors	Memory Analysis
Messaging Function Trigger Failure	RunOnStartup Check	TCP Connections	Timer Trigger Issue Analysis	Web App Restarted	

After selecting a tile, you can see a list of topics related to the issue described in the tile. These topics provide snippets of notable information from the full report. Select any of these topics to investigate the issues further. Also, you can select **View Full Report** to explore all the topics on a single page.

The screenshot shows the Azure Functions Diagnostics interface. At the top, there are two tabs: "Home" and "Availability and Performance" (which is currently selected). Below the tabs, a message from "Genie" says: "Hello! Welcome to Azure Functions Diagnostics! My name is Genie and I'm here to help you diagnose and solve problems." Another message below it says: "Here are some issues related to Availability and Performance that I can help with. Please select the tile that best describes your issue." In the bottom right corner of this area, there is a blue button labeled "I am interested in Function App Down or Reporting Errors". The main content area is titled "Function App Down or Reporting Errors" and contains five items, each with a status icon and a link to "View Full Report":

- Bad Async Function Pattern (green checkmark)
- Check RunFromPackage Logs (green checkmark)
- Function App General Information (blue info icon)
- Function App Offline History (green checkmark)
- Function App Settings Check (orange warning icon)

View a diagnostic report

After you choose a topic, you can view a diagnostic report specific to your function app. Diagnostic reports use status icons to indicate if there are any specific issues with your app. You see detailed description of the issue, recommended actions, related-metrics, and helpful docs. Customized diagnostic reports are generated from a series of checks run on your function app. Diagnostic reports can be a useful tool for pinpointing problems in your function app and guiding you towards resolving the issue.

Find the problem code

For script-based functions, you can use **Function Execution and Errors** under **Function App Down or Reporting Errors** to narrow down on the line of code causing exceptions or errors. You can use this tool for getting to the root cause and fixing issues from a specific line of code. This option isn't available for precompiled C# and Java functions.

Function Executions and Errors

Detects execution statistics and errors for every function inside the function app.

[Send Feedback](#)[Copy Report](#)

[Monitor your function apps](#)

Estimating consumption-based costs

Article • 05/21/2024

This article shows you how to estimate plan costs for the Consumption and Flex Consumption hosting plans.

Azure Functions currently offers four different hosting plans for your function apps, with each plan having its own pricing model:

[+] [Expand table](#)

Plan	Description
Consumption	You're only charged for the time that your function app runs. This plan includes a free grant on a per subscription basis.
Flex Consumption plan	You pay for execution time on the instances on which your functions are running, plus any <i>always ready</i> instances. Instances are dynamically added and removed based on the number of incoming events. Also supports virtual network integration.
Premium	Provides you with the same features and scaling mechanism as the Consumption plan, but with enhanced performance and virtual network integration. Cost is based on your chosen pricing tier. To learn more, see Azure Functions Premium plan .
Dedicated (App Service) (basic tier or higher)	When you need to run in dedicated VMs or in isolation, use custom images, or want to use your excess App Service plan capacity. Uses regular App Service plan billing . Cost is based on your chosen pricing tier.

ⓘ Important

The [Flex Consumption plan](#) is currently in preview.

You should always choose the plan that best supports the feature, performance, and cost requirements for your function executions. To learn more, see [Azure Functions scale and hosting](#).

This article focuses on Consumption and Flex Consumption plans because in these plans billing depends on active periods of executions inside each instance.

Durable Functions can also run in both of these plans. To learn more about the cost considerations when using Durable Functions, see [Durable Functions billing](#).

Consumption-based costs

The way that consumption-based costs are calculated, including free grants, depends on the specific plan. For the most current cost and grant information, see the [Azure Functions pricing page](#).

Consumption plan

The execution *cost* of a single function execution is measured in *GB-seconds*. Execution cost is calculated by combining its memory usage with its execution time. A function that runs for longer costs more, as does a function that consumes more memory.

Consider a case where the amount of memory used by the function stays constant. In this case, calculating the cost is simple multiplication. For example, say that your function consumed 0.5 GB for 3 seconds. Then the execution cost is $0.5\text{GB} * 3\text{s} = 1.5 \text{ GB-seconds}$.

Since memory usage changes over time, the calculation is essentially the integral of memory usage over time. The system does this calculation by sampling the memory usage of the process (along with child processes) at regular intervals. As mentioned on the [pricing page](#), memory usage is rounded up to the nearest 128-MB bucket. When your process is using 160 MB, you're charged for 256 MB. The calculation takes into account concurrency, which is multiple concurrent function executions in the same process.

ⓘ Note

While CPU usage isn't directly considered in execution cost, it can have an impact on the cost when it affects the execution time of the function.

For an HTTP-triggered function, when an error occurs before your function code begins to execute you aren't charged for an execution. This means that 401 responses from the platform due to API key validation or the App Service Authentication / Authorization feature don't count against your execution cost. Similarly, 5xx status code responses aren't counted when they occur in the platform before your function processes the request. A 5xx response generated by the platform after your function code has started to execute is still counted as an execution, even when the error isn't raised from your function code.

Other related costs

When estimating the overall cost of running your functions in any plan, remember that the Functions runtime uses several other Azure services, which are each billed separately. When you estimate pricing for function apps, any triggers and bindings you have that integrate with other Azure services require you to create and pay for those other services.

For functions running in a Consumption plan, the total cost is the execution cost of your functions, plus the cost of bandwidth and other services.

When estimating the overall costs of your function app and related services, use the [Azure pricing calculator](#).

 Expand table

Related cost	Description
Storage account	Each function app requires that you have an associated General Purpose Azure Storage account , which is billed separately . This account is used internally by the Functions runtime, but you can also use it for Storage triggers and bindings. If you don't have a storage account, one is created for you when the function app is created. To learn more, see Storage account requirements .
Application Insights	Functions relies on Application Insights to provide a high-performance monitoring experience for your function apps. While not required, you should enable Application Insights integration . A free grant of telemetry data is included every month. To learn more, see the Azure Monitor pricing page .
Network bandwidth	You can incur costs for data transfer depending on the direction and scenario of the data movement. To learn more, see Bandwidth pricing details .

Behaviors affecting execution time

The following behaviors of your functions can affect the execution time:

- **Triggers and bindings:** The time taken to read input from and write output to your [function bindings](#) is counted as execution time. For example, when your function uses an output binding to write a message to an Azure storage queue, your execution time includes the time taken to write the message to the queue, which is included in the calculation of the function cost.
- **Asynchronous execution:** The time that your function waits for the results of an async request (`await` in C#) is counted as execution time. The GB-second

calculation is based on the start and end time of the function and the memory usage over that period. What is happening over that time in terms of CPU activity isn't factored into the calculation. You may be able to reduce costs during asynchronous operations by using [Durable Functions](#). You're not billed for time spent at awaits in orchestrator functions.

Viewing cost-related data

In [your invoice](#), you can view the cost-related data of **Total Executions - Functions** and **Execution Time - Functions**, along with the actual billed costs. However, this invoice data is a monthly aggregate for a past invoice period.

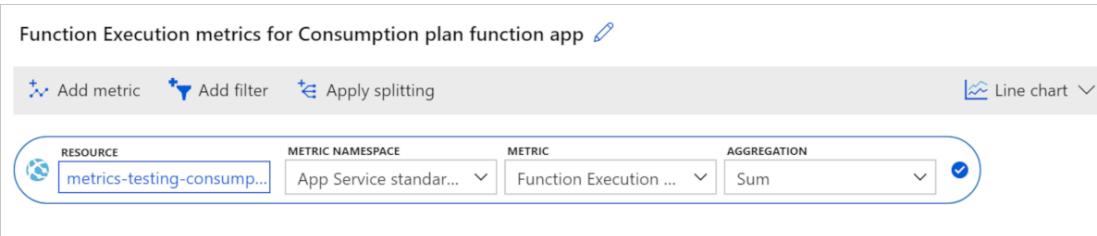

Function app-level metrics

To better understand the cost impact of your functions, you can use Azure Monitor to view cost-related metrics currently being generated by your function apps.

Portal

Use [Azure Monitor metrics explorer](#) to view cost-related data for your Consumption plan function apps in a graphical format.

1. In the [Azure portal](#)  , navigate to your function app.
2. In the left panel, scroll down to **Monitoring** and choose **Metrics**.
3. From **Metric**, choose **Function Execution Count** and **Sum for Aggregation**.
This adds the sum of the execution counts during chosen period to the chart.

4. Select **Add metric** and repeat steps 2-4 to add **Function Execution Units** to the chart.

The resulting chart contains the totals for both execution metrics in the chosen time range, which in this case is two hours.

As the number of execution units is so much greater than the execution count, the chart just shows execution units.

This chart shows a total of 1.11 billion [Function Execution Units](#) consumed in a two-hour period, measured in MB-milliseconds. To convert to GB-seconds, divide by 1024000. In this example, the function app consumed $11100000000 / 1024000 = 1083.98$ GB-seconds. You can take this value and multiply by the current price of execution time on the [Functions pricing page](#), which gives you the cost of these two hours, assuming you've already used any free grants of execution time.

Function-level metrics

Function execution units are a combination of execution time and your memory usage, which makes it a difficult metric for understanding memory usage. Memory data isn't a metric currently available through Azure Monitor. However, if you want to optimize the memory usage of your app, can use the performance counter data collected by Application Insights.

If you haven't already done so, [enable Application Insights in your function app](#). With this integration enabled, you can [query this telemetry data in the portal](#).

You can use either [Azure Monitor metrics explorer](#) in the [Azure portal](#) or REST APIs to get Monitor Metrics data.

Determine memory usage

Under **Monitoring**, select **Logs (Analytics)**, then copy the following telemetry query and paste it into the query window and select **Run**. This query returns the total memory usage at each sampled time.

```
performanceCounters  
| where name == "Private Bytes"  
| project timestamp, name, value
```

The results look like the following example:

[\[...\] Expand table](#)

timestamp [UTC]	name	value
9/12/2019, 1:05:14.947 AM	Private Bytes	209,932,288
9/12/2019, 1:06:14.994 AM	Private Bytes	212,189,184
9/12/2019, 1:06:30.010 AM	Private Bytes	231,714,816
9/12/2019, 1:07:15.040 AM	Private Bytes	210,591,744
9/12/2019, 1:12:16.285 AM	Private Bytes	216,285,184
9/12/2019, 1:12:31.376 AM	Private Bytes	235,806,720

Determine duration

Azure Monitor tracks metrics at the resource level, which for Functions is the function app. Application Insights integration emits metrics on a per-function basis. Here's an example analytics query to get the average duration of a function:

```
customMetrics  
| where name contains "Duration"  
| extend averageDuration = valueSum / valueCount  
| summarize averageDurationMilliseconds=avg(averageDuration) by name
```

[\[...\] Expand table](#)

name	averageDurationMilliseconds
QueueTrigger AvgDurationMs	16.087
QueueTrigger MaxDurationMs	90.249
QueueTrigger MinDurationMs	8.522

[Learn more about Monitoring function apps](#)

Serverless REST APIs using Azure Functions

Article • 11/20/2022

Azure Functions is an essential compute service that you use to build serverless REST-based APIs. HTTP triggers expose REST endpoints that can be called by your clients, like browsers, mobile apps, and other backend services. With [native support for routes](#), a single HTTP triggered function can expose a highly functional REST API. Functions also provides its own basic key-based authorization scheme to help limit access only to specific clients. For more information, see [Azure Functions HTTP trigger](#)

In some scenarios, you may need your API to support a more complex set of REST behaviors. For example, you may need to combine multiple HTTP function endpoints into a single API. You might also want to pass requests through to one or more backend REST-based services. Finally, your APIs might require a higher-degree of security that lets you monetize its use.

Today, the recommended approach to build more complex and robust APIs based on your functions is to use the comprehensive API services provided by [Azure API Management](#). API Management uses a policy-based model to let you control routing, security, and OpenAPI integration. It also supports advanced policies like rate limiting monetization. Previous versions of the Functions runtime used the legacy Functions Proxies feature.

Important

Azure Functions proxies is a legacy feature for [versions 1.x through 3.x](#) of the Azure Functions runtime. Support for proxies can be re-enabled in version 4.x for you to successfully upgrade your function apps to the latest runtime version. As soon as possible, you should switch to integrating your function apps with Azure API Management. API Management lets you take advantage of a more complete set of features for defining, securing, managing, and monetizing your Functions-based APIs. For more information, see [API Management integration](#).

To learn how to re-enable proxies support in Functions version 4.x, see [Re-enable proxies in Functions v4.x](#).

Moving from Functions Proxies to API Management

When moving from Functions Proxies to using API Management, you must integrate your function app with an API Management instance, and then configure the API Management instance to behave like the previous proxy. The following section provides links to the relevant articles that help you succeed in using API Management with Azure Functions.

If you have challenges moving from proxies or if Azure API Management doesn't address your specific scenarios, post a request in the [API Management feedback forum](#).

API Management integration

API Management lets you import an existing function app. After import, each HTTP triggered function endpoint becomes an API that you can modify and manage. After import, you can also use API Management to generate an OpenAPI definition file for your APIs. During import, any endpoints with an `admin` authorization level are ignored. For more information about using API Management with Functions, see the following articles:

Article	Description
Expose serverless APIs from HTTP endpoints using Azure API Management	Shows how to create a new API Management instance from an existing function app in the Azure portal. Supports all languages.
Create serverless APIs in Visual Studio using Azure Functions and API Management integration	Shows how to use Visual Studio to create a C# project that uses the OpenAPI extension . The OpenAPI extension lets you define your .NET APIs by applying attributes directly to your C# code.
Quickstart: Create a new Azure API Management service instance by using the Azure portal	Create a new API Management instance in the portal. After you create an API Management instance, you can connect it to your function app. Other non-portal creation methods are supported.
Import an Azure function app as an API in Azure API Management	Shows how to import an existing function app to expose existing HTTP trigger endpoints as a managed API. This article supports both creating a new API and adding the endpoints to an existing managed API.

After you have your function app endpoints exposed by using API Management, the following articles provide general information about how to manage your Functions-based APIs in the API Management instance.

Article	Description
Edit an API	Shows you how to work with an existing API hosted in API Management.
Policies in Azure API Management	In API Management, publishers can change API behavior through configuration using policies. Policies are a collection of statements that are run sequentially on the request or response of an API.
API Management policy reference	Reference that details all supported API Management policies.
API Management policy samples	Helpful collection of samples using API Management policies in key scenarios.

Legacy Functions Proxies

The legacy [Functions Proxies feature](#) also provides a set of basic API functionality for version 3.x and older version of the Functions runtime.

Important

Azure Functions proxies is a legacy feature for [versions 1.x through 3.x](#) of the Azure Functions runtime. Support for proxies can be re-enabled in version 4.x for you to successfully upgrade your function apps to the latest runtime version. As soon as possible, you should switch to integrating your function apps with Azure API Management. API Management lets you take advantage of a more complete set of features for defining, securing, managing, and monetizing your Functions-based APIs. For more information, see [API Management integration](#).

To learn how to re-enable proxies support in Functions version 4.x, see [Re-enable proxies in Functions v4.x](#).

Some basic hints for how to perform equivalent tasks using API Management have been added to the [Functions Proxies article](#). We don't currently have documentation or tools to help you migrate an existing Functions Proxies implementation to API Management.

Next steps

Expose serverless APIs from HTTP endpoints using Azure API Management

Azure Functions networking options

Article • 06/21/2024

This article describes the networking features available across the hosting options for Azure Functions. All the following networking options give you some ability to access resources without using internet-routable addresses or to restrict internet access to a function app.

The [hosting models](#) have different levels of network isolation available. Choosing the correct one helps you meet your network isolation requirements.

[Expand table

Feature	Consumption plan	Flex Consumption plan	Premium plan	Dedicated plan/ASE	Container Apps*
Inbound IP restrictions	Yes	Yes	Yes	Yes	No
Inbound Private Endpoints	No	Yes	Yes	Yes	No
Virtual network integration	No	Yes (Regional)	Yes (Regional)	Yes (Regional and Gateway)	Yes
Virtual network triggers (non-HTTP)	No	Yes	Yes	Yes	Yes
Hybrid connections (Windows only)	No	No	Yes	Yes	No
Outbound IP restrictions	No	Yes	Yes	Yes	No

*For more information, see [Networking in Azure Container Apps environment](#).

Quickstart resources

Use the following resources to quickly get started with Azure Functions networking scenarios. These resources are referenced throughout the article.

- ARM templates, Bicep files, and Terraform templates:
 - [Private HTTP triggered function app ↗](#)
 - [Private Event Hubs triggered function app ↗](#)
- ARM templates only:
 - [Function app with Azure Storage private endpoints ↗](#).
 - [Azure function app with Virtual Network Integration ↗](#).
- Tutorials:
 - [Integrate Azure Functions with an Azure virtual network by using private endpoints](#)
 - [Restrict your storage account to a virtual network.](#)
 - [Control Azure Functions outbound IP with an Azure virtual network NAT gateway.](#)

Inbound networking features

The following features let you filter inbound requests to your function app.

Inbound access restrictions

You can use access restrictions to define a priority-ordered list of IP addresses that are allowed or denied access to your app. The list can include IPv4 and IPv6 addresses, or specific virtual network subnets using [service endpoints](#). When there are one or more entries, an implicit "deny all" exists at the end of the list. IP restrictions work with all function-hosting options.

Access restrictions are available in the [Flex Consumption plan](#), [Elastic Premium](#), [Consumption](#), and [App Service](#).

Note

With network restrictions in place, you can deploy only from within your virtual network, or when you've put the IP address of the machine you're using to access the Azure portal on the Safe Recipients list. However, you can still manage the function using the portal.

To learn more, see [Azure App Service static access restrictions](#).

Private endpoints

[Azure Private Endpoint](#) is a network interface that connects you privately and securely to a service powered by Azure Private Link. Private Endpoint uses a private IP address from your virtual network, effectively bringing the service into your virtual network.

You can use Private Endpoint for your functions hosted in the [Premium](#) and [App Service](#) plans.

If you want to make calls to Private Endpoints, then you must make sure that your DNS lookups resolve to the private endpoint. You can enforce this behavior in one of the following ways:

- Integrate with Azure DNS private zones. When your virtual network doesn't have a custom DNS server, this is done automatically.
- Manage the private endpoint in the DNS server used by your app. To do this you must know the private endpoint address and then point the endpoint you are trying to reach to that address using an A record.
- Configure your own DNS server to forward to [Azure DNS private zones](#).

To learn more, see [using Private Endpoints for Web Apps](#).

To call other services that have a private endpoint connection, such as storage or service bus, be sure to configure your app to make [outbound calls to private endpoints](#). For more details on using private endpoints with the storage account for your function app, visit [restrict your storage account to a virtual network](#).

Service endpoints

Using service endpoints, you can restrict many Azure services to selected virtual network subnets to provide a higher level of security. Regional virtual network integration enables your function app to reach Azure services that are secured with service endpoints. This configuration is supported on all [plans](#) that support virtual network integration. To access a service endpoint-secured service, you must do the following:

1. Configure regional virtual network integration with your function app to connect to a specific subnet.
2. Go to the destination service and configure service endpoints against the integration subnet.

To learn more, see [Virtual network service endpoints](#).

Use Service Endpoints

To restrict access to a specific subnet, create a restriction rule with a **Virtual Network** type. You can then select the subscription, virtual network, and subnet that you want to allow or deny access to.

If service endpoints aren't already enabled with `Microsoft.Web` for the subnet that you selected, they're automatically enabled unless you select the **Ignore missing Microsoft.Web service endpoints** check box. The scenario where you might want to enable service endpoints on the app but not the subnet depends mainly on whether you have the permissions to enable them on the subnet.

If you need someone else to enable service endpoints on the subnet, select the **Ignore missing Microsoft.Web service endpoints** check box. Your app is configured for service endpoints in anticipation of having them enabled later on the subnet.

Add Access Restriction

X

Name ⓘ

Action

Allow Deny

Description

Type

Subscription *

Virtual Network *

Subnet *

Selected subnet 'networking-demos-vnet/nat-gw-subnet' does not have service endpoint enabled for Microsoft.Web. Enabling access may take up to 15 minutes to complete.

Ignore missing Microsoft.Web service endpoints

Add rule

You can't use service endpoints to restrict access to apps that run in an App Service Environment. When your app is in an App Service Environment, you can control access to it by applying IP access rules.

To learn how to set up service endpoints, see [Establish Azure Functions private site access](#).

Virtual network integration

Virtual network integration allows your function app to access resources inside a virtual network. Azure Functions supports two kinds of virtual network integration:

- The dedicated compute pricing tiers, which include the Basic, Standard, Premium, Premium v2, and Premium v3.
- The App Service Environment, which deploys directly into your virtual network with dedicated supporting infrastructure and is using the Isolated and Isolated v2 pricing tiers.

The virtual network integration feature is used in Azure App Service dedicated compute pricing tiers. If your app is in an [App Service Environment](#), it's already in a virtual network and doesn't require use of the VNet integration feature to reach resources in the same virtual network. For more information on all the networking features, see [App Service networking features](#).

Virtual network integration gives your app access to resources in your virtual network, but it doesn't grant inbound private access to your app from the virtual network. Private site access refers to making an app accessible only from a private network, such as from within an Azure virtual network. Virtual network integration is used only to make outbound calls from your app into your virtual network. The virtual network integration feature behaves differently when it's used with virtual networks in the same region and with virtual networks in other regions. The virtual network integration feature has two variations:

- **Regional virtual network integration:** When you connect to virtual networks in the same region, you must have a dedicated subnet in the virtual network you're integrating with.
- **Gateway-required virtual network integration:** When you connect directly to virtual networks in other regions or to a classic virtual network in the same region, you need an Azure Virtual Network gateway created in the target virtual network.

The virtual network integration feature:

- Requires a [supported Basic or Standard](#), Premium, Premium v2, Premium v3, or Elastic Premium App Service pricing tier.
- Supports TCP and UDP.
- Works with App Service apps and function apps.

There are some things that virtual network integration doesn't support, like:

- Mounting a drive.

- Windows Server Active Directory domain join.
- NetBIOS.

Gateway-required virtual network integration provides access to resources only in the target virtual network or in networks connected to the target virtual network with peering or VPNs. Gateway-required virtual network integration doesn't enable access to resources available across Azure ExpressRoute connections or work with service endpoints.

No matter which version is used, virtual network integration gives your app access to resources in your virtual network, but it doesn't grant inbound private access to your app from the virtual network. Private site access refers to making your app accessible only from a private network, such as from within an Azure virtual network. Virtual network integration is only for making outbound calls from your app into your virtual network.

Virtual network integration in Azure Functions uses shared infrastructure with App Service web apps. To learn more about the two types of virtual network integration, see:

- [Regional virtual network integration](#)
- [Gateway-required virtual network integration](#)

To learn how to set up virtual network integration, see [Enable virtual network integration](#).

Enable virtual network integration

1. In your function app in the [Azure portal](#), select **Networking**, then under **VNet Integration** select [Click here to configure](#).
2. Select **Add VNet**.

The screenshot shows the 'VNet Configuration' section of the 'VNet Integration' blade. It includes a note about securely accessing resources through Azure VNet, a 'Add VNet' button, and sections for 'VNet Details' and 'VNet Address Space'. The 'VNet Details' section shows 'VNet NAME' and 'LOCATION' both set to 'Not Configured'. The 'VNet Address Space' section shows 'Start Address' and 'End Address' both set to 'Not Configured'.

3. The drop-down list contains all of the Azure Resource Manager virtual networks in your subscription in the same region. Select the virtual network you want to integrate with.

The screenshot shows the 'Add VNet Integration' dialog box. It has fields for 'Subscription' (set to 'Private Test Sub CACHAI') and 'Virtual Network'. A dropdown menu under 'Virtual Network' shows 'Search virtual networks' and 'integration-vnet (East US)'. At the bottom is an 'OK' button.

- The Functions Flex Consumption and Elastic Premium plans only supports regional virtual network integration. If the virtual network is in the same region, either create a new subnet or select an empty, pre-existing subnet.
- To select a virtual network in another region, you must have a virtual network gateway provisioned with point to site enabled. Virtual network integration across regions is only supported for Dedicated plans, but global peerings work with regional virtual network integration.

During the integration, your app is restarted. When integration is finished, you see details on the virtual network you're integrated with. By default, Route All is enabled, and all traffic is routed into your virtual network.

If you wish for only your private traffic ([RFC1918](#) traffic) to be routed, please follow the steps in the [app service documentation](#).

Regional virtual network integration

Using regional virtual network integration enables your app to access:

- Resources in the same virtual network as your app.
- Resources in virtual networks peered to the virtual network your app is integrated with.
- Service endpoint secured services.
- Resources across Azure ExpressRoute connections.
- Resources across peered connections, which include Azure ExpressRoute connections.
- Private endpoints

When you use regional virtual network integration, you can use the following Azure networking features:

- **Network security groups (NSGs)**: You can block outbound traffic with an NSG that's placed on your integration subnet. The inbound rules don't apply because you can't use virtual network integration to provide inbound access to your app.
- **Route tables (UDRs)**: You can place a route table on the integration subnet to send outbound traffic where you want.

Note

When you route all of your outbound traffic into your virtual network, it's subject to the NSGs and UDRs that are applied to your integration subnet. When virtual network integrated, your function app's outbound traffic to public IP addresses is still sent from the addresses that are listed in your app properties, unless you provide routes that direct the traffic elsewhere.

Regional virtual network integration isn't able to use port 25.

For the Flex Consumption plan:

1. Ensure that the `Microsoft.App` Azure resource provider is enabled for your subscription by [following these instructions](#). The subnet delegation required by Flex Consumption apps is `Microsoft.App/environments`.
2. The subnet delegation required by Flex Consumption apps is `Microsoft.App/environments`. This is a change from Elastic Premium and App Service which have a different delegation requirement.
3. You can plan for 40 IP addresses to be used at the most for one function app, even if the app scales beyond 40. For example, if you have fifteen Flex Consumption function apps that will be VNet integrated into the same subnet, you can plan for $15 \times 40 = 600$ IP addresses used at the most. This limit is subject to change, and is not enforced.
4. The subnet can't already be in use for other purposes (like private or service endpoints, or [delegated](#) to any other hosting plan or service). While you can share the same subnet with multiple Flex Consumption apps, the networking resources will be shared across these function apps and this can lead to one function app impacting the performance of others on the same subnet.

There are some limitations with using virtual network:

- The feature is available from Flex Consumption, Elastic Premium, and App Service Premium V2 and Premium V3. It's also available in Standard but only from newer App Service deployments. If you are on an older deployment, you can only use the feature from a Premium V2 App Service plan. If you want to make sure you can use the feature in a Standard App Service plan, create your app in a Premium V3 App Service plan. Those plans are only supported on our newest deployments. You can scale down if you desire after that.
- The integration subnet can be used by only one App Service plan.
- The feature can't be used by Isolated plan apps that are in an App Service Environment.
- The feature requires an unused subnet that's a /28 or larger in an Azure Resource Manager virtual network.
- The app and the virtual network must be in the same region.
- You can't delete a virtual network with an integrated app. Remove the integration before you delete the virtual network.
- You can have up to two regional virtual network integrations per App Service plan. Multiple apps in the same App Service plan can use the same integration subnet.
- You can't change the subscription of an app or a plan while there's an app that's using regional virtual network integration.

Subnets

Virtual network integration depends on a dedicated subnet. When you provision a subnet, the Azure subnet loses five IPs from the start. For the Elastic Premium and App Service plans, one address is used from the integration subnet for each plan instance. When you scale your app to four instances, then four addresses are used. For Flex Consumption this does not apply and instances share IP addresses.

When you scale up or down in size, the required address space is doubled for a short period of time. This affects the real, available supported instances for a given subnet size. The following table shows both the maximum available addresses per CIDR block and the effect this has on horizontal scale:

[+] Expand table

CIDR block size	Max available addresses	Max horizontal scale (instances)*
/28	11	5
/27	27	13
/26	59	29

*Assumes that you need to scale up or down in either size or SKU at some point.

Since subnet size can't be changed after assignment, use a subnet that's large enough to accommodate whatever scale your app might reach. To avoid any issues with subnet capacity for Functions Elastic Premium plans, you should use a /24 with 256 addresses for Windows and a /26 with 64 addresses for Linux. When creating subnets in Azure portal as part of integrating with the virtual network, a minimum size of /24 and /26 is required for Windows and Linux respectively.

When you want your apps in another plan to reach a virtual network that's already connected to by apps in another plan, select a different subnet than the one being used by the pre-existing virtual network integration.

The feature is fully supported for both Windows and Linux apps, including [custom containers](#). All of the behaviors act the same between Windows apps and Linux apps.

Network security groups

You can use network security groups to block inbound and outbound traffic to resources in a virtual network. An app that uses regional virtual network integration can use a [network security group](#) to block outbound traffic to resources in your virtual network or the internet. To block traffic to public addresses, you must have virtual network integration with Route All enabled. The inbound rules in an NSG don't apply to

your app because virtual network integration affects only outbound traffic from your app.

To control inbound traffic to your app, use the Access Restrictions feature. An NSG that's applied to your integration subnet is in effect regardless of any routes applied to your integration subnet. If your function app is virtual network integrated with Route All enabled, and you don't have any routes that affect public address traffic on your integration subnet, all of your outbound traffic is still subject to NSGs assigned to your integration subnet. When Route All isn't enabled, NSGs are only applied to RFC1918 traffic.

Routes

You can use route tables to route outbound traffic from your app to wherever you want. By default, route tables only affect your RFC1918 destination traffic. When Route All is enabled, all of your outbound calls are affected. When [Route All](#) is disabled, only private traffic (RFC1918) is affected by your route tables. Routes that are set on your integration subnet won't affect replies to inbound app requests. Common destinations can include firewall devices or gateways.

If you want to route all outbound traffic on-premises, you can use a route table to send all outbound traffic to your ExpressRoute gateway. If you do route traffic to a gateway, be sure to set routes in the external network to send any replies back.

Border Gateway Protocol (BGP) routes also affect your app traffic. If you have BGP routes from something like an ExpressRoute gateway, your app outbound traffic is affected. By default, BGP routes affect only your RFC1918 destination traffic. When your function app is virtual network integrated with Route All enabled, all outbound traffic can be affected by your BGP routes.

Azure DNS private zones

After your app integrates with your virtual network, it uses the same DNS server that your virtual network is configured with and will work with the Azure DNS private zones linked to the virtual network.

Restrict your storage account to a virtual network

Note

To quickly deploy a function app with private endpoints enabled on the storage account, please refer to the following template: [Function app with Azure Storage private endpoints](#).

When you create a function app, you must create or link to a general-purpose Azure Storage account that supports Blob, Queue, and Table storage. You can replace this storage account with one that is secured with service endpoints or private endpoints.

This feature is supported for all Windows and Linux virtual network-supported SKUs in the Dedicated (App Service) plan and for the Elastic Premium plans, as well as the Flex Consumption plan. The Consumption plan isn't supported. To learn how to set up a function with a storage account restricted to a private network, see [Restrict your storage account to a virtual network](#).

Use Key Vault references

You can use Azure Key Vault references to use secrets from Azure Key Vault in your Azure Functions application without requiring any code changes. Azure Key Vault is a service that provides centralized secrets management, with full control over access policies and audit history.

If virtual network integration is configured for the app, [Key Vault references](#) may be used to retrieve secrets from a network-restricted vault.

Virtual network triggers (non-HTTP)

Currently, you can use non-HTTP trigger functions from within a virtual network in one of two ways:

- Run your function app in an [Elastic Premium plan](#) and enable virtual network trigger support.
- Run your function app in a Flex Consumption, App Service plan or App Service Environment.

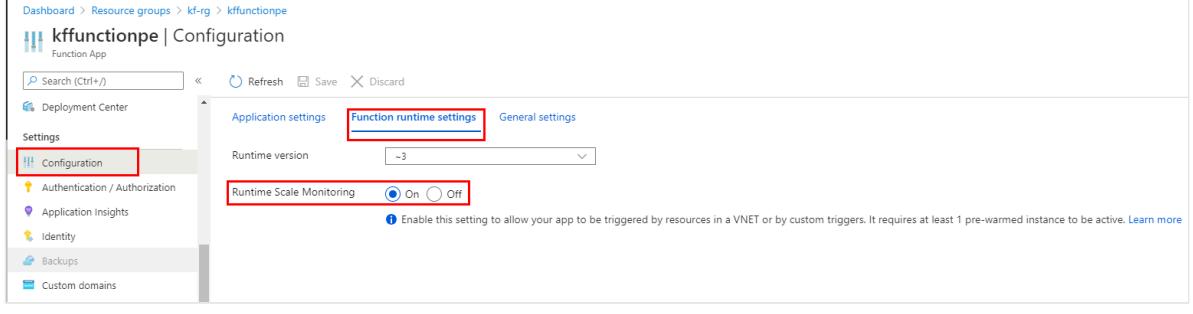

Elastic Premium plan with virtual network triggers

The [Elastic Premium plan](#) lets you create functions that are triggered by services inside a virtual network. These non-HTTP triggers are known as *virtual network triggers*.

By default, virtual network triggers don't cause your function app to scale beyond their pre-warmed instance count. However, certain extensions support virtual network

triggers that cause your function app to scale dynamically. You can enable this *dynamic scale monitoring* in your function app for supported extensions in one of these ways:

Azure portal

1. In the [Azure portal](#), navigate to your function app.
2. Under **Settings** select **Configuration**, then in the **Function runtime settings** tab set **Runtime Scale Monitoring** to **On**.
3. Select **Save** to update the function app configuration and restart the app.

Tip

Enabling the monitoring of virtual network triggers may have an impact on the performance of your application, though this impact is likely to be very small.

Support for dynamic scale monitoring of virtual network triggers isn't available in version 1.x of the Functions runtime.

The extensions in this table support dynamic scale monitoring of virtual network triggers. To get the best scaling performance, you should upgrade to versions that also support [target-based scaling](#).

[Expand table](#)

Extension (minimum version)	Runtime scale monitoring only	With target-based scaling
Microsoft.Azure.WebJobs.Extensions.CosmosDB	> 3.0.5	> 4.1.0
Microsoft.Azure.WebJobs.Extensions.DurableTask	> 2.0.0	n/a
Microsoft.Azure.WebJobs.Extensions.EventHubs	> 4.1.0	> 5.2.0
Microsoft.Azure.WebJobs.Extensions.ServiceBus	> 3.2.0	> 5.9.0

Extension (minimum version)	Runtime scale monitoring only	With target-based scaling
Microsoft.Azure.WebJobs.Extensions.Storage	> 3.0.10	> 5.1.0*

* Queue storage only.

ⓘ Important

When you enable virtual network trigger monitoring, only triggers for these extensions can cause your app to scale dynamically. You can still use triggers from extensions that aren't in this table, but they won't cause scaling beyond their pre-warmed instance count. For a complete list of all trigger and binding extensions, see [Triggers and bindings](#).

App Service plan and App Service Environment with virtual network triggers

When your function app runs in either an App Service plan or an App Service Environment, you can use non-HTTP trigger functions. For your functions to get triggered correctly, you must be connected to a virtual network with access to the resource defined in the trigger connection.

For example, assume you want to configure Azure Cosmos DB to accept traffic only from a virtual network. In this case, you must deploy your function app in an App Service plan that provides virtual network integration with that virtual network. Integration enables a function to be triggered by that Azure Cosmos DB resource.

Hybrid Connections

[Hybrid Connections](#) is a feature of Azure Relay that you can use to access application resources in other networks. It provides access from your app to an application endpoint. You can't use it to access your application. Hybrid Connections is available to functions that run on Windows in all but the Consumption plan.

As used in Azure Functions, each hybrid connection correlates to a single TCP host and port combination. This means that the hybrid connection's endpoint can be on any operating system and any application as long as you're accessing a TCP listening port. The Hybrid Connections feature doesn't know or care what the application protocol is or what you're accessing. It just provides network access.

To learn more, see the [App Service documentation for Hybrid Connections](#). These same configuration steps support Azure Functions.

ⓘ Important

Hybrid Connections is only supported on Windows plans. Linux isn't supported.

Outbound IP restrictions

Outbound IP restrictions are available in a Flex Consumption plan, Elastic Premium plan, App Service plan, or App Service Environment. You can configure outbound restrictions for the virtual network where your App Service Environment is deployed.

When you integrate a function app in an Elastic Premium plan or an App Service plan with a virtual network, the app can still make outbound calls to the internet by default. By integrating your function app with a virtual network with Route All enabled, you force all outbound traffic to be sent into your virtual network, where network security group rules can be used to restrict traffic. For Flex Consumption all traffic is already routed through the virtual network and Route All is not needed.

To learn how to control the outbound IP using a virtual network, see [Tutorial: Control Azure Functions outbound IP with an Azure virtual network NAT gateway](#).

Automation

The following APIs let you programmatically manage regional virtual network integrations:

- **Azure CLI:** Use the [az functionapp vnet-integration](#) commands to add, list, or remove a regional virtual network integration.
- **ARM templates:** Regional virtual network integration can be enabled by using an Azure Resource Manager template. For a full example, see [this Functions quickstart template ↗](#).

Testing considerations

When testing functions in a function app with private endpoints, you must do your testing from within the same virtual network, such as on a virtual machine (VM) in that network. To use the **Code + Test** option in the portal from that VM, you need to add following [CORS origins](#) to your function app:

- `https://functions-next.azure.com`
- `https://functions-staging.azure.com`
- `https://functions.azure.com`
- `https://portal.azure.com`

If you've restricted access to your function app with private endpoints or any other access restriction, you also must add the service tag `AzureCloud` to the allowed list. To update the allowed list:

1. Navigate to your function app and select **Settings > Networking** and then select **Inbound access configuration > Public network access**.
2. Make sure that **Public network access** is set to **Enabled** from **select virtual networks and IP addresses**.
3. **Add a rule** under Site access and rules:
 - a. Select `Service Tag` as the Source settings **Type** and `AzureCloud` as the **Service Tag**.
 - b. Make sure the action is **Allow**, and set your desired name and priority.

Troubleshooting

The feature is easy to set up, but that doesn't mean your experience will be problem free. If you encounter problems accessing your desired endpoint, there are some utilities you can use to test connectivity from the app console. There are two consoles that you can use. One is the Kudu console, and the other is the console in the Azure portal. To reach the Kudu console from your app, go to **Tools > Kudu**. You can also reach the Kudu console at [sitename].scm.azurewebsites.net. After the website loads, go to the **Debug console** tab. To get to the Azure portal-hosted console from your app, go to **Tools > Console**.

Tools

In native Windows apps, the tools `ping`, `nslookup`, and `tracert` won't work through the console because of security constraints (they work in [custom Windows containers](#)). To fill the void, two separate tools are added. To test DNS functionality, we added a tool named `nameresolver.exe`. The syntax is:

Console

```
nameresolver.exe hostname [optional: DNS Server]
```

You can use nameresolver to check the hostnames that your app depends on. This way you can test if you have anything misconfigured with your DNS or perhaps don't have access to your DNS server. You can see the DNS server that your app uses in the console by looking at the environmental variables WEBSITE_DNS_SERVER and WEBSITE_DNS_ALT_SERVER.

ⓘ Note

The nameresolver.exe tool currently doesn't work in custom Windows containers.

You can use the next tool to test for TCP connectivity to a host and port combination. This tool is called **tcpping** and the syntax is:

Console

```
tcpping.exe hostname [optional: port]
```

The **tcpping** utility tells you if you can reach a specific host and port. It can show success only if there's an application listening at the host and port combination, and there's network access from your app to the specified host and port.

Debug access to virtual network-hosted resources

A number of things can prevent your app from reaching a specific host and port. Most of the time it's one of these things:

- **A firewall is in the way.** If you have a firewall in the way, you hit the TCP timeout. The TCP timeout is 21 seconds in this case. Use the **tcpping** tool to test connectivity. TCP timeouts can be caused by many things beyond firewalls, but start there.
- **DNS isn't accessible.** The DNS timeout is 3 seconds per DNS server. If you have two DNS servers, the timeout is 6 seconds. Use nameresolver to see if DNS is working. You can't use nslookup, because that doesn't use the DNS your virtual network is configured with. If inaccessible, you could have a firewall or NSG blocking access to DNS or it could be down.

If those items don't answer your problems, look first for things like:

Regional virtual network integration

- Is your destination a non-RFC1918 address and you don't have **Route All** enabled?
- Is there an NSG blocking egress from your integration subnet?
- If you're going across Azure ExpressRoute or a VPN, is your on-premises gateway configured to route traffic back up to Azure? If you can reach endpoints in your virtual network but not on-premises, check your routes.
- Do you have enough permissions to set delegation on the integration subnet?
During regional virtual network integration configuration, your integration subnet is delegated to Microsoft.Web/serverFarms. The VNet integration UI delegates the subnet to Microsoft.Web/serverFarms automatically. If your account doesn't have sufficient networking permissions to set delegation, you'll need someone who can set attributes on your integration subnet to delegate the subnet. To manually delegate the integration subnet, go to the Azure Virtual Network subnet UI and set the delegation for Microsoft.Web/serverFarms.

Gateway-required virtual network integration

- Is the point-to-site address range in the RFC 1918 ranges (10.0.0.0-10.255.255.255 / 172.16.0.0-172.31.255.255 / 192.168.0.0-192.168.255.255)?
- Does the gateway show as being up in the portal? If your gateway is down, then bring it back up.
- Do certificates show as being in sync, or do you suspect that the network configuration was changed? If your certificates are out of sync or you suspect that a change was made to your virtual network configuration that wasn't synced with your ASPs, select **Sync Network**.
- If you're going across a VPN, is the on-premises gateway configured to route traffic back up to Azure? If you can reach endpoints in your virtual network but not on-premises, check your routes.
- Are you trying to use a coexistence gateway that supports both point to site and ExpressRoute? Coexistence gateways aren't supported with virtual network integration.

Debugging networking issues is a challenge because you can't see what's blocking access to a specific host:port combination. Some causes include:

- You have a firewall up on your host that prevents access to the application port from your point-to-site IP range. Crossing subnets often requires public access.
- Your target host is down.
- Your application is down.
- You had the wrong IP or hostname.
- Your application is listening on a different port than what you expected. You can match your process ID with the listening port by using "netstat -aon" on the endpoint host.

- Your network security groups are configured in such a manner that they prevent access to your application host and port from your point-to-site IP range.

You don't know what address your app actually uses. It could be any address in the integration subnet or point-to-site address range, so you need to allow access from the entire address range.

More debug steps include:

- Connect to a VM in your virtual network and attempt to reach your resource host:port from there. To test for TCP access, use the PowerShell command **Test-NetConnection**. The syntax is:

PowerShell

```
Test-NetConnection hostname [optional: -Port]
```

- Bring up an application on a VM and test access to that host and port from the console from your app by using **tcpping**.

On-premises resources

If your app can't reach a resource on-premises, check if you can reach the resource from your virtual network. Use the **Test-NetConnection** PowerShell command to check for TCP access. If your VM can't reach your on-premises resource, your VPN or ExpressRoute connection might not be configured properly.

If your virtual network-hosted VM can reach your on-premises system but your app can't, the cause is likely one of the following reasons:

- Your routes aren't configured with your subnet or point-to-site address ranges in your on-premises gateway.
- Your network security groups are blocking access for your point-to-site IP range.
- Your on-premises firewalls are blocking traffic from your point-to-site IP range.
- You're trying to reach a non-RFC 1918 address by using the regional virtual network integration feature.

Deleting the App Service plan or web app before disconnecting the VNet integration

If you deleted the web app or the App Service plan without disconnecting the VNet integration first, you will not be able to do any update/delete operations on the virtual network or subnet that was used for the integration with the deleted resource. A subnet

delegation 'Microsoft.Web/serverFarms' will remain assigned to your subnet and will prevent the update/delete operations.

In order to do update/delete the subnet or virtual network again you need to re-create the VNet integration and then disconnect it:

1. Re-create the App Service plan and web app (it is mandatory to use the exact same web app name as before).
2. Navigate to the 'Networking' blade on the web app and configure the VNet integration.
3. After the VNet integration is configured, select the 'Disconnect' button.
4. Delete the App Service plan or web app.
5. Update/Delete the subnet or virtual network.

If you still encounter issues with the VNet integration after following the steps above, please contact Microsoft Support.

Network troubleshooter

You can also use the Network troubleshooter to resolve connection issues. To open the network troubleshooter, go to the app in the Azure portal. Select **Diagnostic and solve problem**, and then search for **Network troubleshooter**.

Connection issues - It checks the status of the virtual network integration, including checking if the Private IP has been assigned to all instances of the plan and the DNS settings. If a custom DNS isn't configured, default Azure DNS is applied. The troubleshooter also checks for common Function app dependencies including connectivity for Azure Storage and other binding dependencies.

IP addresses in Azure Functions

Article • 06/29/2023

This article explains the following concepts related to IP addresses of function apps:

- Locating the IP addresses currently in use by a function app.
- Conditions that cause function app IP addresses to change.
- Restricting the IP addresses that can access a function app.
- Defining dedicated IP addresses for a function app.

IP addresses are associated with function apps, not with individual functions. Incoming HTTP requests can't use the inbound IP address to call individual functions; they must use the default domain name (`functionappname.azurewebsites.net`) or a custom domain name.

Function app inbound IP address

Each function app starts out by using a single inbound IP address. When running in a Consumption or Premium plan, additional inbound IP addresses may be added as event-driven scale-out occurs. To find the inbound IP address or addresses being used by your app, use the `nslookup` utility from your local computer, as in the following example:

```
command  
nslookup <APP_NAME>.azurewebsites.net
```

In this example, replace `<APP_NAME>` with your function app name. If your app uses a [custom domain name](#), use `nslookup` for that custom domain name instead.

Function app outbound IP addresses

Each function app has a set of available outbound IP addresses. Any outbound connection from a function, such as to a back-end database, uses one of the available outbound IP addresses as the origin IP address. You can't know beforehand which IP address a given connection will use. For this reason, your back-end service must open its firewall to all of the function app's outbound IP addresses.

 Tip

For some platform-level features such as [Key Vault references](#), the origin IP might not be one of the outbound IPs, and you should not configure the target resource to rely on these specific addresses. It is recommended that the app instead use a virtual network integration, as the platform will route traffic to the target resource through that network.

To find the outbound IP addresses available to a function app:

Azure portal

1. Sign in to the [Azure Resource Explorer](#).
2. Select **subscriptions** > {your subscription} > **providers** > **Microsoft.Web** > **sites**.
3. In the JSON panel, find the site with an `id` property that ends in the name of your function app.
4. See `outboundIpAddresses` and `possibleOutboundIpAddresses`.

The set of `outboundIpAddresses` is currently available to the function app. The set of `possibleOutboundIpAddresses` includes IP addresses that will be available only if the function app [scales to other pricing tiers](#).

Note

When a function app that runs on the [Consumption plan](#) or the [Premium plan](#) is scaled, a new range of outbound IP addresses may be assigned. When running on either of these plans, you can't rely on the reported outbound IP addresses to create a definitive allowlist. To be able to include all potential outbound addresses used during dynamic scaling, you'll need to add the entire data center to your allowlist.

Data center outbound IP addresses

If you need to add the outbound IP addresses used by your function apps to an allowlist, another option is to add the function apps' data center (Azure region) to an allowlist. You can [download a JSON file that lists IP addresses for all Azure data centers](#). Then find the JSON fragment that applies to the region that your function app runs in.

For example, the following JSON fragment is what the allowlist for Western Europe might look like:

```
JSON

{
  "name": "AzureCloud.westeurope",
  "id": "AzureCloud.westeurope",
  "properties": {
    "changeNumber": 9,
    "region": "westeurope",
    "platform": "Azure",
    "systemService": "",
    "addressPrefixes": [
      "13.69.0.0/17",
      "13.73.128.0/18",
      ... Some IP addresses not shown here
      "213.199.180.192/27",
      "213.199.183.0/24"
    ]
  }
}
```

For information about when this file is updated and when the IP addresses change, expand the **Details** section of the [Download Center page](#).

Inbound IP address changes

The inbound IP address **might** change when you:

- Delete a function app and recreate it in a different resource group.
- Delete the last function app in a resource group and region combination, and recreate it.
- Delete a TLS binding, such as during [certificate renewal](#).

When your function app runs in a [Consumption plan](#) or in a [Premium plan](#), the inbound IP address might also change even when you haven't taken any actions such as the ones [listed above](#).

Outbound IP address changes

The relative stability of the outbound IP address depends on the hosting plan.

Consumption and Premium plans

Because of autoscaling behaviors, the outbound IP can change at any time when running on a [Consumption plan](#) or in a [Premium plan](#).

If you need to control the outbound IP address of your function app, such as when you need to add it to an allow list, consider implementing a [virtual network NAT gateway](#) while running in a Premium hosting plan. You can also do this by running in a Dedicated (App Service) plan.

Dedicated plans

When running on Dedicated (App Service) plans, the set of available outbound IP addresses for a function app might change when you:

- Take any action that can change the inbound IP address.
- Change your Dedicated (App Service) plan pricing tier. The list of all possible outbound IP addresses your app can use, for all pricing tiers, is in the `possibleOutboundIPAddresses` property. See [Find outbound IPs](#).

Forcing an outbound IP address change

Use the following procedure to deliberately force an outbound IP address change in a Dedicated (App Service) plan:

1. Scale your App Service plan up or down between Standard and Premium v2 pricing tiers.
2. Wait 10 minutes.
3. Scale back to where you started.

IP address restrictions

You can configure a list of IP addresses that you want to allow or deny access to a function app. For more information, see [Azure App Service Static IP Restrictions](#).

Dedicated IP addresses

There are several strategies to explore when your function app requires static, dedicated IP addresses.

Virtual network NAT gateway for outbound static IP

You can control the IP address of outbound traffic from your functions by using a virtual network NAT gateway to direct traffic through a static public IP address. You can use this topology when running in a [Premium plan](#) or in a [Dedicated \(App Service\) plan](#). To learn more, see [Tutorial: Control Azure Functions outbound IP with an Azure virtual network NAT gateway](#).

App Service Environments

For full control over the IP addresses, both inbound and outbound, we recommend [App Service Environments](#) (the [Isolated tier](#) of App Service plans). For more information, see [App Service Environment IP addresses](#) and [How to control inbound traffic to an App Service Environment](#).

To find out if your function app runs in an App Service Environment:

Azure portal

1. Sign in to the [Azure portal](#).
2. Navigate to the function app.
3. Select the **Overview** tab.
4. The App Service plan tier appears under **App Service plan/pricing tier**. The App Service Environment pricing tier is **Isolated**.

The App Service Environment `sku` is `Isolated`.

Next steps

A common cause of IP changes is function app scale changes. [Learn more about function app scaling](#).

Azure Functions custom handlers

Article • 12/16/2021

Every Functions app is executed by a language-specific handler. While Azure Functions features many [language handlers](#) by default, there are cases where you may want to use other languages or runtimes.

Custom handlers are lightweight web servers that receive events from the Functions host. Any language that supports HTTP primitives can implement a custom handler.

Custom handlers are best suited for situations where you want to:

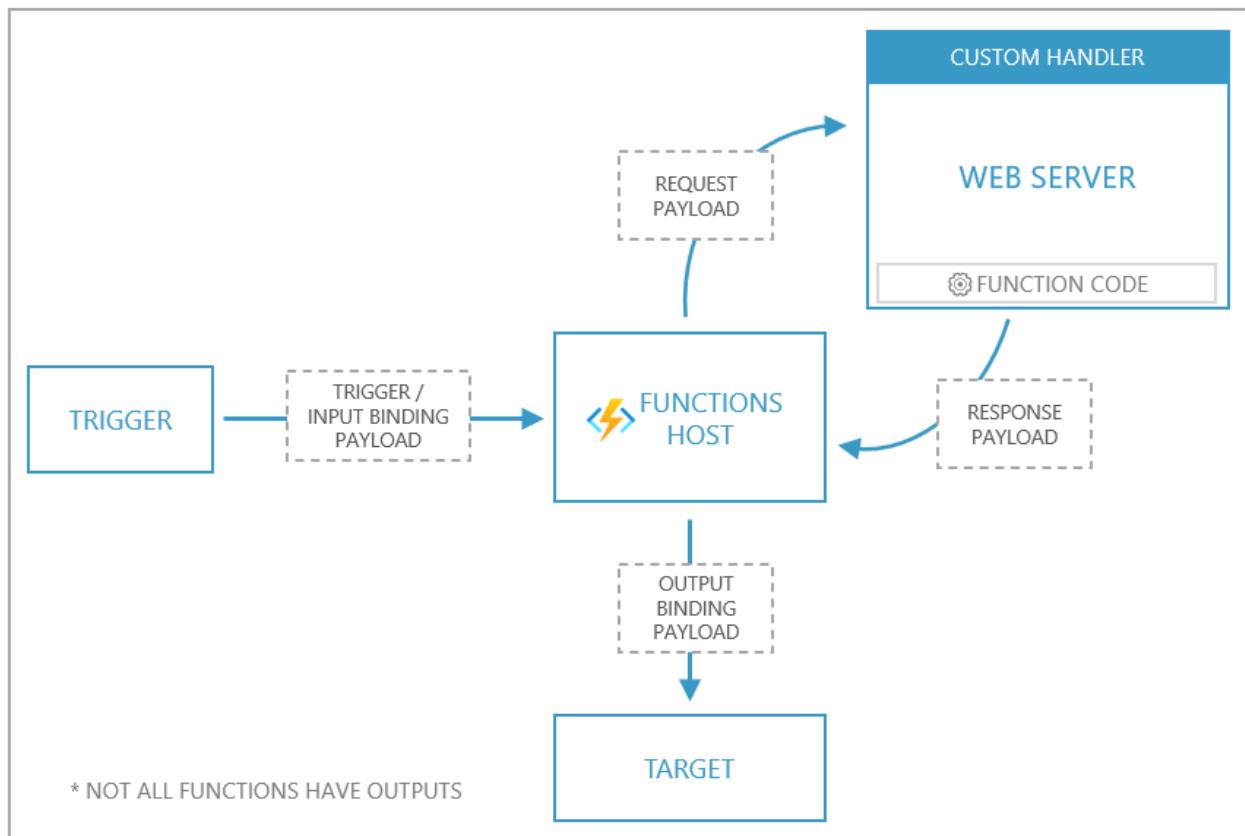

- Implement a function app in a language that's not currently offered out-of-the box, such as Go or Rust.
- Implement a function app in a runtime that's not currently featured by default, such as Deno.

With custom handlers, you can use [triggers and input and output bindings](#) via [extension bundles](#).

Get started with Azure Functions custom handlers with [quickstarts in Go and Rust](#).

Overview

The following diagram shows the relationship between the Functions host and a web server implemented as a custom handler.

1. Each event triggers a request sent to the Functions host. An event is any trigger that is supported by Azure Functions.
2. The Functions host then issues a **request payload** to the web server. The payload holds trigger and input binding data and other metadata for the function.
3. The web server executes the individual function, and returns a **response payload** to the Functions host.
4. The Functions host passes data from the response to the function's output bindings for processing.

An Azure Functions app implemented as a custom handler must configure the *host.json*, *local.settings.json*, and *function.json* files according to a few conventions.

Application structure

To implement a custom handler, you need the following aspects to your application:

- A *host.json* file at the root of your app
- A *local.settings.json* file at the root of your app
- A *function.json* file for each function (inside a folder that matches the function name)
- A command, script, or executable, which runs a web server

The following diagram shows how these files look on the file system for a function named "MyQueueFunction" and a custom handler executable named *handler.exe*.

Bash

```
| /MyQueueFunction  
|   function.json  
|  
| host.json  
| local.settings.json  
| handler.exe
```

Configuration

The application is configured via the *host.json* and *local.settings.json* files.

host.json

host.json tells the Functions host where to send requests by pointing to a web server capable of processing HTTP events.

A custom handler is defined by configuring the *host.json* file with details on how to run the web server via the `customHandler` section.

JSON

```
{  
  "version": "2.0",  
  "customHandler": {  
    "description": {  
      "defaultExecutablePath": "handler.exe"  
    }  
  }  
}
```

The `customHandler` section points to a target as defined by the `defaultExecutablePath`.

The execution target may either be a command, executable, or file where the web server is implemented.

Use the `arguments` array to pass any arguments to the executable. Arguments support expansion of environment variables (application settings) using `%%` notation.

You can also change the working directory used by the executable with `workingDirectory`.

JSON

```
{  
  "version": "2.0",  
  "customHandler": {  
    "description": {  
      "defaultExecutablePath": "app/handler.exe",  
      "arguments": [  
        "--database-connection-string",  
        "%DATABASE_CONNECTION_STRING%"  
      ],  
      "workingDirectory": "app"  
    }  
  }  
}
```

Bindings support

Standard triggers along with input and output bindings are available by referencing [extension bundles](#) in your `host.json` file.

local.settings.json

`local.settings.json` defines application settings used when running the function app locally. As it may contain secrets, `local.settings.json` should be excluded from source control. In Azure, use application settings instead.

For custom handlers, set `FUNCTIONS_WORKER_RUNTIME` to `Custom` in `local.settings.json`.

JSON

```
{  
  "IsEncrypted": false,  
  "Values": {  
    "FUNCTIONS_WORKER_RUNTIME": "Custom"  
  }  
}
```

Function metadata

When used with a custom handler, the `function.json` contents are no different from how you would define a function under any other context. The only requirement is that `function.json` files must be in a folder named to match the function name.

The following `function.json` configures a function that has a queue trigger and a queue output binding. Because it's in a folder named `MyQueueFunction`, it defines a function

named *MyQueueFunction*.

MyQueueFunction/function.json

```
JSON

{
  "bindings": [
    {
      "name": "myQueueItem",
      "type": "queueTrigger",
      "direction": "in",
      "queueName": "messages-incoming",
      "connection": "AzureWebJobsStorage"
    },
    {
      "name": "$return",
      "type": "queue",
      "direction": "out",
      "queueName": "messages-outgoing",
      "connection": "AzureWebJobsStorage"
    }
  ]
}
```

Request payload

When a queue message is received, the Functions host sends an HTTP post request to the custom handler with a payload in the body.

The following code represents a sample request payload. The payload includes a JSON structure with two members: `Data` and `Metadata`.

The `Data` member includes keys that match input and trigger names as defined in the bindings array in the *function.json* file.

The `Metadata` member includes [metadata generated from the event source](#).

```
JSON

{
  "Data": {
    "myQueueItem": "{ message: \"Message sent\" }"
  },
  "Metadata": {
    "DequeueCount": 1,
    "ExpirationTime": "2019-10-16T17:58:31+00:00",
    "Id": "800ae4b3-bdd2-4c08-badd-f08e5a34b865",
    "InsertionTime": "2019-10-09T17:58:31+00:00",
    "LastModifiedTime": "2019-10-09T17:58:31+00:00"
  }
}
```

```

    "NextVisibleTime": "2019-10-09T18:08:32+00:00",
    "PopReceipt": "AgAAAAAMAAAAAAAAGtnj8x+1QE=",
    "sys": {
        "MethodName": "QueueTrigger",
        "UtcNow": "2019-10-09T17:58:32.2205399Z",
        "RandGuid": "24ad4c06-24ad-4e5b-8294-3da9714877e9"
    }
}

```

Response payload

By convention, function responses are formatted as key/value pairs. Supported keys include:

Payload key	Data type	Remarks
Outputs	object	Holds response values as defined by the <code>bindings</code> array in <code>function.json</code> . For instance, if a function is configured with a queue output binding named "myQueueOutput", then <code>Outputs</code> contains a key named <code>myQueueOutput</code> , which is set by the custom handler to the messages that are sent to the queue.
Logs	array	Messages appear in the Functions invocation logs. When running in Azure, messages appear in Application Insights.
ReturnValue	string	Used to provide a response when an output is configured as <code>\$return</code> in the <code>function.json</code> file.

This is an example of a response payload.

JSON

```
{
  "Outputs": {
    "res": {
      "body": "Message enqueued"
    },
    "myQueueOutput": [
      "queue message 1",
      "queue message 2"
    ]
  },
  "Logs": [
    "Log message 1",
    "Log message 2"
  ]
}
```

```
],
  "ReturnValue": "{\"hello\":\"world\"}"
}
```

Examples

Custom handlers can be implemented in any language that supports receiving HTTP events. The following examples show how to implement a custom handler using the Go programming language.

Function with bindings

The scenario implemented in this example features a function named `order` that accepts a `POST` with a payload representing a product order. As an order is posted to the function, a Queue Storage message is created and an HTTP response is returned.

Implementation

In a folder named `order`, the `function.json` file configures the HTTP-triggered function.

order/function.json

JSON

```
{
  "bindings": [
    {
      "type": "httpTrigger",
      "direction": "in",
      "name": "req",
      "methods": ["post"]
    },
    {
      "type": "http",
      "direction": "out",
      "name": "res"
    },
    {
      "type": "queue",
      "name": "message",
      "direction": "out",
      "queueName": "orders",
      "connection": "AzureWebJobsStorage"
    }
  ]
}
```

This function is defined as an [HTTP triggered function](#) that returns an [HTTP response](#) and outputs a [Queue storage](#) message.

At the root of the app, the `host.json` file is configured to run an executable file named `handler.exe` (`handler` in Linux or macOS).

JSON

```
{  
  "version": "2.0",  
  "customHandler": {  
    "description": {  
      "defaultExecutablePath": "handler.exe"  
    }  
  },  
  "extensionBundle": {  
    "id": "Microsoft.Azure.Functions.ExtensionBundle",  
    "version": "[1.*, 2.0.0)"  
  }  
}
```

This is the HTTP request sent to the Functions runtime.

HTTP

```
POST http://127.0.0.1:7071/api/order HTTP/1.1  
Content-Type: application/json  
  
{  
  "id": 1005,  
  "quantity": 2,  
  "color": "black"  
}
```

The Functions runtime will then send the following HTTP request to the custom handler:

HTTP

```
POST http://127.0.0.1:<FUNCTIONS_CUSTOMHANDLER_PORT>/order HTTP/1.1  
Content-Type: application/json  
  
{  
  "Data": {  
    "req": {  
      "Url": "http://localhost:7071/api/order",  
      "Method": "POST",  
      "Query": "{}",  
      "Headers": {  
        "Content-Type": [  
          "application/json"  
        ]  
      }  
    }  
  }  
}
```

```
        ]
    },
    "Params": {},
    "Body": "{\"id\":1005,\"quantity\":2,\"color\":\"black\"}"
}
},
"Metadata": {
}
}
```

ⓘ Note

Some portions of the payload were removed for brevity.

handler.exe is the compiled Go custom handler program that runs a web server and responds to function invocation requests from the Functions host.

Go

```
package main

import (
    "encoding/json"
    "fmt"
    "log"
    "net/http"
    "os"
)

type InvokeRequest struct {
    Data      map[string]json.RawMessage
    Metadata map[string]interface{}
}

type InvokeResponse struct {
    Outputs    map[string]interface{}
    Logs       []string
    ReturnValue interface{}
}

func orderHandler(w http.ResponseWriter, r *http.Request) {
    var invokeRequest InvokeRequest

    d := json.NewDecoder(r.Body)
    d.Decode(&invokeRequest)

    var reqData map[string]interface{}
    json.Unmarshal(invokeRequest.Data["req"], &reqData)

    outputs := make(map[string]interface{})
    outputs["message"] = reqData["Body"]
```

```

resData := make(map[string]interface{})
resData["body"] = "Order enqueued"
outputs["res"] = resData
invokeResponse := InvokeResponse{outputs, nil, nil}

responseJson, _ := json.Marshal(invokeResponse)

w.Header().Set("Content-Type", "application/json")
w.Write(responseJson)
}

func main() {
    customHandlerPort, exists :=
os.LookupEnv("FUNCTIONS_CUSTOMHANDLER_PORT")
    if !exists {
        customHandlerPort = "8080"
    }
    mux := http.NewServeMux()
    mux.HandleFunc("/order", orderHandler)
    fmt.Println("Go server Listening on: ", customHandlerPort)
    log.Fatal(http.ListenAndServe(": "+customHandlerPort, mux))
}

```

In this example, the custom handler runs a web server to handle HTTP events and is set to listen for requests via the `FUNCTIONS_CUSTOMHANDLER_PORT`.

Even though the Functions host received original HTTP request at `/api/order`, it invokes the custom handler using the function name (its folder name). In this example, the function is defined at the path of `/order`. The host sends the custom handler an HTTP request at the path of `/order`.

As `POST` requests are sent to this function, the trigger data and function metadata are available via the HTTP request body. The original HTTP request body can be accessed in the payload's `Data.req.Body`.

The function's response is formatted into key/value pairs where the `Outputs` member holds a JSON value where the keys match the outputs as defined in the `function.json` file.

This is an example payload that this handler returns to the Functions host.

JSON

```
{
  "Outputs": {
    "message": "{\"id\":1005,\"quantity\":2,\"color\":\"black\"}",
    "res": {
      "body": "Order enqueued"
    }
}
```

```
  },
  "Logs": null,
  "ReturnValue": null
}
```

By setting the `message` output equal to the order data that came in from the request, the function outputs that order data to the configured queue. The Functions host also returns the HTTP response configured in `res` to the caller.

HTTP-only function

For HTTP-triggered functions with no additional bindings or outputs, you may want your handler to work directly with the HTTP request and response instead of the custom handler `request` and `response` payloads. This behavior can be configured in `host.json` using the `enableForwardingHttpRequest` setting.

ⓘ Important

The primary purpose of the custom handlers feature is to enable languages and runtimes that do not currently have first-class support on Azure Functions. While it may be possible to run web applications using custom handlers, Azure Functions is not a standard reverse proxy. Some features such as response streaming, HTTP/2, and WebSockets are not available. Some components of the HTTP request such as certain headers and routes may be restricted. Your application may also experience excessive **cold start**.

To address these circumstances, consider running your web apps on [Azure App Service](#).

The following example demonstrates how to configure an HTTP-triggered function with no additional bindings or outputs. The scenario implemented in this example features a function named `hello` that accepts a `GET` or `POST`.

Implementation

In a folder named `hello`, the `function.json` file configures the HTTP-triggered function.

hello/function.json

JSON

```
{  
  "bindings": [  
    {  
      "type": "httpTrigger",  
      "authLevel": "anonymous",  
      "direction": "in",  
      "name": "req",  
      "methods": ["get", "post"]  
    },  
    {  
      "type": "http",  
      "direction": "out",  
      "name": "res"  
    }  
  ]  
}
```

The function is configured to accept both `GET` and `POST` requests and the result value is provided via an argument named `res`.

At the root of the app, the `host.json` file is configured to run `handler.exe` and `enableForwardingHttpRequest` is set to `true`.

JSON

```
{  
  "version": "2.0",  
  "customHandler": {  
    "description": {  
      "defaultExecutablePath": "handler.exe"  
    },  
    "enableForwardingHttpRequest": true  
  }  
}
```

When `enableForwardingHttpRequest` is `true`, the behavior of HTTP-only functions differs from the default custom handlers behavior in these ways:

- The HTTP request does not contain the custom handlers `request` payload. Instead, the Functions host invokes the handler with a copy of the original HTTP request.
- The Functions host invokes the handler with the same path as the original request including any query string parameters.
- The Functions host returns a copy of the handler's HTTP response as the response to the original request.

The following is a POST request to the Functions host. The Functions host then sends a copy of the request to the custom handler at the same path.

HTTP

```
POST http://127.0.0.1:7071/api/hello HTTP/1.1
Content-Type: application/json

{
  "message": "Hello World!"
}
```

The file `handler.go` file implements a web server and HTTP function.

Go

```
package main

import (
    "fmt"
    "io/ioutil"
    "log"
    "net/http"
    "os"
)

func helloHandler(w http.ResponseWriter, r *http.Request) {
    w.Header().Set("Content-Type", "application/json")
    if r.Method == "GET" {
        w.Write([]byte("hello world"))
    } else {
        body, _ := ioutil.ReadAll(r.Body)
        w.Write(body)
    }
}

func main() {
    customHandlerPort, exists :=
    os.LookupEnv("FUNCTIONS_CUSTOMHANDLER_PORT")
    if !exists {
        customHandlerPort = "8080"
    }
    mux := http.NewServeMux()
    mux.HandleFunc("/api/hello", helloHandler)
    fmt.Println("Go server Listening on: ", customHandlerPort)
    log.Fatal(http.ListenAndServe(": "+customHandlerPort, mux))
}
```

In this example, the custom handler creates a web server to handle HTTP events and is set to listen for requests via the `FUNCTIONS_CUSTOMHANDLER_PORT`.

`GET` requests are handled by returning a string, and `POST` requests have access to the request body.

The route for the order function here is `/api/hello`, same as the original request.

ⓘ Note

The `FUNCTIONS_CUSTOMHANDLER_PORT` is not the public facing port used to call the function. This port is used by the Functions host to call the custom handler.

Deploying

A custom handler can be deployed to every Azure Functions hosting option. If your handler requires operating system or platform dependencies (such as a language runtime), you may need to use a [custom container](#).

When creating a function app in Azure for custom handlers, we recommend you select .NET Core as the stack.

To deploy a custom handler app using Azure Functions Core Tools, run the following command.

```
Bash
```

```
func azure functionapp publish $functionAppName
```

ⓘ Note

Ensure all files required to run your custom handler are in the folder and included in the deployment. If your custom handler is a binary executable or has platform-specific dependencies, ensure these files match the target deployment platform.

Restrictions

- The custom handler web server needs to start within 60 seconds.

Samples

Refer to the [custom handler samples GitHub repo](#) ↗ for examples of how to implement functions in a variety of different languages.

Troubleshooting and support

Trace logging

If your custom handler process fails to start up or if it has problems communicating with the Functions host, you can increase the function app's log level to `Trace` to see more diagnostic messages from the host.

To change the function app's default log level, configure the `logLevel` setting in the `logging` section of `host.json`.

```
JSON

{
  "version": "2.0",
  "customHandler": {
    "description": {
      "defaultExecutablePath": "handler.exe"
    }
  },
  "logging": {
    "logLevel": {
      "default": "Trace"
    }
  }
}
```

The Functions host outputs extra log messages including information related to the custom handler process. Use the logs to investigate problems starting your custom handler process or invoking functions in your custom handler.

Locally, logs are printed to the console.

In Azure, [query Application Insights traces](#) to view the log messages. If your app produces a high volume of logs, only a subset of log messages are sent to Application Insights. [Disable sampling](#) to ensure all messages are logged.

Test custom handler in isolation

Custom handler apps are a web server process, so it may be helpful to start it on its own and test function invocations by sending mock [HTTP requests](#) using a tool like [cURL](#) ↗ or [Postman](#) ↗.

You can also use this strategy in your CI/CD pipelines to run automated tests on your custom handler.

Execution environment

Custom handlers run in the same environment as a typical Azure Functions app. Test your handler to ensure the environment contains all the dependencies it needs to run. For apps that require additional dependencies, you may need to run them using a [custom container image](#) hosted on Azure Functions [Premium plan](#).

Get support

If you need help on a function app with custom handlers, you can submit a request through regular support channels. However, due to the wide variety of possible languages used to build custom handlers apps, support is not unlimited.

Support is available if the Functions host has problems starting or communicating with the custom handler process. For problems specific to the inner workings of your custom handler process, such as issues with the chosen language or framework, our Support Team is unable to provide assistance in this context.

Supported languages in Azure Functions

Article • 02/25/2024

This article explains the levels of support offered for your preferred language when using Azure Functions. It also describes strategies for creating functions using languages not natively supported.

There are two levels of support:

- **Generally available (GA)** - Fully supported and approved for production use.
- Preview - Not yet supported, but expected to reach GA status in the future.

Languages by runtime version

The following table shows the .NET versions supported by Azure Functions. Select your preferred development language at the top of the article.

The supported version of .NET depends on both your Functions runtime version and your chosen execution model:

Isolated worker model		
Your function code runs in a separate .NET worker process. Use with supported versions of .NET and .NET Framework . To learn more, see Develop .NET isolated worker process functions .		
v4.x		
Expand table		
Supported version	Support level	Expected community EOL date
.NET 8	GA	November 10, 2026
.NET 6	GA	November 12, 2024
.NET Framework 4.8	GA	See policy

.NET 7 was previously supported on the isolated worker model but reached the end of official support on [May 14, 2024](#).

For more information, see [Guide for running C# Azure Functions in an isolated worker process](#).

For information about planned changes to language support, see [Azure roadmap](#).

Language support details

The following table shows which languages supported by Functions can run on Linux or Windows. It also indicates whether your language supports editing in the Azure portal. The language is based on the **Runtime stack** option you choose when [creating your function app in the Azure portal](#). This is the same as the `--worker-runtime` option when using the `func init` command in Azure Functions Core Tools.

[+] Expand table

Language	Runtime stack	Linux	Windows	In-portal editing
C# (isolated worker model)	.NET	✓	✓	
C# (in-process model)	.NET	✓	✓	
C# script	.NET	✓	✓	✓
JavaScript	Node.js	✓	✓	✓
Python	Python	✓	X	✓
Java	Java	✓	✓	
PowerShell	PowerShell Core	✓	✓	✓
TypeScript	Node.js	✓	✓	
Go/Rust/other	Custom Handlers	✓	✓	

For more information on operating system and language support, see [Operating system/runtime support](#).

When in-portal editing isn't available, you must instead [develop your functions locally](#).

Language major version support

Azure Functions provides a guarantee of support for the major versions of supported programming languages. For most languages, there are minor or patch versions released to update a supported major version. Examples of minor or patch versions include such as Python 3.9.1 and Node 14.17. After new minor versions of supported languages become available, the minor versions used by your functions apps are automatically upgraded to these newer minor or patch versions.

Note

Because Azure Functions can remove the support of older minor versions at any time after a new minor version is available, you shouldn't pin your function apps to a specific minor/patch version of a programming language.

Custom handlers

Custom handlers are lightweight web servers that receive events from the Azure Functions host. Any language that supports HTTP primitives can implement a custom handler. This means that custom handlers can be used to create functions in languages that aren't officially supported. To learn more, see [Azure Functions custom handlers](#).

Language extensibility

Starting with version 2.x, the runtime is designed to offer [language extensibility](#). The JavaScript and Java languages in the 2.x runtime are built with this extensibility.

Isolated worker model

[.NET isolated worker process reference](#)

Guide for running C# Azure Functions in the isolated worker model

Article • 10/16/2024

This article is an introduction to working with Azure Functions in .NET, using the isolated worker model. This model allows your project to target versions of .NET independently of other runtime components. For information about specific .NET versions supported, see [supported version](#).

Use the following links to get started right away building .NET isolated worker model functions.

 Expand table

Getting started	Concepts	Samples
<ul style="list-style-type: none">• Using Visual Studio Code• Using command line tools• Using Visual Studio	<ul style="list-style-type: none">• Hosting options• Monitoring	<ul style="list-style-type: none">• Reference samples ↗

To learn just about deploying an isolated worker model project to Azure, see [Deploy to Azure Functions](#).

Benefits of the isolated worker model

There are two modes in which you can run your .NET class library functions: either [in the same process](#) as the Functions host runtime (*in-process*) or in an isolated worker process. When your .NET functions run in an isolated worker process, you can take advantage of the following benefits:

- **Fewer conflicts:** Because your functions run in a separate process, assemblies used in your app don't conflict with different versions of the same assemblies used by the host process.
- **Full control of the process:** You control the start-up of the app, which means that you can manage the configurations used and the middleware started.
- **Standard dependency injection:** Because you have full control of the process, you can use current .NET behaviors for dependency injection and incorporating middleware into your function app.
- **.NET version flexibility:** Running outside of the host process means that your functions can run on versions of .NET not natively supported by the Functions

runtime, including the .NET Framework.

If you have an existing C# function app that runs in-process, you need to migrate your app to take advantage of these benefits. For more information, see [Migrate .NET apps from the in-process model to the isolated worker model](#).

For a comprehensive comparison between the two modes, see [Differences between in-process and isolate worker process .NET Azure Functions](#).

Supported versions

Versions of the Functions runtime support specific versions of .NET. To learn more about Functions versions, see [Azure Functions runtime versions overview](#). Version support also depends on whether your functions run in-process or isolated worker process.

 **Note**

To learn how to change the Functions runtime version used by your function app, see [view and update the current runtime version](#).

The following table shows the highest level of .NET or .NET Framework that can be used with a specific version of Functions.

 Expand table

Functions runtime version	Isolated worker model	In-process model ⁵
Functions 4.x ¹	.NET 9.0 (preview) .NET 8.0 .NET 6.0 ² .NET Framework 4.8 ³	.NET 8.0 .NET 6.0 ²
Functions 1.x ⁴	n/a	.NET Framework 4.8

¹ .NET 7 was previously supported on the isolated worker model but reached the [end of official support](#) on May 14, 2024.

² .NET 6 reaches the [end of official support](#) on November 12, 2024.

³ The build process also requires the [.NET SDK](#).

⁴ Support ends for version 1.x of the Azure Functions runtime on September 14, 2026. For more information, see [this support announcement](#). For continued full support, you should [migrate your apps to version 4.x](#).

⁵ Support ends for the in-process model on November 10, 2026. For more information, see [this support announcement](#). For continued full support, you should [migrate your apps to the isolated worker model](#).

For the latest news about Azure Functions releases, including the removal of specific older minor versions, monitor [Azure App Service announcements](#).

Project structure

A .NET project for Azure Functions using the isolated worker model is basically a .NET console app project that targets a supported .NET runtime. The following are the basic files required in any .NET isolated project:

- C# project file (.csproj) that defines the project and dependencies.
- Program.cs file that's the entry point for the app.
- Any code files [defining your functions](#).
- `host.json` file that defines configuration shared by functions in your project.
- `local.settings.json` file that defines environment variables used by your project when run locally on your machine.

For complete examples, see the [.NET 8 sample project](#) and the [.NET Framework 4.8 sample project](#).

Package references

A .NET project for Azure Functions using the isolated worker model uses a unique set of packages, for both core functionality and binding extensions.

Core packages

The following packages are required to run your .NET functions in an isolated worker process:

- `Microsoft.Azure.Functions.Worker`
- `Microsoft.Azure.Functions.Worker.Sdk`

Version 2.x (Preview)

The 2.x versions of the core packages change the supported frameworks and bring in support for new .NET APIs from these later versions. When you target .NET 9 (Preview) or later, your app needs to reference version 2.0.0-preview1 or later of both packages.

The initial preview versions are compatible with code written against version 1.x. However, during the preview period, newer versions may introduce behavior changes that could influence the code you write.

When updating to the 2.x versions, note the following changes:

- Starting with version 2.0.0-preview2, [Microsoft.Azure.Functions.Worker.Sdk](#) adds default configurations for [SDK container builds](#).
- Starting with version 2.0.0-preview2 of [Microsoft.Azure.Functions.Worker](#):
 - This version adds support for `IHostApplicationBuilder`. Some examples in this guide include tabs to show alternatives using `IHostApplicationBuilder`. These examples require the 2.x versions.
 - Service provider scope validation is included by default if run in a development environment. This behavior matches ASP.NET Core.
 - The `EnableUserCodeException` option is enabled by default. The property is now marked as obsolete.
 - The `IncludeEmptyEntriesInMessagePayload` option is enabled by default. With this option enabled, trigger payloads that represent collections always include empty entries. For example, if a message is sent without a body, an empty entry would still be present in `string[]` for the trigger data. The inclusion of empty entries facilitates cross-referencing with metadata arrays which the function may also reference. You can disable this behavior by setting `IncludeEmptyEntriesInMessagePayload` to `false` in the `WorkerOptions` service configuration.
 - The `ILoggerExtensions` class is renamed to `FunctionsLoggerExtensions`. The rename prevents an ambiguous call error when using `LogMetric()` on an `ILogger` instance.

Extension packages

Because .NET isolated worker process functions use different binding types, they require a unique set of binding extension packages.

You find these extension packages under [Microsoft.Azure.Functions.Worker.Extensions](#).

Start-up and configuration

When you use the isolated worker model, you have access to the start-up of your function app, which is usually in `Program.cs`. You're responsible for creating and starting

your own host instance. As such, you also have direct access to the configuration pipeline for your app. With .NET Functions isolated worker process, you can much more easily add configurations, inject dependencies, and run your own middleware.

IHostBuilder

The following code shows an example of a [HostBuilder](#) pipeline:

```
C#  
  
var host = new HostBuilder()  
    .ConfigureFunctionsWorkerDefaults()  
    .ConfigureServices(s =>  
    {  
        s.AddApplicationInsightsTelemetryWorkerService();  
        s.ConfigureFunctionsApplicationInsights();  
        s.AddSingleton<IHttpResponderService,  
DefaultHttpResponderService>();  
        s.Configure<LoggerFilterOptions>(options =>  
        {  
            // The Application Insights SDK adds a default logging  
            filter that instructs ILogger to capture only Warning and more severe  
            logs. Application Insights requires an explicit override.  
            // Log levels can also be configured using appsettings.json.  
            // For more information, see https://learn.microsoft.com/en-us/azure/azure-  
            monitor/app/worker-service#ilogger-logs  
            LoggerFilterRule toRemove =  
            options.Rules.FirstOrDefault(rule => rule.ProviderName  
                ==  
                "Microsoft.Extensions.Logging.ApplicationInsights.ApplicationInsightsLog  
                gerProvider");  
  
            if (toRemove is not null)  
            {  
                options.Rules.Remove(toRemove);  
            }  
        });  
    })  
    .Build();
```

This code requires `using Microsoft.Extensions.DependencyInjection;`.

Before calling `Build()` on the `IHostBuilder`, you should:

- Call either `ConfigureFunctionsWebApplication()` if using [ASP.NET Core integration](#) or `ConfigureFunctionsWorkerDefaults()` otherwise. See [HTTP trigger](#) for details on these options.
If you're writing your application using F#, some trigger and binding extensions require extra configuration. See the setup documentation for the

[Blobs extension](#), the [Tables extension](#), and the [Cosmos DB extension](#) when you plan to use these extensions in an F# app.

- Configure any services or app configuration your project requires. See [Configuration](#) for details.

If you're planning to use Application Insights, you need to call

```
AddApplicationInsightsTelemetryWorkerService()
```

```
ConfigureFunctionsApplicationInsights()
```

in the `ConfigureServices()` delegate. See [Application Insights](#) for details.

If your project targets .NET Framework 4.8, you also need to add `FunctionsDebugger.Enable();` before creating the HostBuilder. It should be the first line of your `Main()` method. For more information, see [Debugging when targeting .NET Framework](#).

The [HostBuilder](#) is used to build and return a fully initialized [IHost](#) instance, which you run asynchronously to start your function app.

```
C#
```

```
await host.RunAsync();
```

Configuration

The type of builder you use determines how you can configure the application.

```
IHostBuilder
```

The [ConfigureFunctionsWorkerDefaults](#) method is used to add the settings required for the function app to run. The method includes the following functionality:

- Default set of converters.
- Set the default [JsonSerializerOptions](#) to ignore casing on property names.
- Integrate with Azure Functions logging.
- Output binding middleware and features.
- Function execution middleware.
- Default gRPC support.

```
C#
```

```
.ConfigureFunctionsWorkerDefaults()
```

Having access to the host builder pipeline means that you can also set any app-specific configurations during initialization. You can call the [ConfigureAppConfiguration](#) method on [HostBuilder](#) one or more times to add any configuration sources required by your code. To learn more about app configuration, see [Configuration in ASP.NET Core](#).

These configurations only apply to the worker code you author, and they don't directly influence the configuration of the Functions host or triggers and bindings. To make changes to the functions host or trigger and binding configuration, you still need to use the [host.json file](#).

ⓘ Note

Custom configuration sources cannot be used for configuration of triggers and bindings. Trigger and binding configuration must be available to the Functions platform, and not just your application code. You can provide this configuration through the [application settings](#), [Key Vault references](#), or [App Configuration references](#) features.

Dependency injection

The isolated worker model uses standard .NET mechanisms for injecting services.

IHostBuilder

When you use a `HostBuilder`, call [ConfigureServices](#) on the host builder and use the extension methods on [IServiceCollection](#) to inject specific services. The following example injects a singleton service dependency:

C#

```
.ConfigureServices(services =>
{
    services.AddSingleton<IHttpResponderService,
DefaultHttpResponderService>();
})
```

This code requires `using Microsoft.Extensions.DependencyInjection;`. To learn more, see [Dependency injection in ASP.NET Core](#).

Register Azure clients

Dependency injection can be used to interact with other Azure services. You can inject clients from the [Azure SDK for .NET](#) using the [Microsoft.Extensions.Azure](#) package. After installing the package, [register the clients](#) by calling `AddAzureClients()` on the service collection in `Program.cs`. The following example configures a [named client](#) for Azure Blobs:

```
IHostBuilder

C#

using Microsoft.Azure.Functions.Worker;
using Microsoft.Extensions.Azure;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;

var host = new HostBuilder()
    .ConfigureFunctionsWorkerDefaults()
    .ConfigureServices((hostContext, services) =>
{
    services.AddAzureClients(clientBuilder =>
    {

        clientBuilder.AddBlobServiceClient(hostContext.Configuration.GetSection(
            "MyStorageConnection"))
            .WithName("copierOutputBlob");
    });
})
.Build();

host.Run();
```

The following example shows how we can use this registration and [SDK types](#) to copy blob contents as a stream from one container to another using an injected client:

```
C#

using Microsoft.Extensions.Azure;
using Microsoft.Extensions.Logging;

namespace MyFunctionApp
{
    public class BlobCopier
    {
        private readonly ILogger<BlobCopier> _logger;
        private readonly BlobContainerClient _copyContainerClient;
```

```

        public BlobCopier	ILogger<BlobCopier> logger,
IAzureClientFactory<BlobServiceClient> blobClientFactory)
{
    _logger = logger;
    _copyContainerClient =
blobClientFactory.CreateClient("copierOutputBlob").GetBlobContainerClient("s
amples-workitems-copy");
    _copyContainerClient.CreateIfNotExists();
}

[Function("BlobCopier")]
public async Task Run([BlobTrigger("samples-workitems/{name}", Connection = "MyStorageConnection")] Stream myBlob, string name)
{
    await _copyContainerClient.UploadBlobAsync(name, myBlob);
    _logger.LogInformation($"Blob {name} copied!");
}
}

```

The `ILogger<T>` in this example was also obtained through dependency injection, so it's registered automatically. To learn more about configuration options for logging, see [Logging](#).

💡 Tip

The example used a literal string for the name of the client in both `Program.cs` and the function. Consider instead using a shared constant string defined on the function class. For example, you could add `public const string CopyStorageClientName = nameof(_copyContainerClient);` and then reference `BlobCopier.CopyStorageClientName` in both locations. You could similarly define the configuration section name with the function rather than in `Program.cs`.

Middleware

The isolated worker model also supports middleware registration, again by using a model similar to what exists in ASP.NET. This model gives you the ability to inject logic into the invocation pipeline, and before and after functions execute.

The `ConfigureFunctionsWorkerDefaults` extension method has an overload that lets you register your own middleware, as you can see in the following example.

IHostBuilder

C#

```
var host = new HostBuilder()
    .ConfigureFunctionsWorkerDefaults(workerApplication =>
{
    // Register our custom middlewares with the worker

    workerApplication.UseMiddleware<ExceptionHandlingMiddleware>();

    workerApplication.UseMiddleware<MyCustomMiddleware>();

    workerApplication.UseWhen<StampHttpHeaderMiddleware>((context)
=>
{
    // We want to use this middleware only for http trigger
    invocations.
    return context.FunctionDefinition.InputBindings.Values
        .First(a => a.Type.EndsWith("Trigger")).Type
== "httpTrigger";
});
})
.Build();
```

The `UseWhen` extension method can be used to register a middleware that gets executed conditionally. You must pass to this method a predicate that returns a boolean value, and the middleware participates in the invocation processing pipeline when the return value of the predicate is `true`.

The following extension methods on `FunctionContext` make it easier to work with middleware in the isolated model.

[] [Expand table](#)

Method	Description
<code>GetHttpRequestDataAsync</code>	Gets the <code>HttpRequestData</code> instance when called by an HTTP trigger. This method returns an instance of <code>ValueTask<HttpRequestData?></code> , which is useful when you want to read message data, such as request headers and cookies.
<code>GetHttpResponseData</code>	Gets the <code>HttpResponseData</code> instance when called by an HTTP trigger.
<code>GetInvocationResult</code>	Gets an instance of <code>InvocationResult</code> , which represents the result of the current function execution. Use the <code>Value</code> property to get or set the value as needed.
<code>GetOutputBindings</code>	Gets the output binding entries for the current function execution. Each entry in the result of this method is of type <code>OutputBindingData</code> .

Method	Description
	You can use the <code>Value</code> property to get or set the value as needed.
<code>BindInputAsync</code>	Binds an input binding item for the requested <code>BindingMetadata</code> instance. For example, you can use this method when you have a function with a <code>BlobInput</code> input binding that needs to be used by your middleware.

This is an example of a middleware implementation that reads the `HttpRequestData` instance and updates the `HttpResponseData` instance during function execution:

C#

```
internal sealed class StampHttpHeaderMiddleware : IFunctionsWorkerMiddleware
{
    public async Task Invoke(FunctionContext context,
    FunctionExecutionDelegate next)
    {
        var requestData = await context.GetHttpRequestDataAsync();

        string correlationId;
        if (requestData!.Headers.TryGetValues("x-correlationId", out var
values))
        {
            correlationId = values.First();
        }
        else
        {
            correlationId = Guid.NewGuid().ToString();
        }

        await next(context);

        context.GetHttpResponseData()!.Headers.Add("x-correlationId",
correlationId);
    }
}
```

This middleware checks for the presence of a specific request header(x-correlationId), and when present uses the header value to stamp a response header. Otherwise, it generates a new GUID value and uses that for stamping the response header. For a more complete example of using custom middleware in your function app, see the [custom middleware reference sample ↗](#).

Customizing JSON serialization

The isolated worker model uses `System.Text.Json` by default. You can customize the behavior of the serializer by configuring services as part of your `Program.cs` file. This section covers general-purpose serialization and won't influence [HTTP trigger JSON serialization with ASP.NET Core integration](#), which must be configured separately.

IHostBuilder

The following example shows this using `ConfigureFunctionsWebApplication`, but it will also work for `ConfigureFunctionsWorkerDefaults`:

C#

```
using Microsoft.Azure.Functions.Worker;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;

var host = new HostBuilder()

.ConfigureFunctionsWebApplication((IFunctionsWorkerApplicationBuilder
builder) =>
{
    builder.Services.Configure<JsonSerializerOptions>
(jsonSerializerOptions =>
{
    jsonSerializerOptions.PropertyNamingPolicy =
JsonNamingPolicy.CamelCase;
    jsonSerializerOptions.DefaultIgnoreCondition =
JsonIgnoreCondition.WhenWritingNull;
    jsonSerializerOptions.ReferenceHandler =
ReferenceHandler.Preserve;

    // override the default value
    jsonSerializerOptions.PropertyNameCaseInsensitive = false;
});
})
.Build();

host.Run();
```

You might want to instead use JSON.NET (`Newtonsoft.Json`) for serialization. To do this, you would install the [Microsoft.Azure.Core.NewtonsoftJson](#) package. Then, in your service registration, you would reassign the `Serializer` property on the `WorkerOptions` configuration. The following example shows this using `ConfigureFunctionsWebApplication`, but it will also work for `ConfigureFunctionsWorkerDefaults`:

IHostBuilder

C#

```
using Microsoft.Azure.Functions.Worker;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;

var host = new HostBuilder()

.ConfigureFunctionsWebApplication((IFunctionsWorkerApplicationBuilder
builder) =>
{
    builder.Services.Configure<WorkerOptions>(workerOptions =>
    {
        var settings =
NewtonsoftJsonObjectSerializer.CreateJsonSerializerSettings();
        settings.ContractResolver = new
CamelCasePropertyNamesContractResolver();
        settings.NullValueHandling = NullValueHandling.Ignore;

        workerOptions.Serializer = new
NewtonsoftJsonObjectSerializer(settings);
    });
})
.Build();

host.Run();
```

Methods recognized as functions

A function method is a public method of a public class with a `Function` attribute applied to the method and a trigger attribute applied to an input parameter, as shown in the following example:

C#

```
[Function(nameof(QueueFunction))]
[QueueOutput("output-queue")]
public string[] Run([QueueTrigger("input-queue")] Album myQueueItem,
FunctionContext context)
```

The trigger attribute specifies the trigger type and binds input data to a method parameter. The previous example function is triggered by a queue message, and the queue message is passed to the method in the `myQueueItem` parameter.

The `Function` attribute marks the method as a function entry point. The name must be unique within a project, start with a letter and only contain letters, numbers, `_`, and `-`, up to 127 characters in length. Project templates often create a method named `Run`, but the method name can be any valid C# method name. The method must be a public member of a public class. It should generally be an instance method so that services can be passed in via [dependency injection](#).

Function parameters

Here are some of the parameters that you can include as part of a function method signature:

- [Bindings](#), which are marked as such by decorating the parameters as attributes. The function must contain exactly one trigger parameter.
- An [execution context object](#), which provides information about the current invocation.
- A [cancellation token](#), used for graceful shutdown.

Execution context

.NET isolated passes a `FunctionContext` object to your function methods. This object lets you get an `ILogger` instance to write to the logs by calling the `GetLogger` method and supplying a `categoryName` string. You can use this context to obtain an `ILogger` without having to use dependency injection. To learn more, see [Logging](#).

Cancellation tokens

A function can accept a `CancellationToken` parameter, which enables the operating system to notify your code when the function is about to be terminated. You can use this notification to make sure the function doesn't terminate unexpectedly in a way that leaves data in an inconsistent state.

Cancellation tokens are supported in .NET functions when running in an isolated worker process. The following example raises an exception when a cancellation request is received:

C#

```
[Function(nameof(ThrowOnCancellation))]
public async Task ThrowOnCancellation(
    [EventHubTrigger("sample-workitem-1", Connection =
    "EventHubConnection")] string[] messages,
```

```

        FunctionContext context,
        CancellationToken cancellationToken)
{
    _logger.LogInformation("C# EventHub {functionName} trigger function
processing a request.", nameof(ThrowOnCancellation));

    foreach (var message in messages)
    {
        cancellationToken.ThrowIfCancellationRequested();
        await Task.Delay(6000); // task delay to simulate message processing
        _logger.LogInformation("Message '{msg}' was processed.", message);
    }
}

```

The following example performs clean-up actions when a cancellation request is received:

C#

```

[Function(nameof(HandleCancellationCleanup))]
public async Task HandleCancellationCleanup(
    [EventHubTrigger("sample-workitem-2", Connection =
"EventHubConnection")] string[] messages,
    FunctionContext context,
    CancellationToken cancellationToken)
{
    _logger.LogInformation("C# EventHub {functionName} trigger function
processing a request.", nameof(HandleCancellationCleanup));

    foreach (var message in messages)
    {
        if (cancellationToken.IsCancellationRequested)
        {
            _logger.LogInformation("A cancellation token was received,
taking precautionary actions.");
            // Take precautions like noting how far along you are with
processing the batch
            _logger.LogInformation("Precautionary activities complete.");
            break;
        }

        await Task.Delay(6000); // task delay to simulate message processing
        _logger.LogInformation("Message '{msg}' was processed.", message);
    }
}

```

Bindings

Bindings are defined by using attributes on methods, parameters, and return types. Bindings can provide data as strings, arrays, and serializable types, such as plain old

class objects (POCOs). For some binding extensions, you can also [bind to service-specific types](#) defined in service SDKs.

For HTTP triggers, see the [HTTP trigger](#) section.

For a complete set of reference samples using triggers and bindings with isolated worker process functions, see the [binding extensions reference sample ↗](#).

Input bindings

A function can have zero or more input bindings that can pass data to a function. Like triggers, input bindings are defined by applying a binding attribute to an input parameter. When the function executes, the runtime tries to get data specified in the binding. The data being requested is often dependent on information provided by the trigger using binding parameters.

Output bindings

To write to an output binding, you must apply an output binding attribute to the function method, which defines how to write to the bound service. The value returned by the method is written to the output binding. For example, the following example writes a string value to a message queue named `output-queue` by using an output binding:

C#

```
[Function(nameof(QueueFunction))]
[QueueOutput("output-queue")]
public string[] Run([QueueTrigger("input-queue")] Album myQueueItem,
FunctionContext context)
{
    // Use a string array to return more than one message.
    string[] messages = {
        $"Album name = {myQueueItem.Name}",
        $"Album songs = {myQueueItem.Songs.ToString()}};

    _logger.LogInformation("{msg1},{msg2}", messages[0], messages[1]);

    // Queue Output messages
    return messages;
}
```

Multiple output bindings

The data written to an output binding is always the return value of the function. If you need to write to more than one output binding, you must create a custom return type. This return type must have the output binding attribute applied to one or more properties of the class. The following example is an HTTP-triggered function using [ASP.NET Core integration](#) which writes to both the HTTP response and a queue output binding:

C#

```
public class MultipleOutputBindings
{
    private readonly ILogger<MultipleOutputBindings> _logger;

    public MultipleOutputBindings(ILogger<MultipleOutputBindings> logger)
    {
        _logger = logger;
    }

    [Function("MultipleOutputBindings")]
    public MyOutputType Run([HttpTrigger(AuthorizationLevel.Function,
    "post")] HttpRequest req)
    {
        _logger.LogInformation("C# HTTP trigger function processed a
request.");
        var myObject = new MyOutputType
        {
            Result = new OkObjectResult("C# HTTP trigger function processed
a request."),
            MessageText = "some output"
        };
        return myObject;
    }

    public class MyOutputType
    {
        [HttpPost]
        public IActionResult Result { get; set; }

        [QueueOutput("myQueue")]
        public string MessageText { get; set; }
    }
}
```

When using custom return types for multiple output bindings with ASP.NET Core integration, you must add the `[HttpPost]` attribute to the property that provides the result. The `HttpPost` attribute is available when using [SDK 1.17.3-preview2 or later](#) along with [version 3.2.0 or later of the HTTP extension](#) and [version 1.3.0 or later of the ASP.NET Core extension](#).

SDK types

For some service-specific binding types, binding data can be provided using types from service SDKs and frameworks. These provide more capability beyond what a serialized string or plain-old CLR object (POCO) can offer. To use the newer types, your project needs to be updated to use newer versions of core dependencies.

[+] Expand table

Dependency	Version requirement
Microsoft.Azure.Functions.Worker	1.18.0 or later
Microsoft.Azure.Functions.Worker.Sdk	1.13.0 or later

When testing SDK types locally on your machine, you also need to use [Azure Functions Core Tools](#), version 4.0.5000 or later. You can check your current version using the `func version` command.

Each trigger and binding extension also has its own minimum version requirement, which is described in the extension reference articles. The following service-specific bindings provide SDK types:

[+] Expand table

Service	Trigger	Input binding	Output binding
Azure Blobs	Generally Available	Generally Available	<i>SDK types not recommended.¹</i>
Azure Queues	Generally Available	<i>Input binding doesn't exist</i>	<i>SDK types not recommended.¹</i>
Azure Service Bus	Generally Available	<i>Input binding doesn't exist</i>	<i>SDK types not recommended.¹</i>
Azure Event Hubs	Generally Available	<i>Input binding doesn't exist</i>	<i>SDK types not recommended.¹</i>
Azure Cosmos DB	<i>SDK types not used²</i>	Generally Available	<i>SDK types not recommended.¹</i>
Azure Tables	<i>Trigger doesn't exist</i>	Generally Available	<i>SDK types not recommended.¹</i>
Azure Event Grid	Generally Available	<i>Input binding doesn't exist</i>	<i>SDK types not recommended.¹</i>

¹ For output scenarios in which you would use an SDK type, you should create and work with SDK clients directly instead of using an output binding. See [Register Azure clients](#) for a dependency injection example.

² The Cosmos DB trigger uses the [Azure Cosmos DB change feed](#) and exposes change feed items as JSON-serializable types. The absence of SDK types is by-design for this scenario.

ⓘ Note

When using [binding expressions](#) that rely on trigger data, SDK types for the trigger itself cannot be used.

HTTP trigger

[HTTP triggers](#) allow a function to be invoked by an HTTP request. There are two different approaches that can be used:

- An [ASP.NET Core integration model](#) that uses concepts familiar to ASP.NET Core developers
- A [built-in model](#), which doesn't require extra dependencies and uses custom types for HTTP requests and responses. This approach is maintained for backward compatibility with previous .NET isolated worker apps.

ASP.NET Core integration

This section shows how to work with the underlying HTTP request and response objects using types from ASP.NET Core including [HttpRequest](#), [HttpResponse](#), and [IActionResult](#). This model isn't available to [apps targeting .NET Framework](#), which should instead use the [built-in model](#).

ⓘ Note

Not all features of ASP.NET Core are exposed by this model. Specifically, the ASP.NET Core middleware pipeline and routing capabilities are not available. ASP.NET Core integration requires you to use updated packages.

To enable ASP.NET Core integration for HTTP:

1. Add a reference in your project to the [Microsoft.Azure.Functions.Worker.Extensions.Http.AspNetCore](#) package, version 1.0.0 or later.

2. Update your project to use these specific package versions:

- [Microsoft.Azure.Functions.Worker.Sdk](#), version 1.11.0 or later
- [Microsoft.Azure.Functions.Worker](#), version 1.16.0 or later.

3. In your `Program.cs` file, update the host builder configuration to call

`ConfigureFunctionsWebApplication()`. This replaces

`ConfigureFunctionsWorkerDefaults()` if you would use that method otherwise. The following example shows a minimal setup without other customizations:

IHostBuilder

C#

```
using Microsoft.Azure.Functions.Worker;
using Microsoft.Extensions.Hosting;

var host = new HostBuilder()
    .ConfigureFunctionsWebApplication()
    .Build();

host.Run();
```

4. Update any existing HTTP-triggered functions to use the ASP.NET Core types. This example shows the standard `HttpRequest` and an `IActionResult` used for a simple "hello, world" function:

C#

```
[Function("HttpFunction")]
public IActionResult Run(
    [HttpTrigger(AuthorizationLevel.Anonymous, "get")] HttpRequest req)
{
    return new OkObjectResult($"Welcome to Azure Functions,
{req.Query["name"]}");
}
```

JSON serialization with ASP.NET Core integration

ASP.NET Core has its own serialization layer, and it is not affected by [customizing general serialization configuration](#). To customize the serialization behavior used for your HTTP triggers, you need to include an `.AddMvc()` call as part of service registration. The returned `IMvcBuilder` can be used to modify ASP.NET Core's JSON serialization settings. The following example shows how to configure JSON.NET (`Newtonsoft.Json`) for serialization using this approach:

```
IHostBuilder

C#

using Microsoft.Azure.Functions.Worker;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;

var host = new HostBuilder()
    .ConfigureFunctionsWebApplication()
    .ConfigureServices(services =>
{
    services.AddApplicationInsightsTelemetryWorkerService();
    services.ConfigureFunctionsApplicationInsights();
    services.AddMvc().AddNewtonsoftJson();
})
.Build();
host.Run();
```

Built-in HTTP model

In the built-in model, the system translates the incoming HTTP request message into an `HttpRequestData` object that is passed to the function. This object provides data from the request, including `Headers`, `Cookies`, `Identities`, `URL`, and optionally a message `Body`. This object is a representation of the HTTP request but isn't directly connected to the underlying HTTP listener or the received message.

Likewise, the function returns an `HttpResponseData` object, which provides data used to create the HTTP response, including message `StatusCode`, `Headers`, and optionally a message `Body`.

The following example demonstrates the use of `HttpRequestData` and `HttpResponseData`:

```
C#
```

```
[Function(nameof(HttpFunction))]
public static HttpResponseData
```

```

Run([HttpTrigger(AuthorizationLevel.Anonymous, "get", "post", Route = null)])
HttpRequestData req,
    FunctionContext executionContext)
{
    var logger = executionContext.GetLogger(nameof(HttpFunction));
    logger.LogInformation("message logged");

    var response = req.CreateResponse(HttpStatusCode.OK);
    response.Headers.Add("Content-Type", "text/plain; charset=utf-8");
    response.WriteString("Welcome to .NET isolated worker !!");

    return response;
}

```

Logging

You can write to logs by using an [ILogger<T>](#) or [ILogger](#) instance. The logger can be obtained through [dependency injection](#) of an [ILogger<T>](#) or of an [ILoggerFactory](#):

C#

```

public class MyFunction {

    private readonly ILogger<MyFunction> _logger;

    public MyFunction(ILogger<MyFunction> logger) {
        _logger = logger;
    }

    [Function(nameof(MyFunction))]
    public void Run([BlobTrigger("samples-workitems/{name}", Connection =
    "")] string myBlob, string name)
    {
        _logger.LogInformation($"C# Blob trigger function Processed blob\n
Name: {name} \n Data: {myBlob}");
    }
}

```

The logger can also be obtained from a [FunctionContext](#) object passed to your function. Call the [GetLogger<T>](#) or [GetLogger](#) method, passing a string value that is the name for the category in which the logs are written. The category is usually the name of the specific function from which the logs are written. To learn more about categories, see the [monitoring article](#).

Use the methods of [ILogger<T>](#) and [ILogger](#) to write various log levels, such as [LogWarning](#) or [.LogError](#). To learn more about log levels, see the [monitoring article](#). You can customize the log levels for components added to your code by registering filters:

IHostBuilder

C#

```
using Microsoft.Azure.Functions.Worker;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;
using Microsoft.Extensions.Logging;

var host = new HostBuilder()
    .ConfigureFunctionsWorkerDefaults()
    .ConfigureServices(services =>
{
    // Registers IHttpClientFactory.
    // By default this sends a lot of Information-level logs.
    services.AddHttpClient();
})
.ConfigureLogging(logging =>
{
    // Disable IHttpClientFactory Informational logs.
    // Note -- you can also remove the handler that does the
    logging:
https://github.com/aspnet/HttpClientFactory/issues/196#issuecomment-432755765
    logging.AddFilter("System.Net.Http.HttpClient",
LogLevel.Warning);
})
.Build();
```

As part of configuring your app in `Program.cs`, you can also define the behavior for how errors are surfaced to your logs. The default behavior depends on the type of builder you're using.

IHostBuilder

When you use a `HostBuilder`, by default, exceptions thrown by your code can end up wrapped in an `RpcException`. To remove this extra layer, set the `EnableUserCodeException` property to "true" as part of configuring the builder:

C#

```
using Microsoft.Azure.Functions.Worker;
using Microsoft.Extensions.Hosting;

var host = new HostBuilder()
    .ConfigureFunctionsWorkerDefaults(builder => {}, options =>
{
    options.EnableUserCodeException = true;
```

```
    })
    .Build();

host.Run();
```

Application Insights

You can configure your isolated process application to emit logs directly to [Application Insights](#). This behavior replaces the default behavior of [relaying logs through the host](#), and is recommended because it gives you control over how those logs are emitted.

Install packages

To write logs directly to Application Insights from your code, add references to these packages in your project:

- [Microsoft.Azure.Functions.Worker.ApplicationInsights](#), version 1.0.0 or later.
- [Microsoft.ApplicationInsights.WorkerService](#).

You can run the following commands to add these references to your project:

.NET CLI

```
dotnet add package Microsoft.ApplicationInsights.WorkerService
dotnet add package Microsoft.Azure.Functions.Worker.ApplicationInsights
```

Configure startup

With the packages installed, you must call

`AddApplicationInsightsTelemetryWorkerService()` and

`ConfigureFunctionsApplicationInsights()` during service configuration in your `Program.cs` file, as in this example:

IHostBuilder

C#

```
using Microsoft.Azure.Functions.Worker;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;

var host = new HostBuilder()
    .ConfigureFunctionsWorkerDefaults()
```

```
.ConfigureServices(services => {
    services.AddApplicationInsightsTelemetryWorkerService();
    services.ConfigureFunctionsApplicationInsights();
})
.Build();

host.Run();
```

The call to `ConfigureFunctionsApplicationInsights()` adds an `ITelemetryModule`, which listens to a Functions-defined `ActivitySource`. This creates the dependency telemetry required to support distributed tracing. To learn more about `AddApplicationInsightsTelemetryWorkerService()` and how to use it, see [Application Insights for Worker Service applications](#).

Managing log levels

Important

The Functions host and the isolated process worker have separate configuration for log levels, etc. Any [Application Insights configuration in host.json](#) will not affect the logging from the worker, and similarly, configuration made in your worker code will not impact logging from the host. You need to apply changes in both places if your scenario requires customization at both layers.

The rest of your application continues to work with `ILogger` and `ILogger<T>`. However, by default, the Application Insights SDK adds a logging filter that instructs the logger to capture only warnings and more severe logs. If you want to disable this behavior, remove the filter rule as part of service configuration:

IHostBuilder

C#

```
using Microsoft.Azure.Functions.Worker;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;
using Microsoft.Extensions.Logging;

var host = new HostBuilder()
    .ConfigureFunctionsWorkerDefaults()
    .ConfigureServices(services => {
        services.AddApplicationInsightsTelemetryWorkerService();
        services.ConfigureFunctionsApplicationInsights();
```

```
        })
    .ConfigureLogging(logging =>
{
    logging.Services.Configure<LoggerFilterOptions>(options =>
    {
        LoggerFilterRule defaultRule =
options.Rules.FirstOrDefault(rule => rule.ProviderName
            ==
"Microsoft.Extensions.Logging.ApplicationInsights.ApplicationInsightsLog
gerProvider");
        if (defaultRule is not null)
        {
            options.Rules.Remove(defaultRule);
        }
    });
})
.Build();

host.Run();
```

Performance optimizations

This section outlines options you can enable that improve performance around [cold start](#).

In general, your app should use the latest versions of its core dependencies. At a minimum, you should update your project as follows:

1. Upgrade [Microsoft.Azure.Functions.Worker](#) to version 1.19.0 or later.
2. Upgrade [Microsoft.Azure.Functions.Worker.Sdk](#) to version 1.16.4 or later.
3. Add a framework reference to `Microsoft.AspNetCore.App`, unless your app targets .NET Framework.

The following snippet shows this configuration in the context of a project file:

XML

```
<ItemGroup>
    <FrameworkReference Include="Microsoft.AspNetCore.App" />
    <PackageReference Include="Microsoft.Azure.Functions.Worker"
Version="1.21.0" />
    <PackageReference Include="Microsoft.Azure.Functions.Worker.Sdk"
Version="1.16.4" />
</ItemGroup>
```

Placeholders

Placeholders are a platform capability that improves cold start for apps targeting .NET 6 or later. To use this optimization, you must explicitly enable placeholders using these steps:

1. Update your project configuration to use the latest dependency versions, as detailed in the previous section.
2. Set the [WEBSITE_USE_PLACEHOLDER_DOTNETISOLATED](#) application setting to 1, which you can do by using this [az functionapp config appsettings set](#) command:

Azure CLI

```
az functionapp config appsettings set -g <groupName> -n <appName> --  
settings 'WEBSITE_USE_PLACEHOLDER_DOTNETISOLATED=1'
```

In this example, replace `<groupName>` with the name of the resource group, and replace `<appName>` with the name of your function app.

3. Make sure that the [netFrameworkVersion](#) property of the function app matches your project's target framework, which must be .NET 6 or later. You can do this by using this [az functionapp config set](#) command:

Azure CLI

```
az functionapp config set -g <groupName> -n <appName> --net-framework-  
version <framework>
```

In this example, also replace `<framework>` with the appropriate version string, such as `v8.0`, according to your target .NET version.

4. Make sure that your function app is configured to use a 64-bit process, which you can do by using this [az functionapp config set](#) command:

Azure CLI

```
az functionapp config set -g <groupName> -n <appName> --use-32bit-  
worker-process false
```

 **Important**

When setting the [WEBSITE_USE_PLACEHOLDER_DOTNETISOLATED](#) to 1, all other function app configurations must be set correctly. Otherwise, your function app might fail to start.

Optimized executor

The function executor is a component of the platform that causes invocations to run. An optimized version of this component is enabled by default starting with version 1.16.2 of the SDK. No other configuration is required.

ReadyToRun

You can compile your function app as [ReadyToRun binaries](#). ReadyToRun is a form of ahead-of-time compilation that can improve startup performance to help reduce the effect of cold starts when running in a [Consumption plan](#). ReadyToRun is available in .NET 6 and later versions and requires [version 4.0 or later](#) of the Azure Functions runtime.

ReadyToRun requires you to build the project against the runtime architecture of the hosting app. **If these are not aligned, your app will encounter an error at startup.** Select your runtime identifier from this table:

[+] [Expand table](#)

Operating System	App is 32-bit ¹	Runtime identifier
Windows	True	win-x86
Windows	False	win-x64
Linux	True	N/A (not supported)
Linux	False	linux-x64

¹ Only 64-bit apps are eligible for some other performance optimizations.

To check if your Windows app is 32-bit or 64-bit, you can run the following CLI command, substituting `<group_name>` with the name of your resource group and `<app_name>` with the name of your application. An output of "true" indicates that the app is 32-bit, and "false" indicates 64-bit.

Azure CLI

```
az functionapp config show -g <group_name> -n <app_name> --query  
"use32BitWorkerProcess"
```

You can change your application to 64-bit with the following command, using the same substitutions:

Azure CLI

```
az functionapp config set -g <group_name> -n <app_name> --use-32bit-worker-process false`
```

To compile your project as ReadyToRun, update your project file by adding the `<PublishReadyToRun>` and `<RuntimeIdentifier>` elements. The following example shows a configuration for publishing to a Windows 64-bit function app.

XML

```
<PropertyGroup>
  <TargetFramework>net8.0</TargetFramework>
  <AzureFunctionsVersion>v4</AzureFunctionsVersion>
  <RuntimeIdentifier>win-x64</RuntimeIdentifier>
  <PublishReadyToRun>true</PublishReadyToRun>
</PropertyGroup>
```

If you don't want to set the `<RuntimeIdentifier>` as part of the project file, you can also configure this as part of the publishing gesture itself. For example, with a Windows 64-bit function app, the .NET CLI command would be:

.NET CLI

```
dotnet publish --runtime win-x64
```

In Visual Studio, the **Target Runtime** option in the publish profile should be set to the correct runtime identifier. When set to the default value of **Portable**, ReadyToRun isn't used.

Deploy to Azure Functions

When you deploy your function code project to Azure, it must run in either a function app or in a Linux container. The function app and other required Azure resources must exist before you deploy your code.

You can also deploy your function app in a Linux container. For more information, see [Working with containers and Azure Functions](#).

Create Azure resources

You can create your function app and other required resources in Azure using one of these methods:

- [Visual Studio](#): Visual Studio can create resources for you during the code publishing process.
- [Visual Studio Code](#): Visual Studio Code can connect to your subscription, create the resources needed by your app, and then publish your code.
- [Azure CLI](#): You can use the Azure CLI to create the required resources in Azure.
- [Azure PowerShell](#): You can use Azure PowerShell to create the required resources in Azure.
- [Deployment templates](#): You can use ARM templates and Bicep files to automate the deployment of the required resources to Azure. Make sure your template includes any [required settings](#).
- [Azure portal](#): You can create the required resources in the [Azure portal](#) ↗.

Publish your application

After creating your function app and other required resources in Azure, you can deploy the code project to Azure using one of these methods:

- [Visual Studio](#): Simple manual deployment during development.
- [Visual Studio Code](#): Simple manual deployment during development.
- [Azure Functions Core Tools](#): Deploy project file from the command line.
- [Continuous deployment](#): Useful for ongoing maintenance, frequently to a [staging slot](#).
- [Deployment templates](#): You can use ARM templates or Bicep files to automate package deployments.

For more information, see [Deployment technologies in Azure Functions](#).

Deployment payload

Many of the deployment methods make use of a zip archive. If you're creating the zip archive yourself, it must follow the structure outlined in this section. If it doesn't, your app may experience errors at startup.

The deployment payload should match the output of a `dotnet publish` command, though without the enclosing parent folder. The zip archive should be made from the following files:

- `.azurefunctions/`
- `extensions.json`
- `functions.metadata`
- `host.json`

- `worker.config.json`
- Your project executable (a console app)
- Other supporting files and directories peer to that executable

These files are generated by the build process, and they aren't meant to be edited directly.

When preparing a zip archive for deployment, you should only compress the contents of the output directory, not the enclosing directory itself. When the archive is extracted into the current working directory, the files listed above need to be immediately visible.

Deployment requirements

There are a few requirements for running .NET functions in the isolated worker model in Azure, depending on the operating system:

Windows

- `FUNCTIONS_WORKER_RUNTIME` must be set to a value of `dotnet-isolated`.
- `netFrameworkVersion` must be set to the desired version.

When you create your function app in Azure using the methods in the previous section, these required settings are added for you. When you create these resources [by using ARM templates or Bicep files for automation](#), you must make sure to set them in the template.

Debugging

When running locally using Visual Studio or Visual Studio Code, you're able to debug your .NET isolated worker project as normal. However, there are two debugging scenarios that don't work as expected.

Remote Debugging using Visual Studio

Because your isolated worker process app runs outside the Functions runtime, you need to attach the remote debugger to a separate process. To learn more about debugging using Visual Studio, see [Remote Debugging](#).

Debugging when targeting .NET Framework

If your isolated project targets .NET Framework 4.8, the current preview scope requires manual steps to enable debugging. These steps aren't required if using another target framework.

Your app should start with a call to `FunctionsDebugger.Enable();` as its first operation. This occurs in the `Main()` method before initializing a HostBuilder. Your `Program.cs` file should look similar to this:

```
IHostBuilder  
C#  
  
using System;  
using System.Diagnostics;  
using Microsoft.Extensions.Hosting;  
using Microsoft.Azure.Functions.Worker;  
using NetFxWorker;  
  
namespace MyDotnetFrameworkProject  
{  
    internal class Program  
    {  
        static void Main(string[] args)  
        {  
            FunctionsDebugger.Enable();  
  
            var host = new HostBuilder()  
                .ConfigureFunctionsWorkerDefaults()  
                .Build();  
  
            host.Run();  
        }  
    }  
}
```

Next, you need to manually attach to the process using a .NET Framework debugger. Visual Studio doesn't do this automatically for isolated worker process .NET Framework apps yet, and the "Start Debugging" operation should be avoided.

In your project directory (or its build output directory), run:

```
Azure CLI  
  
func host start --dotnet-isolated-debug
```

This starts your worker, and the process stops with the following message:

Azure CLI

```
Azure Functions .NET Worker (PID: <process id>) initialized in debug mode.  
Waiting for debugger to attach...
```

Where `<process id>` is the ID for your worker process. You can now use Visual Studio to manually attach to the process. For instructions on this operation, see [How to attach to a running process](#).

After the debugger is attached, the process execution resumes, and you'll be able to debug.

Preview .NET versions

Before a generally available release, a .NET version might be released in a *Preview* or *Go-live* state. See the [.NET Official Support Policy](#) for details on these states.

While it might be possible to target a given release from a local Functions project, function apps hosted in Azure might not have that release available. Azure Functions can only be used with Preview or Go-live releases noted in this section.

Azure Functions currently can be used with the following "Preview" or "Go-live" .NET releases:

[] [Expand table](#)

Operating system	.NET preview version
Windows	.NET 9 Preview 6 ^{1, 2}
Linux	.NET 9 RC2 ^{1, 3}

¹ To successfully target .NET 9, your project needs to reference the [2.x versions of the core packages](#). If using Visual Studio, .NET 9 requires version 17.12 or later.

² Support for Windows might not appear in some clients during the preview period.

³ .NET 9 is not yet supported on the Flex Consumption SKU.

See [Supported versions](#) for a list of generally available releases that you can use.

Using a preview .NET SDK

To use Azure Functions with a preview version of .NET, you need to update your project by:

1. Installing the relevant .NET SDK version in your development
2. Changing the `TargetFramework` setting in your `.csproj` file

When you deploy to your function app in Azure, you also need to ensure that the framework is made available to the app. During the preview period, some tools and experiences may not surface the new preview version as an option. If you don't see the preview version included in the Azure portal, for example, you can use the REST API, Bicep templates, or the Azure CLI to configure the version manually.

Windows

For apps hosted on Windows, use the following Azure CLI command. Replace `<groupName>` with the name of the resource group, and replace `<appName>` with the name of your function app. Replace `<framework>` with the appropriate version string, such as `v8.0`.

Azure CLI

```
az functionapp config set -g <groupName> -n <appName> --net-framework-version <framework>
```

Considerations for using .NET preview versions

Keep these considerations in mind when using Functions with preview versions of .NET:

- When you author your functions in Visual Studio, you must use [Visual Studio Preview](#), which supports building Azure Functions projects with .NET preview SDKs.
- Make sure you have the latest Functions tools and templates. To update your tools:
 1. Navigate to **Tools > Options**, choose **Azure Functions** under **Projects and Solutions**.
 2. Select **Check for updates** and install updates as prompted.
- During a preview period, your development environment might have a more recent version of the .NET preview than the hosted service. This can cause your function app to fail when deployed. To address this, you can specify the version of the SDK to use in [global.json](#).

1. Run the `dotnet --list-sdks` command and note the preview version you're currently using during local development.
2. Run the `dotnet new globaljson --sdk-version <SDK_VERSION> --force` command, where `<SDK_VERSION>` is the version you're using locally. For example, `dotnet new globaljson --sdk-version dotnet-sdk-8.0.100-preview.7.23376.3 --force` causes the system to use the .NET 8 Preview 7 SDK when building your project.

 Note

Because of the just-in-time loading of preview frameworks, function apps running on Windows can experience increased cold start times when compared against earlier GA versions.

Develop C# class library functions using Azure Functions

Article • 07/07/2024

ⓘ Important

[Support will end for the in-process model on November 10, 2026](#). We highly recommend that you [migrate your apps to the isolated worker model](#) for full support.

This article is an introduction to developing Azure Functions by using C# in .NET class libraries. These class libraries are used to run *in-process with the Functions runtime*. Your .NET functions can alternatively run *_isolated* from the Functions *runtime*, which offers several advantages. To learn more, see [the isolated worker model](#). For a comprehensive comparison between these two models, see [Differences between the in-process model and the isolated worker model](#).

ⓘ Important

This article supports .NET class library functions that run in-process with the runtime. Your C# functions can also run out-of-process and isolated from the Functions runtime. The isolated worker process model is the only way to run non-LTS versions of .NET and .NET Framework apps in current versions of the Functions runtime. To learn more, see [.NET isolated worker process functions](#). For a comprehensive comparison between isolated worker process and in-process .NET Functions, see [Differences between in-process and isolate worker process .NET Azure Functions](#).

As a C# developer, you may also be interested in one of the following articles:

[+] Expand table

Getting started	Concepts	Guided learning/samples
<ul style="list-style-type: none">Using Visual StudioUsing Visual Studio CodeUsing command line tools	<ul style="list-style-type: none">Hosting optionsPerformance considerationsVisual Studio developmentDependency injection	<ul style="list-style-type: none">Create serverless applicationsC# samples

Azure Functions supports C# and C# script programming languages. If you're looking for guidance on [using C# in the Azure portal](#), see [C# script \(.csx\) developer reference](#).

Supported versions

Versions of the Functions runtime support specific versions of .NET. To learn more about Functions versions, see [Azure Functions runtime versions overview](#). Version support also depends on whether your functions run in-process or isolated worker process.

ⓘ Note

To learn how to change the Functions runtime version used by your function app, see [view and update the current runtime version](#).

The following table shows the highest level of .NET or .NET Framework that can be used with a specific version of Functions.

[] Expand table

Functions runtime version	Isolated worker model	In-process model ⁵
Functions 4.x ¹	.NET 8.0 .NET 6.0 ² .NET Framework 4.8 ³	.NET 8.0 .NET 6.0 ²
Functions 1.x ⁴	n/a	.NET Framework 4.8

¹ .NET 7 was previously supported on the isolated worker model but reached the [end of official support](#) on May 14, 2024.

² .NET 6 reaches the [end of official support](#) on November 12, 2024.

³ The build process also requires the [.NET SDK](#).

⁴ Support ends for version 1.x of the Azure Functions runtime on September 14, 2026. For more information, see [this support announcement](#). For continued full support, you should [migrate your apps to version 4.x](#).

⁵ Support ends for the in-process model on November 10, 2026. For more information, see [this support announcement](#). For continued full support, you should [migrate your apps to the isolated worker model](#).

For the latest news about Azure Functions releases, including the removal of specific older minor versions, monitor [Azure App Service announcements](#).

Updating to target .NET 8

ⓘ Note

Targeting .NET 8 with the in-process model is not yet enabled for Linux, for apps hosted in App Service Environments, or for apps in sovereign clouds. Updates will be communicated on [this tracking thread on GitHub](#).

Apps using the in-process model can target .NET 8 by following the steps outlined in this section. However, if you choose to exercise this option, you should still begin planning your [migration to the isolated worker model](#) in advance of [support ending for the in-process model on November 10, 2026](#).

Many apps can change the configuration of the function app in Azure without updates to code or redeployment. To run .NET 8 with the in-process model, three configurations are required:

- The application setting `FUNCTIONS_WORKER_RUNTIME` must be set with the value "dotnet".
- The application setting `FUNCTIONS_EXTENSION_VERSION` must be set with the value "~4".
- The application setting `FUNCTIONS_INPROC_NET8_ENABLED` must be set with the value "1".
- You must [update the stack configuration](#) to reference .NET 8.

Support for .NET 8 still uses version 4.x of the Functions runtime, and no change to the configured runtime version is required.

To update your local project, first make sure you are using the latest versions of local tools. Then ensure that the project references [version 4.4.0 or later of Microsoft.NET.Sdk.Functions](#). You can then change your `TargetFramework` to "net8.0". You must also update `local.settings.json` to include both `FUNCTIONS_WORKER_RUNTIME` set to "dotnet" and `FUNCTIONS_INPROC_NET8_ENABLED` set to "1".

The following is an example of a minimal `local.settings.json` file with these changes:

XML

```
<Project Sdk="Microsoft.NET.Sdk">
  <PropertyGroup>
    <TargetFramework>net8.0</TargetFramework>
    <AzureFunctionsVersion>V4</AzureFunctionsVersion>
  </PropertyGroup>
```

```
<ItemGroup>
  <PackageReference Include="Microsoft.NET.Sdk.Functions" Version="4.4.0"
/>
</ItemGroup>
<ItemGroup>
  <None Update="host.json">
    <CopyToOutputDirectory>PreserveNewest</CopyToOutputDirectory>
  </None>
  <None Update="local.settings.json">
    <CopyToOutputDirectory>PreserveNewest</CopyToOutputDirectory>
    <CopyToPublishDirectory>Never</CopyToPublishDirectory>
  </None>
</ItemGroup>
</Project>
```

The following is an example of a minimal `local.settings.json` file with these changes:

JSON

```
{
  "IsEncrypted": false,
  "Values": {
    "AzureWebJobsStorage": "UseDevelopmentStorage=true",
    "FUNCTIONS_INPROC_NET8_ENABLED": "1",
    "FUNCTIONS_WORKER_RUNTIME": "dotnet"
  }
}
```

If your app uses [Microsoft.Azure.DurableTask.Netherite.AzureFunctions](#), ensure it targets version 1.5.3 or later. Due to a behavior change in .NET 8, apps with older versions of the package will throw an ambiguous constructor exception.

You might need to make other changes to your app based on the version support of its other dependencies.

Functions class library project

In Visual Studio, the **Azure Functions** project template creates a C# class library project that contains the following files:

- [host.json](#) - stores configuration settings that affect all functions in the project when running locally or in Azure.
- [local.settings.json](#) - stores app settings and connection strings that are used when running locally. This file contains secrets and isn't published to your function app in Azure. Instead, [add app settings to your function app](#).

When you build the project, a folder structure that looks like the following example is generated in the build output directory:

```
<framework.version>
| - bin
| - MyFirstFunction
| | - function.json
| - MySecondFunction
| | - function.json
| - host.json
```

This directory is what gets deployed to your function app in Azure. The binding extensions required in [version 2.x](#) of the Functions runtime are [added to the project as NuGet packages](#).

ⓘ Important

The build process creates a *function.json* file for each function. This *function.json* file is not meant to be edited directly. You can't change binding configuration or disable the function by editing this file. To learn how to disable a function, see [How to disable functions](#).

Methods recognized as functions

In a class library, a function is a method with a `FunctionName` and a trigger attribute, as shown in the following example:

C#

```
public static class SimpleExample
{
    [FunctionName("QueueTrigger")]
    public static void Run(
        [QueueTrigger("myqueue-items")] string myQueueItem,
        ILogger log)
    {
        log.LogInformation($"C# function processed: {myQueueItem}");
    }
}
```

The `FunctionName` attribute marks the method as a function entry point. The name must be unique within a project, start with a letter and only contain letters, numbers, `_`, and

- , up to 127 characters in length. Project templates often create a method named `Run`, but the method name can be any valid C# method name. The above example shows a static method being used, but functions aren't required to be static.

The trigger attribute specifies the trigger type and binds input data to a method parameter. The example function is triggered by a queue message, and the queue message is passed to the method in the `myQueueItem` parameter.

Method signature parameters

The method signature may contain parameters other than the one used with the trigger attribute. Here are some of the other parameters that you can include:

- [Input and output bindings](#) marked as such by decorating them with attributes.
- An `ILogger` or `TraceWriter` (version 1.x-only) parameter for [logging](#).
- A `CancellationToken` parameter for [graceful shutdown](#).
- [Binding expressions](#) parameters to get trigger metadata.

The order of parameters in the function signature doesn't matter. For example, you can put trigger parameters before or after other bindings, and you can put the logger parameter before or after trigger or binding parameters.

Output bindings

A function can have zero or multiple output bindings defined by using output parameters.

The following example modifies the preceding one by adding an output queue binding named `myQueueItemCopy`. The function writes the contents of the message that triggers the function to a new message in a different queue.

```
C#  
  
public static class SimpleExampleWithOutput  
{  
    [FunctionName("CopyQueueMessage")]  
    public static void Run(  
        [QueueTrigger("myqueue-items-source")] string myQueueItem,  
        [Queue("myqueue-items-destination")] out string myQueueItemCopy,  
        ILogger log)  
    {  
        log.LogInformation($"CopyQueueMessage function processed:  
{myQueueItem}");  
        myQueueItemCopy = myQueueItem;  
    }  
}
```

```
    }  
}
```

Values assigned to output bindings are written when the function exits. You can use more than one output binding in a function by simply assigning values to multiple output parameters.

The binding reference articles ([Storage queues](#), for example) explain which parameter types you can use with trigger, input, or output binding attributes.

Binding expressions example

The following code gets the name of the queue to monitor from an app setting, and it gets the queue message creation time in the `insertionTime` parameter.

C#

```
public static class BindingExpressionsExample  
{  
    [FunctionName("LogQueueMessage")]  
    public static void Run(  
        [QueueTrigger("%queueappsetting%")] string myQueueItem,  
        DateTimeOffset insertionTime,  
        ILogger log)  
    {  
        log.LogInformation($"Message content: {myQueueItem}");  
        log.LogInformation($"Created at: {insertionTime}");  
    }  
}
```

Autogenerated function.json

The build process creates a `function.json` file in a function folder in the build folder. As noted earlier, this file isn't meant to be edited directly. You can't change binding configuration or disable the function by editing this file.

The purpose of this file is to provide information to the scale controller to use for [scaling decisions on the Consumption plan](#). For this reason, the file only has trigger info, not input/output bindings.

The generated `function.json` file includes a `configurationSource` property that tells the runtime to use .NET attributes for bindings, rather than `function.json` configuration. Here's an example:

JSON

```
{  
  "generatedBy": "Microsoft.NET.Sdk.Functions-1.0.0.0",  
  "configurationSource": "attributes",  
  "bindings": [  
    {  
      "type": "queueTrigger",  
      "queueName": "%input-queue-name%",  
      "name": "myQueueItem"  
    }  
  ],  
  "disabled": false,  
  "scriptFile": "..\bin\FunctionApp1.dll",  
  "entryPoint": "FunctionApp1.QueueTrigger.Run"  
}
```

Microsoft.NET.Sdk.Functions

The `function.json` file generation is performed by the NuGet package [Microsoft.NET.Sdk.Functions](#).

The following example shows the relevant parts of the `.csproj` files that have different target frameworks of the same `Sdk` package:

v4.x

XML

```
<PropertyGroup>  
  <TargetFramework>net8.0</TargetFramework>  
  <AzureFunctionsVersion>v4</AzureFunctionsVersion>  
</PropertyGroup>  
<ItemGroup>  
  <PackageReference Include="Microsoft.NET.Sdk.Functions"  
    Version="4.4.0" />  
</ItemGroup>
```

Among the `Sdk` package dependencies are triggers and bindings. A 1.x project refers to 1.x triggers and bindings because those triggers and bindings target the .NET Framework, while 4.x triggers and bindings target .NET Core.

The `Sdk` package also depends on [Newtonsoft.Json](#), and indirectly on [WindowsAzure.Storage](#). These dependencies make sure that your project uses the versions of those packages that work with the Functions runtime version that the project

targets. For example, `Newtonsoft.Json` has version 11 for .NET Framework 4.6.1, but the Functions runtime that targets .NET Framework 4.6.1 is only compatible with `Newtonsoft.Json` 9.0.1. So your function code in that project also has to use `Newtonsoft.Json` 9.0.1.

The source code for `Microsoft.NET.Sdk.Functions` is available in the GitHub repo [azure-functions-vs-build-sdk](#).

Local runtime version

Visual Studio uses the [Azure Functions Core Tools](#) to run Functions projects on your local computer. The Core Tools is a command-line interface for the Functions runtime.

If you install the Core Tools using the Windows installer (MSI) package or by using npm, it doesn't affect the Core Tools version used by Visual Studio. For the Functions runtime version 1.x, Visual Studio stores Core Tools versions in `%USERPROFILE%\AppData\Local\Azure.Functions.Cli` and uses the latest version stored there. For Functions 4.x, the Core Tools are included in the [Azure Functions and Web Jobs Tools](#) extension. For Functions 1.x, you can see what version is being used in the console output when you run a Functions project:

terminal

```
[3/1/2018 9:59:53 AM] Starting Host (HostId=contoso2-1518597420,  
Version=2.0.11353.0, ProcessId=22020, Debug=False, Attempt=0,  
FunctionsExtensionVersion=)
```

ReadyToRun

You can compile your function app as [ReadyToRun binaries](#). ReadyToRun is a form of ahead-of-time compilation that can improve startup performance to help reduce the impact of [cold-start](#) when running in a [Consumption plan](#).

ReadyToRun is available in .NET 6 and later versions and requires [version 4.0 of the Azure Functions runtime](#).

To compile your project as ReadyToRun, update your project file by adding the `<PublishReadyToRun>` and `<RuntimeIdentifier>` elements. The following is the configuration for publishing to a Windows 32-bit function app.

XML

```
<PropertyGroup>
  <TargetFramework>net8.0</TargetFramework>
  <AzureFunctionsVersion>v4</AzureFunctionsVersion>
  <PublishReadyToRun>true</PublishReadyToRun>
  <RuntimeIdentifier>win-x86</RuntimeIdentifier>
</PropertyGroup>
```

ⓘ Important

Starting in .NET 6, support for Composite ReadyToRun compilation has been added. Check out [ReadyToRun Cross platform and architecture restrictions](#).

You can also build your app with ReadyToRun from the command line. For more information, see the `-p:PublishReadyToRun=true` option in [dotnet publish](#).

Supported types for bindings

Each binding has its own supported types; for instance, a blob trigger attribute can be applied to a string parameter, a POCO parameter, a `CloudBlockBlob` parameter, or any of several other supported types. The [binding reference article for blob bindings](#) lists all supported parameter types. For more information, see [Triggers and bindings](#) and the [binding reference docs for each binding type](#).

ⓘ Tip

If you plan to use the HTTP or WebHook bindings, plan to avoid port exhaustion that can be caused by improper instantiation of `HttpClient`. For more information, see [How to manage connections in Azure Functions](#).

Binding to method return value

You can use a method return value for an output binding, by applying the attribute to the method return value. For examples, see [Triggers and bindings](#).

Use the return value only if a successful function execution always results in a return value to pass to the output binding. Otherwise, use `ICollector` or `IAsyncCollector`, as shown in the following section.

Writing multiple output values

To write multiple values to an output binding, or if a successful function invocation might not result in anything to pass to the output binding, use the [ICollector](#) or [IAsyncCollector](#) types. These types are write-only collections that are written to the output binding when the method completes.

This example writes multiple queue messages into the same queue using [ICollector](#):

```
C#  
  
public static class ICollectorExample  
{  
    [FunctionName("CopyQueueMessageICollector")]  
    public static void Run(  
        [QueueTrigger("myqueue-items-source-3")] string myQueueItem,  
        [Queue("myqueue-items-destination")] ICollector<string>  
myDestinationQueue,  
        ILogger log)  
    {  
        log.LogInformation($"C# function processed: {myQueueItem}");  
        myDestinationQueue.Add($"Copy 1: {myQueueItem}");  
        myDestinationQueue.Add($"Copy 2: {myQueueItem}");  
    }  
}
```

Async

To make a function [asynchronous](#), use the `async` keyword and return a `Task` object.

```
C#  
  
public static class AsyncExample  
{  
    [FunctionName("BlobCopy")]  
    public static async Task RunAsync(  
        [BlobTrigger("sample-images/{blobName}")] Stream blobInput,  
        [Blob("sample-images-copies/{blobName}", FileAccess.Write)] Stream  
blobOutput,  
        CancellationToken token,  
        ILogger log)  
    {  
        log.LogInformation($"BlobCopy function processed.");  
        await blobInput.CopyToAsync(blobOutput, 4096, token);  
    }  
}
```

You can't use `out` parameters in `async` functions. For output bindings, use the [function return value](#) or a [collector object](#) instead.

Cancellation tokens

A function can accept a [CancellationToken](#) parameter, which enables the operating system to notify your code when the function is about to be terminated. You can use this notification to make sure the function doesn't terminate unexpectedly in a way that leaves data in an inconsistent state.

Consider the case when you have a function that processes messages in batches. The following Azure Service Bus-triggered function processes an array of [ServiceBusReceivedMessage](#) objects, which represents a batch of incoming messages to be processed by a specific function invocation:

C#

```
using Azure.Messaging.ServiceBus;
using System.Threading;

namespace ServiceBusCancellationToken
{
    public static class servicebus
    {
        [FunctionName("servicebus")]
        public static void Run([ServiceBusTrigger("csharpguitar", Connection
= "SB_CONN")]
                               ServiceBusReceivedMessage[] messages, CancellationToken
cancellationToken, ILogger log)
        {
            try
            {
                foreach (var message in messages)
                {
                    if (cancellationToken.IsCancellationRequested)
                    {
                        log.LogInformation("A cancellation token was
received. Taking precautionary actions.");
                        //Take precautions like noting how far along you are
with processing the batch
                        log.LogInformation("Precautionary activities --
complete--.");
                        break;
                    }
                    else
                    {
                        //business logic as usual
                        log.LogInformation($"Message: {message} was
processed.");
                    }
                }
            }
            catch (Exception ex)
            {
```

```
        log.LogInformation($"Something unexpected happened:  
{ex.Message}");  
    }  
}  
}
```

Logging

In your function code, you can write output to logs that appear as traces in Application Insights. The recommended way to write to the logs is to include a parameter of type [ILogger](#), which is typically named `log`. Version 1.x of the Functions runtime used `TraceWriter`, which also writes to Application Insights, but doesn't support structured logging. Don't use `Console.WriteLine` to write your logs, since this data isn't captured by Application Insights.

ILogger

In your function definition, include an [ILogger](#) parameter, which supports [structured logging](#).

With an `ILogger` object, you call `Log<level>` extension methods on `ILogger` to create logs. The following code writes `Information` logs with category `Function`.

```
<YOUR_FUNCTION_NAME>.User.:
```

```
cs
```

```
public static async Task<HttpResponseMessage> Run(HttpRequestMessage req,  
ILogger logger)  
{  
    logger.LogInformation("Request for item with key={itemKey}.", id);
```

To learn more about how Functions implements `ILogger`, see [Collecting telemetry data](#). Categories prefixed with `Function` assume you're using an `ILogger` instance. If you choose to instead use an `ILogger<T>`, the category name may instead be based on `T`.

Structured logging

The order of placeholders, not their names, determines which parameters are used in the log message. Suppose you have the following code:

```
C#
```

```
string partitionKey = "partitionKey";
string rowKey = "rowKey";
logger.LogInformation("partitionKey={partitionKey}, rowKey={rowKey}",
partitionKey, rowKey);
```

If you keep the same message string and reverse the order of the parameters, the resulting message text would have the values in the wrong places.

Placeholders are handled this way so that you can do structured logging. Application Insights stores the parameter name-value pairs and the message string. The result is that the message arguments become fields that you can query on.

If your logger method call looks like the previous example, you can query the field `customDimensions.prop__rowKey`. The `prop__` prefix is added to ensure there are no collisions between fields the runtime adds and fields your function code adds.

You can also query on the original message string by referencing the field `customDimensions.prop__{OriginalFormat}`.

Here's a sample JSON representation of `customDimensions` data:

JSON

```
{
  "customDimensions": {
    "prop__{OriginalFormat}":"C# Queue trigger function processed:
{message}",
    "Category":"Function",
    "LogLevel":"Information",
    "prop__message":"c9519cbf-b1e6-4b9b-bf24-cb7d10b1bb89"
  }
}
```

Log custom telemetry

There's a Functions-specific version of the Application Insights SDK that you can use to send custom telemetry data from your functions to Application Insights:

[Microsoft.Azure.WebJobs.Logging.ApplicationInsights](#). Use the following command from the command prompt to install this package:

Command

Windows Command Prompt

```
dotnet add package Microsoft.Azure.WebJobs.Logging.ApplicationInsights -  
-version <VERSION>
```

In this command, replace `<VERSION>` with a version of this package that supports your installed version of [Microsoft.Azure.WebJobs](#).

The following C# examples uses the [custom telemetry API](#). The example is for a .NET class library, but the Application Insights code is the same for C# script.

v4.x

Version 2.x and later versions of the runtime use newer features in Application Insights to automatically correlate telemetry with the current operation. There's no need to manually set the operation `Id`, `ParentId`, or `Name` fields.

cs

```
using System;  
using System.Threading.Tasks;  
using Microsoft.AspNetCore.Mvc;  
using Microsoft.Azure.WebJobs;  
using Microsoft.Azure.WebJobs.Extensions.Http;  
using Microsoft.AspNetCore.Http;  
using Microsoft.Extensions.Logging;  
  
using Microsoft.ApplicationInsights;  
using Microsoft.ApplicationInsights.DataContracts;  
using Microsoft.ApplicationInsights.Extensibility;  
using System.Linq;  
  
namespace functionapp0915  
{  
    public class HttpTrigger2  
    {  
        private readonly TelemetryClient telemetryClient;  
  
        /// Using dependency injection will guarantee that you use the  
        /// same configuration for telemetry collected automatically and manually.  
        public HttpTrigger2(TelemetryConfiguration  
telemetryConfiguration)  
        {  
            this.telemetryClient = new  
TelemetryClient(telemetryConfiguration);  
        }  
  
        [FunctionName("HttpTrigger2")]  
        public Task<IActionResult> Run(  
            [HttpTrigger(AuthorizationLevel.Anonymous, "get", Route =
```

```

    null)];
        HttpRequest req, ExecutionContext context, ILogger log)
    {
        log.LogInformation("C# HTTP trigger function processed a
request.");
        DateTime start = DateTime.UtcNow;

        // Parse query parameter
        string name = req.Query
            .FirstOrDefault(q => string.Compare(q.Key, "name", true)
== 0)
            .Value;

        // Write an event to the customEvents table.
        var evt = new EventTelemetry("Function called");
        evt.Context.User.Id = name;
        this.telemetryClient.TrackEvent(evt);

        // Generate a custom metric, in this case let's use
ContentLength.

        this.telemetryClient.GetMetric("contentLength").TrackValue(req.ContentLe
ngth);

        // Log a custom dependency in the dependencies table.
        var dependency = new DependencyTelemetry
        {
            Name = "GET api/planets/1/",
            Target = "swapi.co",
            Data = "https://swapi.co/api/planets/1/",
            Timestamp = start,
            Duration = DateTime.UtcNow - start,
            Success = true
        };
        dependency.Context.User.Id = name;
        this.telemetryClient.TrackDependency(dependency);

        return Task.FromResult<IActionResult>(new OkResult());
    }
}
}

```

In this example, the custom metric data gets aggregated by the host before being sent to the customMetrics table. To learn more, see the [GetMetric](#) documentation in Application Insights.

When running locally, you must add the `APPINSIGHTS_INSTRUMENTATIONKEY` setting, with the Application Insights key, to the [local.settings.json](#) file.

Don't call `TrackRequest` or `StartOperation<RequestTelemetry>` because you'll see duplicate requests for a function invocation. The Functions runtime automatically tracks

requests.

Don't set `telemetryClient.Context.Operation.Id`. This global setting causes incorrect correlation when many functions are running simultaneously. Instead, create a new telemetry instance (`DependencyTelemetry`, `EventTelemetry`) and modify its `Context` property. Then pass in the telemetry instance to the corresponding `Track` method on `TelemetryClient` (`TrackDependency()`, `TrackEvent()`, `TrackMetric()`). This method ensures that the telemetry has the correct correlation details for the current function invocation.

Testing functions

The following articles show how to run an in-process C# class library function locally for testing purposes:

- [Visual Studio](#)
- [Visual Studio Code](#)
- [Command line](#)

Environment variables

To get an environment variable or an app setting value, use

`System.Environment.GetEnvironmentVariable`, as shown in the following code example:

C#

```
public static class EnvironmentVariablesExample
{
    [FunctionName("GetEnvironmentVariables")]
    public static void Run([TimerTrigger("0 */5 * * *")]TimerInfo myTimer,
    ILogger log)
    {
        log.LogInformation($"C# Timer trigger function executed at:
{DateTime.Now}");
        log.LogInformation(GetEnvironmentVariable("AzureWebJobsStorage"));
        log.LogInformation(GetEnvironmentVariable("WEBSITE_SITE_NAME"));
    }

    private static string GetEnvironmentVariable(string name)
    {
        return name + ": " +
            System.Environment.GetEnvironmentVariable(name,
            EnvironmentVariableTarget.Process);
    }
}
```

App settings can be read from environment variables both when developing locally and when running in Azure. When developing locally, app settings come from the `Values` collection in the `local.settings.json` file. In both environments, local and Azure, `GetEnvironmentVariable("<app setting name>")` retrieves the value of the named app setting. For instance, when you're running locally, "My Site Name" would be returned if your `local.settings.json` file contains `{ "Values": { "WEBSITE_SITE_NAME": "My Site Name" } }`.

The `System.Configuration.ConfigurationManager.AppSettings` property is an alternative API for getting app setting values, but we recommend that you use `GetEnvironmentVariable` as shown here.

Binding at runtime

In C# and other .NET languages, you can use an [imperative ↗](#) binding pattern, as opposed to the [declarative ↗](#) bindings in attributes. Imperative binding is useful when binding parameters need to be computed at runtime rather than design time. With this pattern, you can bind to supported input and output bindings on-the-fly in your function code.

Define an imperative binding as follows:

- **Do not** include an attribute in the function signature for your desired imperative bindings.
- Pass in an input parameter `Binder binder` or `IBinder binder`.
- Use the following C# pattern to perform the data binding.

cs

```
using (var output = await binder.BindAsync<T>(new
    BindingTypeAttribute(...)))
{
    ...
}
```

`BindingTypeAttribute` is the .NET attribute that defines your binding, and `T` is an input or output type that's supported by that binding type. `T` can't be an `out` parameter type (such as `out JObject`). For example, the Mobile Apps table output binding supports [six output types ↗](#), but you can only use `ICollector<T>` or `IAsyncCollector<T>` with imperative binding.

Single attribute example

The following example code creates a [Storage blob output binding](#) with blob path that's defined at run time, then writes a string to the blob.

```
cs

public static class IBinderExample
{
    [FunctionName("CreateBlobUsingBinder")]
    public static void Run(
        [QueueTrigger("myqueue-items-source-4")] string myQueueItem,
        IBinder binder,
        ILogger log)
    {
        log.LogInformation($"CreateBlobUsingBinder function processed:
{myQueueItem}");
        using (var writer = binder.Bind<TextWriter>(new BlobAttribute(
            $"samples-output/{myQueueItem}", FileAccess.Write)))
        {
            writer.WriteLine("Hello World!");
        };
    }
}
```

[BlobAttribute](#) defines the [Storage blob](#) input or output binding, and [TextWriter](#) is a supported output binding type.

Multiple attributes example

The preceding example gets the app setting for the function app's main Storage account connection string (which is [AzureWebJobsStorage](#)). You can specify a custom app setting to use for the Storage account by adding the [StorageAccountAttribute](#) and passing the attribute array into [BindAsync<T>\(\)](#). Use a [Binder](#) parameter, not [IBinder](#). For example:

```
cs

public static class IBinderExampleMultipleAttributes
{
    [FunctionName("CreateBlobInDifferentStorageAccount")]
    public async static Task RunAsync(
        [QueueTrigger("myqueue-items-source-binder2")] string
myQueueItem,
        Binder binder,
        ILogger log)
    {
        log.LogInformation($"CreateBlobInDifferentStorageAccount function
```

```

    processed: {myQueueItem}");
    var attributes = new Attribute[]
    {
        new BlobAttribute($"samples-output/{myQueueItem}",
FileAccess.Write),
        new StorageAccountAttribute("MyStorageAccount")
    };
    using (var writer = await binder.BindAsync<TextWriter>(attributes))
    {
        await writer.WriteAsync("Hello World!!!");
    }
}
}

```

Triggers and bindings

This table shows the bindings that are supported in the major versions of the Azure Functions runtime:

[\[\] Expand table](#)

Type	1.x ¹	2.x and higher ²	Trigger	Input	Output
Blob storage	✓	✓	✓	✓	✓
Azure Cosmos DB	✓	✓	✓	✓	✓
Azure Data Explorer		✓		✓	✓
Azure SQL		✓	✓	✓	✓
Dapr ⁴		✓	✓	✓	✓
Event Grid	✓	✓	✓		✓
Event Hubs	✓	✓	✓		✓
HTTP & webhooks	✓	✓	✓		✓
IoT Hub	✓	✓	✓		
Kafka ³		✓	✓		✓
Mobile Apps	✓			✓	✓
Notification Hubs	✓				✓
Queue storage	✓	✓	✓		✓
Redis		✓	✓		

Type	1.x ¹	2.x and higher ²	Trigger	Input	Output
RabbitMQ ³		✓	✓		✓
SendGrid	✓	✓			✓
Service Bus	✓	✓	✓		✓
SignalR		✓	✓	✓	✓
Table storage	✓	✓		✓	✓
Timer	✓	✓	✓		
Twilio	✓	✓			✓

¹ Support will end for version 1.x of the Azure Functions runtime on September 14, 2026 [↗](#). We highly recommend that you [migrate your apps to version 4.x](#) for full support.

² Starting with the version 2.x runtime, all bindings except HTTP and Timer must be registered. See [Register binding extensions](#).

³ Triggers aren't supported in the Consumption plan. Requires [runtime-driven triggers](#).

⁴ Supported only in Kubernetes, IoT Edge, and other self-hosted modes only.

Azure Functions C# script (.csx) developer reference

Article • 09/27/2023

This article is an introduction to developing Azure Functions by using C# script (.csx).

Azure Functions lets you develop functions using C# in one of the following ways:

Type	Execution process	Code extension	Development environment	Reference
C# script	in-process	.csx	Portal Core Tools	This article
C# class library	in-process	.cs	Visual Studio Visual Studio Code Core Tools	In-process C# class library functions
C# class library (isolated worker process)	in an isolated worker process	.cs	Visual Studio Visual Studio Code Core Tools	.NET isolated worker process functions

This article assumes that you've already read the [Azure Functions developers guide](#).

How .csx works

Data flows into your C# function via method arguments. Argument names are specified in a `function.json` file, and there are predefined names for accessing things like the function logger and cancellation tokens.

The .csx format allows you to write less "boilerplate" and focus on writing just a C# function. Instead of wrapping everything in a namespace and class, just define a `Run` method. Include any assembly references and namespaces at the beginning of the file as usual.

A function app's .csx files are compiled when an instance is initialized. This compilation step means things like cold start may take longer for C# script functions compared to C# class libraries. This compilation step is also why C# script functions are editable in the Azure portal, while C# class libraries aren't.

Folder structure

The folder structure for a C# script project looks like the following example:

```
FunctionsProject
| - MyFirstFunction
| | - run.csx
| | - function.json
| | - function.proj
| - MySecondFunction
| | - run.csx
| | - function.json
| | - function.proj
| - host.json
| - extensions.csproj
| - bin
```

There's a shared [host.json](#) file that can be used to configure the function app. Each function has its own code file (.csx) and binding configuration file (function.json).

The binding extensions required in [version 2.x and later versions](#) of the Functions runtime are defined in the `extensions.csproj` file, with the actual library files in the `bin` folder. When developing locally, you must [register binding extensions](#). When you develop functions in the Azure portal, this registration is done for you.

Binding to arguments

Input or output data is bound to a C# script function parameter via the `name` property in the `function.json` configuration file. The following example shows a `function.json` file and `run.csx` file for a queue-triggered function. The parameter that receives data from the queue message is named `myQueueItem` because that's the value of the `name` property.

JSON

```
{
  "disabled": false,
  "bindings": [
    {
      "type": "queueTrigger",
      "direction": "in",
      "name": "myQueueItem",
      "queueName": "myqueue-items",
      "connection": "MyStorageConnectionAppSetting"
    }
  ]
}
```

C#

```
#r "Microsoft.WindowsAzure.Storage"

using Microsoft.Extensions.Logging;
using Microsoft.WindowsAzure.Storage.Queue;
using System;

public static void Run(CloudQueueMessage myQueueItem, ILogger log)
{
    log.LogInformation($"C# Queue trigger function processed:
{myQueueItem.AsString}");
}
```

The `#r` statement is explained [later in this article](#).

Supported types for bindings

Each binding has its own supported types; for instance, a blob trigger can be used with a string parameter, a POCO parameter, a `CloudBlockBlob` parameter, or any of several other supported types. The [binding reference article for blob bindings](#) lists all supported parameter types for blob triggers. For more information, see [Triggers and bindings](#) and the [binding reference docs](#) for each binding type.

Tip

If you plan to use the HTTP or WebHook bindings, plan to avoid port exhaustion that can be caused by improper instantiation of `HttpClient`. For more information, see [How to manage connections in Azure Functions](#).

Referencing custom classes

If you need to use a custom Plain Old CLR Object (POCO) class, you can include the class definition inside the same file or put it in a separate file.

The following example shows a `run.csx` example that includes a POCO class definition.

C#

```
public static void Run(string myBlob, out MyClass myQueueItem)
{
    log.Verbose($"C# Blob trigger function processed: {myBlob}");
    myQueueItem = new MyClass() { Id = "myid" };
}
```

```
public class MyClass
{
    public string Id { get; set; }
}
```

A POCO class must have a getter and setter defined for each property.

Reusing .csx code

You can use classes and methods defined in other .csx files in your *run.csx* file. To do that, use `#load` directives in your *run.csx* file. In the following example, a logging routine named `MyLogger` is shared in *myLogger.csx* and loaded into *run.csx* using the `#load` directive:

Example *run.csx*:

```
C#  
  
#load "mylogger.csx"  
  
using Microsoft.Extensions.Logging;  
  
public static void Run(TimerInfo myTimer, ILogger log)  
{  
    log.LogInformation($"Log by run.csx: {DateTime.Now}");  
    MyLogger(log, $"Log by MyLogger: {DateTime.Now}");  
}
```

Example *mylogger.csx*:

```
C#  
  
public static void MyLogger(ILogger log, string logtext)  
{  
    log.LogInformation(logtext);  
}
```

Using a shared .csx file is a common pattern when you want to strongly type the data passed between functions by using a POCO object. In the following simplified example, an HTTP trigger and queue trigger share a POCO object named `Order` to strongly type the order data:

Example *run.csx* for HTTP trigger:

```
C#
```

```

#load "..\shared\order.csx"

using System.Net;
using Microsoft.Extensions.Logging;

public static async Task<HttpResponseMessage> Run(Order req,
IAsyncCollector<Order> outputQueueItem, ILogger log)
{
    log.LogInformation("C# HTTP trigger function received an order.");
    log.LogInformation(req.ToString());
    log.LogInformation("Submitting to processing queue.");

    if (req.orderId == null)
    {
        return new HttpResponseMessage(HttpStatusCode.BadRequest);
    }
    else
    {
        await outputQueueItem.AddAsync(req);
        return new HttpResponseMessage(HttpStatusCode.OK);
    }
}

```

Example *run.csx* for queue trigger:

```

C#

#load "..\shared\order.csx"

using System;
using Microsoft.Extensions.Logging;

public static void Run(Order myQueueItem, out Order outputQueueItem, ILogger log)
{
    log.LogInformation($"C# Queue trigger function processed order{myQueueItem}");
    log.LogInformation(myQueueItem.ToString());

    outputQueueItem = myQueueItem;
}

```

Example *order.csx*:

```

C#

public class Order
{
    public string orderId {get; set; }
    public string custName {get; set;}
    public string custAddress {get; set;}
    public string custEmail {get; set;}
}

```

```

    public string cartId {get; set; }

    public override String ToString()
    {
        return "\n{\n\torderId : " + orderId +
               "\n\tcustName : " + custName +
               "\n\tcustAddress : " + custAddress +
               "\n\tcustEmail : " + custEmail +
               "\n\tcartId : " + cartId + "\n}";
    }
}

```

You can use a relative path with the `#load` directive:

- `#load "mylogger.csx"` loads a file located in the function folder.
- `#load "loadedfiles\mylogger.csx"` loads a file located in a folder in the function folder.
- `#load "..\shared\mylogger.csx"` loads a file located in a folder at the same level as the function folder, that is, directly under `wwwroot`.

The `#load` directive works only with `.csx` files, not with `.cs` files.

Binding to method return value

You can use a method return value for an output binding, by using the name `$return` in `function.json`.

JSON

```
{
    "name": "$return",
    "type": "blob",
    "direction": "out",
    "path": "output-container/{id}"
}
```

Here's the C# script code using the return value, followed by an async example:

C#

```

public static string Run(WorkItem input, ILogger log)
{
    string json = string.Format("{{ \"id\": \"{0}\", \"name\": \"HelloWorld\", \"value\": \"Hello {1}!\" }}", input.Id);
    log.LogInformation($"C# script processed queue message. Item={json}");
    return json;
}

```

C#

```
public static Task<string> Run(WorkItem input, ILogger log)
{
    string json = string.Format("{{ \"id\": \"{0}\" }}", input.Id);
    log.LogInformation($"C# script processed queue message. Item={json}");
    return Task.FromResult(json);
}
```

Use the return value only if a successful function execution always results in a return value to pass to the output binding. Otherwise, use [ICollector](#) or [IAsyncCollector](#), as shown in the following section.

Writing multiple output values

To write multiple values to an output binding, or if a successful function invocation might not result in anything to pass to the output binding, use the [ICollector](#) or [IAsyncCollector](#) types. These types are write-only collections that are written to the output binding when the method completes.

This example writes multiple queue messages into the same queue using [ICollector](#):

C#

```
public static void Run(ICollector<string> myQueue, ILogger log)
{
    myQueue.Add("Hello");
    myQueue.Add("World!");
}
```

Logging

To log output to your streaming logs in C#, include an argument of type [ILogger](#). We recommend that you name it `log`. Avoid using `Console.WriteLine` in Azure Functions.

C#

```
public static void Run(string myBlob, ILogger log)
{
    log.LogInformation($"C# Blob trigger function processed: {myBlob}");
}
```

 Note

For information about a newer logging framework that you can use instead of `TraceWriter`, see the [ILogger](#) documentation in the .NET class library developer guide.

Custom metrics logging

You can use the `LogMetric` extension method on `ILogger` to create custom metrics in Application Insights. Here's a sample method call:

C#

```
logger.LogMetric("TestMetric", 1234);
```

This code is an alternative to calling `TrackMetric` by using the Application Insights API for .NET.

Async

To make a function [asynchronous](#), use the `async` keyword and return a `Task` object.

C#

```
public async static Task ProcessQueueMessageAsync(
    string blobName,
    Stream blobInput,
    Stream blobOutput)
{
    await blobInput.CopyToAsync(blobOutput, 4096);
}
```

You can't use `out` parameters in `async` functions. For output bindings, use the [function return value](#) or a [collector object](#) instead.

Cancellation tokens

A function can accept a `CancellationToken` parameter, which enables the operating system to notify your code when the function is about to be terminated. You can use this notification to make sure the function doesn't terminate unexpectedly in a way that leaves data in an inconsistent state.

The following example shows how to check for impending function termination.

C#

```
using System;
using System.IO;
using System.Threading;

public static void Run(
    string inputText,
    TextWriter logger,
    CancellationToken token)
{
    for (int i = 0; i < 100; i++)
    {
        if (token.IsCancellationRequested)
        {
            logger.WriteLine("Function was cancelled at iteration {0}", i);
            break;
        }
        Thread.Sleep(5000);
        logger.WriteLine("Normal processing for queue message={0}",
inputText);
    }
}
```

Importing namespaces

If you need to import namespaces, you can do so as usual, with the `using` clause.

C#

```
using System.Net;
using System.Threading.Tasks;
using Microsoft.Extensions.Logging;

public static Task<HttpResponseMessage> Run(HttpRequestMessage req, ILogger
log)
```

The following namespaces are automatically imported and are therefore optional:

- `System`
- `System.Collections.Generic`
- `System.IO`
- `System.Linq`
- `System.Net.Http`
- `System.Threading.Tasks`
- `Microsoft.Azure.WebJobs`

- Microsoft.Azure.WebJobs.Host

Referencing external assemblies

For framework assemblies, add references by using the `#r "AssemblyName"` directive.

C#

```
#r "System.Web.Http"

using System.Net;
using System.Net.Http;
using System.Threading.Tasks;
using Microsoft.Extensions.Logging;

public static Task<HttpResponseMessage> Run(HttpRequestMessage req, ILogger
log)
```

The following assemblies are automatically added by the Azure Functions hosting environment:

- mscorelib
- System
- System.Core
- System.Xml
- System.Net.Http
- Microsoft.Azure.WebJobs
- Microsoft.Azure.WebJobs.Host
- Microsoft.Azure.WebJobs.Extensions
- System.Web.Http
- System.Net.Http.Formatting

The following assemblies may be referenced by simple-name, by runtime version:

v2.x+

- Newtonsoft.Json
- Microsoft.WindowsAzure.Storage^{*}

^{*}Removed in version 4.x of the runtime.

In code, assemblies are referenced like the following example:

C#

```
#r "AssemblyName"
```

Referencing custom assemblies

To reference a custom assembly, you can use either a *shared* assembly or a *private* assembly:

- Shared assemblies are shared across all functions within a function app. To reference a custom assembly, upload the assembly to a folder named `bin` in the root folder (`wwwroot`) of your function app.
- Private assemblies are part of a given function's context, and support side-loading of different versions. Private assemblies should be uploaded in a `bin` folder in the function directory. Reference the assemblies using the file name, such as `#r "MyAssembly.dll"`.

For information on how to upload files to your function folder, see the section on [package management](#).

Watched directories

The directory that contains the function script file is automatically watched for changes to assemblies. To watch for assembly changes in other directories, add them to the `watchDirectories` list in [host.json](#).

Using NuGet packages

The way that both binding extension packages and other NuGet packages are added to your function app depends on the [targeted version of the Functions runtime](#).

v2.x+

By default, the [supported set of Functions extension NuGet packages](#) are made available to your C# script function app by using extension bundles. To learn more, see [Extension bundles](#).

If for some reason you can't use extension bundles in your project, you can also use the Azure Functions Core Tools to install extensions based on bindings defined in

the function.json files in your app. When using Core Tools to register extensions, make sure to use the `--csx` option. To learn more, see [func extensions install](#).

By default, Core Tools reads the function.json files and adds the required packages to an `extensions.csproj` C# class library project file in the root of the function app's file system (`wwwroot`). Because Core Tools uses `dotnet.exe`, you can use it to add any NuGet package reference to this extensions file. During installation, Core Tools builds the `extensions.csproj` to install the required libraries. Here's an example `extensions.csproj` file that adds a reference to `Microsoft.ProjectOxford.Face` version `1.1.0`:

XML

```
<Project Sdk="Microsoft.NET.Sdk">
  <PropertyGroup>
    <TargetFramework>netstandard2.0</TargetFramework>
  </PropertyGroup>
  <ItemGroup>
    <PackageReference Include="Microsoft.ProjectOxford.Face"
Version="1.1.0" />
  </ItemGroup>
</Project>
```

① Note

For C# script (.csx), you must set `TargetFramework` to a value of `netstandard2.0`. Other target frameworks, such as `net6.0`, aren't supported.

To use a custom NuGet feed, specify the feed in a `Nuget.Config` file in the function app root folder. For more information, see [Configuring NuGet behavior](#).

If you're working on your project only in the portal, you'll need to manually create the `extensions.csproj` file or a `Nuget.Config` file directly in the site. To learn more, see [Manually install extensions](#).

Environment variables

To get an environment variable or an app setting value, use `System.Environment.GetEnvironmentVariable`, as shown in the following code example:

C#

```

public static void Run(TimerInfo myTimer, ILogger log)
{
    log.LogInformation($"C# Timer trigger function executed at:
{DateTime.Now}");
    log.LogInformation(GetEnvironmentVariable("AzureWebJobsStorage"));
    log.LogInformation(GetEnvironmentVariable("WEBSITE_SITE_NAME"));
}

public static string GetEnvironmentVariable(string name)
{
    return name + ": " +
        System.Environment.GetEnvironmentVariable(name,
        EnvironmentVariableTarget.Process);
}

```

Retry policies

Functions supports two built-in retry policies. For more information, see [Retry policies](#).

Fixed delay

Here's the retry policy in the *function.json* file:

JSON

```
{
  "disabled": false,
  "bindings": [
    {
      ....
    }
  ],
  "retry": {
    "strategy": "fixedDelay",
    "maxRetryCount": 4,
    "delayInterval": "00:00:10"
  }
}
```

function.json property	Description
strategy	Use <code>fixedDelay</code> .
maxRetryCount	Required. The maximum number of retries allowed per function execution. <code>-1</code> means to retry indefinitely.
delayInterval	The delay that's used between retries. Specify it as a string with

function.json property	Description
	the format <code>HH:mm:ss</code> .

Binding at runtime

In C# and other .NET languages, you can use an [imperative](#) binding pattern, as opposed to the [declarative](#) bindings in *function.json*. Imperative binding is useful when binding parameters need to be computed at runtime rather than design time. With this pattern, you can bind to supported input and output bindings on-the-fly in your function code.

Define an imperative binding as follows:

- **Do not** include an entry in *function.json* for your desired imperative bindings.
- Pass in an input parameter [Binder binder](#) or [IBinder binder](#).
- Use the following C# pattern to perform the data binding.

C#

```
using (var output = await binder.BindAsync<T>(new
BindingTypeAttribute(...)))
{
    ...
}
```

`BindingTypeAttribute` is the .NET attribute that defines your binding and `T` is an input or output type that's supported by that binding type. `T` can't be an `out` parameter type (such as `out JObject`). For example, the Mobile Apps table output binding supports [six output types](#), but you can only use [ICollector<T>](#) or [IAsyncCollector<T>](#) for `T`.

Single attribute example

The following example code creates a [Storage blob output binding](#) with blob path that's defined at run time, then writes a string to the blob.

C#

```
using Microsoft.Azure.WebJobs;
using Microsoft.Azure.WebJobs.Host.Bindings.Runtime;

public static async Task Run(string input, Binder binder)
{
    using (var writer = await binder.BindAsync<TextWriter>(new
```

```

        BlobAttribute("samples-output/path")))
    {
        writer.WriteLine("Hello World!!");
    }
}

```

`BlobAttribute` [defines the Storage blob input or output binding](#), and `TextWriter` is a supported output binding type.

Multiple attributes example

The preceding example gets the app setting for the function app's main Storage account connection string (which is `AzureWebJobsStorage`). You can specify a custom app setting to use for the Storage account by adding the `StorageAccountAttribute` [and passing the attribute array into `BindAsync<T>\(\)`](#). Use a `Binder` parameter, not `IBinder`. For example:

C#

```

using Microsoft.Azure.WebJobs;
using Microsoft.Azure.WebJobs.Host.Bindings.Runtime;

public static async Task Run(string input, Binder binder)
{
    var attributes = new Attribute[]
    {
        new BlobAttribute("samples-output/path"),
        new StorageAccountAttribute("MyStorageAccount")
    };

    using (var writer = await binder.BindAsync<TextWriter>(attributes))
    {
        writer.WriteLine("Hello World!");
    }
}

```

The following table lists the .NET attributes for each binding type and the packages in which they're defined.

Binding	Attribute	Add reference
Azure Cosmos DB	<code>Microsoft.Azure.WebJobs.DocumentDBAttribute</code> ↳	#r "Microsoft.Azure.WebJobs.Extensions.CosmosDB"
Event Hubs	<code>Microsoft.Azure.WebJobs.ServiceBus.EventHubAttribute</code> ↳ , <code>Microsoft.Azure.WebJobs.ServiceBusAccountAttribute</code> ↳	#r "Microsoft.Azure.WebJobs.ServiceBus"

Binding	Attribute	Add reference
Mobile Apps	Microsoft.Azure.WebJobs.MobileTableAttribute	#r "Microsoft.Azure.WebJobs.Extensions.MobileApps"
Notification Hubs	Microsoft.Azure.WebJobs.NotificationHubAttribute	#r "Microsoft.Azure.WebJobs.Extensions.NotificationHubs"
Service Bus	Microsoft.Azure.WebJobs.ServiceBusAttribute , Microsoft.Azure.WebJobs.ServiceBusAccountAttribute	#r "Microsoft.Azure.WebJobs.ServiceBus"
Storage queue	Microsoft.Azure.WebJobs.QueueAttribute , Microsoft.Azure.WebJobs.StorageAccountAttribute	
Storage blob	Microsoft.Azure.WebJobs.BlobAttribute , Microsoft.Azure.WebJobs.StorageAccountAttribute	
Storage table	Microsoft.Azure.WebJobs.TableAttribute , Microsoft.Azure.WebJobs.StorageAccountAttribute	
Twilio	Microsoft.Azure.WebJobs.TwilioSmsAttribute	#r "Microsoft.Azure.WebJobs.Extensions.Twilio"

Convert a C# script app to a C# project

The easiest way to convert a C# script function app to a compiled C# class library project is to start with a new project. You can then, for each function, migrate the code and configuration from each run.csx file and function.json file in a function folder to a single new .cs class library code file. For example, when you have a C# script function named `HelloWorld` you'll have two files: `HelloWorld/run.csx` and `HelloWorld/function.json`. For this function, you create a code file named `HelloWorld.cs` in your new class library project.

If you are using C# scripting for portal editing, you can [download the app content to your local machine](#). Choose the **Site content** option instead of **Content and Visual Studio project**. You don't need to generate a project, and don't include application settings in the download. You're defining a new development environment, and this environment shouldn't have the same permissions as your hosted app environment.

These instructions show you how to convert C# script functions (which run in-process with the Functions host) to C# class library functions that run in an [isolated worker process](#).

1. Complete the [Create a functions app project](#) section from your preferred quickstart:

Azure CLI

[Create a C# function in Azure from the command line](#)

1. If your original C# script code includes an `extensions.csproj` file or any `function.proj` files, copy the package references from these file and add them to the new project's `.csproj` file in the same `ItemGroup` with the Functions core dependencies.

 Tip

Conversion provides a good opportunity to update to the latest versions of your dependencies. Doing so may require additional code changes in a later step.

2. Copy the contents of the original `host.json` file into the new project's `host.json` file, except for the `extensionBundles` section (compiled C# projects don't use [extension bundles](#) and you must explicitly add references to all extensions used by your functions). When merging `host.json` files, remember that the `host.json` schema is versioned, with most apps using version 2.0. The contents of the `extensions` section can differ based on specific versions of the binding extensions used by your functions. See individual extension reference articles to learn how to correctly configure the `host.json` for your specific versions.
3. For any [shared files referenced by a #load directive](#), create a new `.cs` file for each of these shared references. It's simplest to create a new `.cs` file for each shared class definition. If there are static methods without a class, you need to define new classes for these methods.
4. Perform the following tasks for each `<FUNCTION_NAME>` folder in your original project:
 - a. Create a new file named `<FUNCTION_NAME>.cs`, replacing `<FUNCTION_NAME>` with the name of the folder that defined your C# script function. You can create a new function code file from one of the trigger-specific templates in the following way:

Azure CLI

Using the `func new --name <FUNCTION_NAME>` command and choosing the correct trigger template at the prompt.

- b. Copy the `using` statements from your `run.csx` file and add them to the new file. You do not need any `#r` directives.
 - c. For any `#load` statement in your `run.csx` file, add a new `using` statement for the namespace you used for the shared code.
 - d. In the new file, define a class for your function under the namespace you are using for the project.
 - e. Create a new method named `RunHandler` or something similar. This new method serves as the new entry point for the function.
 - f. Copy the static method that represents your function, along with any functions it calls, from `run.csx` into your new class as a second method. From the new method you created in the previous step, call into this static method. This indirection step is helpful for navigating any differences as you continue the upgrade. You can keep the original method exactly the same and simply control its inputs from the new context. You may need to create parameters on the new method which you then pass into the static method call. After you have confirmed that the migration has worked as intended, you can remove this extra level of indirection.
 - g. For each binding in the `function.json` file, add the corresponding attribute to your new method. To quickly find binding examples, see [Manually add bindings based on examples](#).
 - h. Add any extension packages required by the bindings to your project, if you haven't already done so.
5. Recreate any application settings required by your app in the `Values` collection of the [local.settings.json file](#).
 6. Verify that your project runs locally:

Azure CLI

Use `func start` to run your app from the command line. For more information, see [Run functions locally](#).

7. Publish your project to a new function app in Azure:

Azure CLI

Create your Azure resources and deploy the code project to Azure by using the `func azure functionapp publish <APP_NAME>` command. For more information, see [Deploy project files](#).

Example function conversion

This section shows an example of the migration for a single function.

The original function in C# scripting has two files:

- `HelloWorld/function.json`
- `HelloWorld/run.csx`

The contents of `HelloWorld/function.json` are:

JSON

```
{  
  "bindings": [  
    {  
      "authLevel": "FUNCTION",  
      "name": "req",  
      "type": "httpTrigger",  
      "direction": "in",  
      "methods": [  
        "get",  
        "post"  
      ]  
    },  
    {  
      "name": "$return",  
      "type": "http",  
      "direction": "out"  
    }  
  ]  
}
```

The contents of `HelloWorld/run.csx` are:

C#

```
#r "Newtonsoft.Json"

using System.Net;
using Microsoft.AspNetCore.Mvc;
using Microsoft.Extensions.Primitives;
using Newtonsoft.Json;

public static async Task<IActionResult> Run(HttpContext req, ILogger log)
{
    log.LogInformation("C# HTTP trigger function processed a request.");

    string name = req.Query["name"];

    string requestBody = await new StreamReader(req.Body).ReadToEndAsync();
    dynamic data = JsonConvert.DeserializeObject(requestBody);
    name = name ?? data?.name;

    string responseMessage = string.IsNullOrEmpty(name)
        ? "This HTTP triggered function executed successfully. Pass a name
        in the query string or in the request body for a personalized response."
        : $"Hello, {name}. This HTTP triggered function executed
        successfully.";

    return new OkObjectResult(responseMessage);
}
```

After migrating to the isolated worker model with ASP.NET Core integration, these are replaced by a single `HelloWorld.cs`:

C#

```
using System.Net;
using Microsoft.Azure.Functions.Worker;
using Microsoft.AspNetCore.Http;
using Microsoft.AspNetCore.Mvc;
using Microsoft.Extensions.Logging;
using Microsoft.AspNetCore.Routing;
using Microsoft.Extensions.Primitives;
using Newtonsoft.Json;

namespace MyFunctionApp
{
    public class HelloWorld
    {
        private readonly ILogger _logger;

        public HelloWorld	ILoggerFactory loggerFactory
        {
            _logger = loggerFactory.CreateLogger<HelloWorld>();
        }
    }
}
```

```

[Function("HelloWorld")]
public async Task<IActionResult>
RunHandler([HttpTrigger(AuthorizationLevel.Function, "get")] HttpRequest
req)
{
    return await Run(req, _logger);
}

// From run.csx
public static async Task<IActionResult> Run(HttpContext req, ILogger
log)
{
    log.LogInformation("C# HTTP trigger function processed a
request.");

    string name = req.Query["name"];

    string requestBody = await new
StreamReader(req.Body).ReadToEndAsync();
    dynamic data = JsonConvert.DeserializeObject(requestBody);
    name = name ?? data?.name;

    string responseMessage = string.IsNullOrEmpty(name)
        ? "This HTTP triggered function executed successfully. Pass
a name in the query string or in the request body for a personalized
response."
        : $"Hello, {name}. This HTTP triggered function
executed successfully.";

    return new OkObjectResult(responseMessage);
}
}
}

```

Binding configuration and examples

This section contains references and examples for defining triggers and bindings in C# script.

Blob trigger

The following table explains the binding configuration properties for C# script that you set in the *function.json* file.

function.json	Description
property	
type	Must be set to <code>blobTrigger</code> . This property is set automatically when you create the trigger in the Azure portal.
direction	Must be set to <code>in</code> . This property is set automatically when you create the trigger in the Azure portal.
name	The name of the variable that represents the blob in function code.
path	The <code>container</code> to monitor. May be a blob name pattern .
connection	The name of an app setting or setting collection that specifies how to connect to Azure Blobs. See Connections .

The following example shows a blob trigger definition in a `function.json` file and code that uses the binding. The function writes a log when a blob is added or updated in the `samples-workitems` container.

Here's the binding data in the `function.json` file:

JSON

```
{
  "disabled": false,
  "bindings": [
    {
      "name": "myBlob",
      "type": "blobTrigger",
      "direction": "in",
      "path": "samples-workitems/{name}",
      "connection": "MyStorageAccountAppSetting"
    }
  ]
}
```

The string `{name}` in the blob trigger path `samples-workitems/{name}` creates a [binding expression](#) that you can use in function code to access the file name of the triggering blob. For more information, see [Blob name patterns](#).

Here's C# script code that binds to a `Stream`:

C#

```
public static void Run(Stream myBlob, string name, ILogger log)
{
  log.LogInformation($"C# Blob trigger function Processed blob\n Name: {name}");
}
```

```
{name} \n Size: {myBlob.Length} Bytes");  
}
```

Here's C# script code that binds to a `CloudBlockBlob`:

C#

```
#r "Microsoft.WindowsAzure.Storage"  
  
using Microsoft.WindowsAzure.Storage.Blob;  
  
public static void Run(CloudBlockBlob myBlob, string name, ILogger log)  
{  
    log.LogInformation($"C# Blob trigger function Processed blob\n Name:  
{name}\nURI:{myBlob.StorageUri}");  
}
```

Blob input

The following table explains the binding configuration properties for C# script that you set in the `function.json` file.

function.json property	Description
<code>type</code>	Must be set to <code>blob</code> .
<code>direction</code>	Must be set to <code>in</code> .
<code>name</code>	The name of the variable that represents the blob in function code.
<code>path</code>	The path to the blob.
<code>connection</code>	The name of an app setting or setting collection that specifies how to connect to Azure Blobs. See Connections .

The following example shows blob input and output bindings in a `function.json` file and C# script code that uses the bindings. The function makes a copy of a text blob. The function is triggered by a queue message that contains the name of the blob to copy. The new blob is named `{originalblobname}-Copy`.

In the `function.json` file, the `queueTrigger` metadata property is used to specify the blob name in the `path` properties:

JSON

```
{
  "bindings": [
    {
      "queueName": "myqueue-items",
      "connection": "MyStorageConnectionAppSetting",
      "name": "myQueueItem",
      "type": "queueTrigger",
      "direction": "in"
    },
    {
      "name": "myInputBlob",
      "type": "blob",
      "path": "samples-workitems/{queueTrigger}",
      "connection": "MyStorageConnectionAppSetting",
      "direction": "in"
    },
    {
      "name": "myOutputBlob",
      "type": "blob",
      "path": "samples-workitems/{queueTrigger}-Copy",
      "connection": "MyStorageConnectionAppSetting",
      "direction": "out"
    }
  ],
  "disabled": false
}
```

Here's the C# script code:

C#

```
public static void Run(string myQueueItem, string myInputBlob, out string
myOutputBlob, ILogger log)
{
    log.LogInformation($"C# Queue trigger function processed:
{myQueueItem}");
    myOutputBlob = myInputBlob;
}
```

Blob output

The following table explains the binding configuration properties for C# script that you set in the *function.json* file.

function.json property	Description
type	Must be set to <code>blob</code> .

function.json	Description
property	
direction	Must be set to <code>out</code> .
name	The name of the variable that represents the blob in function code.
path	The path to the blob.
connection	The name of an app setting or setting collection that specifies how to connect to Azure Blobs. See Connections .

The following example shows blob input and output bindings in a `function.json` file and C# script code that uses the bindings. The function makes a copy of a text blob. The function is triggered by a queue message that contains the name of the blob to copy. The new blob is named `{originalblobname}-Copy`.

In the `function.json` file, the `queueTrigger` metadata property is used to specify the blob name in the `path` properties:

JSON

```
{
  "bindings": [
    {
      "queueName": "myqueue-items",
      "connection": "MyStorageConnectionAppSetting",
      "name": "myQueueItem",
      "type": "queueTrigger",
      "direction": "in"
    },
    {
      "name": "myInputBlob",
      "type": "blob",
      "path": "samples-workitems/{queueTrigger}",
      "connection": "MyStorageConnectionAppSetting",
      "direction": "in"
    },
    {
      "name": "myOutputBlob",
      "type": "blob",
      "path": "samples-workitems/{queueTrigger}-Copy",
      "connection": "MyStorageConnectionAppSetting",
      "direction": "out"
    }
  ],
  "disabled": false
}
```

Here's the C# script code:

C#

```
public static void Run(string myQueueItem, string myInputBlob, out string myOutputBlob, ILogger log)
{
    log.LogInformation($"C# Queue trigger function processed:
{myQueueItem}");
    myOutputBlob = myInputBlob;
}
```

RabbitMQ trigger

The following example shows a RabbitMQ trigger binding in a *function.json* file and a [C# script function](#) that uses the binding. The function reads and logs the RabbitMQ message.

Here's the binding data in the *function.json* file:

JSON

```
{
  "bindings": [
    {
      "name": "myQueueItem",
      "type": "rabbitMQTrigger",
      "direction": "in",
      "queueName": "queue",
      "connectionStringSetting": "rabbitMQConnectionStringAppSetting"
    }
  ]
}
```

Here's the C# script code:

C#

```
using System;

public static void Run(string myQueueItem, ILogger log)
{
    log.LogInformation($"C# Script RabbitMQ trigger function processed: {
myQueueItem}");
}
```

Queue trigger

The following table explains the binding configuration properties for C# script that you set in the *function.json* file.

function.json property	Description
type	Must be set to <code>queueTrigger</code> . This property is set automatically when you create the trigger in the Azure portal.
direction	In the <i>function.json</i> file only. Must be set to <code>in</code> . This property is set automatically when you create the trigger in the Azure portal.
name	The name of the variable that contains the queue item payload in the function code.
queueName	The name of the queue to poll.
connection	The name of an app setting or setting collection that specifies how to connect to Azure Queues. See Connections .

The following example shows a queue trigger binding in a *function.json* file and C# script code that uses the binding. The function polls the `myqueue-items` queue and writes a log each time a queue item is processed.

Here's the *function.json* file:

```
JSON

{
  "disabled": false,
  "bindings": [
    {
      "type": "queueTrigger",
      "direction": "in",
      "name": "myQueueItem",
      "queueName": "myqueue-items",
      "connection": "MyStorageConnectionAppSetting"
    }
  ]
}
```

Here's the C# script code:

```
C#

#r "Microsoft.WindowsAzure.Storage"

using Microsoft.Extensions.Logging;
using Microsoft.WindowsAzure.Storage.Queue;
```

```

using System;

public static void Run(CloudQueueMessage myQueueItem,
    DateTimeOffset expirationTime,
    DateTimeOffset insertionTime,
    DateTimeOffset nextVisibleTime,
    string queueTrigger,
    string id,
    string popReceipt,
    int dequeueCount,
    ILogger log)
{
    log.LogInformation($"C# Queue trigger function processed:
{myQueueItemAsString}\n" +
    $"queueTrigger={queueTrigger}\n" +
    $"expirationTime={expirationTime}\n" +
    $"insertionTime={insertionTime}\n" +
    $"nextVisibleTime={nextVisibleTime}\n" +
    $"id={id}\n" +
    $"popReceipt={popReceipt}\n" +
    $"dequeueCount={dequeueCount}");
}

```

Queue output

The following table explains the binding configuration properties for C# script that you set in the *function.json* file.

function.json property	Description
type	Must be set to <code>queue</code> . This property is set automatically when you create the trigger in the Azure portal.
direction	Must be set to <code>out</code> . This property is set automatically when you create the trigger in the Azure portal.
name	The name of the variable that represents the queue in function code. Set to <code>\$return</code> to reference the function return value.
queueName	The name of the queue.
connection	The name of an app setting or setting collection that specifies how to connect to Azure Queues. See Connections .

The following example shows an HTTP trigger binding in a *function.json* file and C# script code that uses the binding. The function creates a queue item with a `CustomQueueMessage` object payload for each HTTP request received.

Here's the `function.json` file:

JSON

```
{  
  "bindings": [  
    {  
      "type": "httpTrigger",  
      "direction": "in",  
      "authLevel": "function",  
      "name": "input"  
    },  
    {  
      "type": "http",  
      "direction": "out",  
      "name": "$return"  
    },  
    {  
      "type": "queue",  
      "direction": "out",  
      "name": "$return",  
      "queueName": "outqueue",  
      "connection": "MyStorageConnectionAppSetting"  
    }  
  ]  
}
```

Here's C# script code that creates a single queue message:

C#

```
public class CustomQueueMessage  
{  
    public string PersonName { get; set; }  
    public string Title { get; set; }  
}  
  
public static CustomQueueMessage Run(CustomQueueMessage input, ILogger log)  
{  
    return input;  
}
```

You can send multiple messages at once by using an `ICollector` or `IAsyncCollector` parameter. Here's C# script code that sends multiple messages, one with the HTTP request data and one with hard-coded values:

C#

```
public static void Run(  
    CustomQueueMessage input,
```

```

    ICollector<CustomQueueMessage> myQueueItems,
    ILogger log)
{
    myQueueItems.Add(input);
    myQueueItems.Add(new CustomQueueMessage { PersonName = "You", Title =
    "None" });
}

```

Table input

This section outlines support for the [Tables API version of the extension](#) only.

The following table explains the binding configuration properties for C# script that you set in the *function.json* file.

function.json	Description
property	
type	Must be set to <code>table</code> . This property is set automatically when you create the binding in the Azure portal.
direction	Must be set to <code>in</code> . This property is set automatically when you create the binding in the Azure portal.
name	The name of the variable that represents the table or entity in function code.
tableName	The name of the table.
partitionKey	Optional. The partition key of the table entity to read.
rowKey	Optional. The row key of the table entity to read. Can't be used with <code>take</code> or <code>filter</code> .
take	Optional. The maximum number of entities to return. Can't be used with <code>rowKey</code> .
filter	Optional. An OData filter expression for the entities to return from the table. Can't be used with <code>rowKey</code> .
connection	The name of an app setting or setting collection that specifies how to connect to the table service. See Connections .

The following example shows a table input binding in a *function.json* file and C# script code that uses the binding. The function uses a queue trigger to read a single table row.

The *function.json* file specifies a `partitionKey` and a `rowKey`. The `rowKey` value `{queueTrigger}` indicates that the row key comes from the queue message string.

JSON

```
{  
  "bindings": [  
    {  
      "queueName": "myqueue-items",  
      "connection": "MyStorageConnectionAppSetting",  
      "name": "myQueueItem",  
      "type": "queueTrigger",  
      "direction": "in"  
    },  
    {  
      "name": "personEntity",  
      "type": "table",  
      "tableName": "Person",  
      "partitionKey": "Test",  
      "rowKey": "{queueTrigger}",  
      "connection": "MyStorageConnectionAppSetting",  
      "direction": "in"  
    }  
,  
    {"disabled": false  
  }  
}
```

Here's the C# script code:

C#

```
#r "Azure.Data.Tables"  
using Microsoft.Extensions.Logging;  
using Azure.Data.Tables;  
  
public static void Run(string myQueueItem, Person personEntity, ILogger log)  
{  
    log.LogInformation($"C# Queue trigger function processed:  
{myQueueItem}");  
    log.LogInformation($"Name in Person entity: {personEntity.Name}");  
}  
  
public class Person : ITableEntity  
{  
    public string Name { get; set; }  
  
    public string PartitionKey { get; set; }  
    public string RowKey { get; set; }  
    public DateTimeOffset? Timestamp { get; set; }  
    public ETag ETag { get; set; }  
}
```

Table output

This section outlines support for the [Tables API version of the extension](#) only.

The following table explains the binding configuration properties for C# script that you set in the *function.json* file.

function.json property	Description
type	Must be set to <code>table</code> . This property is set automatically when you create the binding in the Azure portal.
direction	Must be set to <code>out</code> . This property is set automatically when you create the binding in the Azure portal.
name	The variable name used in function code that represents the table or entity. Set to <code>\$return</code> to reference the function return value.
tableName	The name of the table to which to write.
partitionKey	The partition key of the table entity to write.
rowKey	The row key of the table entity to write.
connection	The name of an app setting or setting collection that specifies how to connect to the table service. See Connections .

The following example shows a table output binding in a *function.json* file and C# script code that uses the binding. The function writes multiple table entities.

Here's the *function.json* file:

JSON

```
{
  "bindings": [
    {
      "name": "input",
      "type": "manualTrigger",
      "direction": "in"
    },
    {
      "tableName": "Person",
      "connection": "MyStorageConnectionAppSetting",
      "name": "tableBinding",
      "type": "table",
      "direction": "out"
    }
  ],
  "disabled": false
}
```

Here's the C# script code:

C#

```
public static void Run(string input, ICollector<Person> tableBinding,
ILogger log)
{
    for (int i = 1; i < 10; i++)
    {
        log.LogInformation($"Adding Person entity {i}");
        tableBinding.Add(
            new Person() {
                PartitionKey = "Test",
                RowKey = i.ToString(),
                Name = "Name" + i.ToString() })
    }
}

public class Person
{
    public string PartitionKey { get; set; }
    public string RowKey { get; set; }
    public string Name { get; set; }
}
```

Timer trigger

The following table explains the binding configuration properties for C# script that you set in the *function.json* file.

function.json	Description
property	
type	Must be set to <code>timerTrigger</code> . This property is set automatically when you create the trigger in the Azure portal.
direction	Must be set to <code>in</code> . This property is set automatically when you create the trigger in the Azure portal.
name	The name of the variable that represents the timer object in function code.
schedule	A CRON expression or a TimeSpan value. A <code>TimeSpan</code> can be used only for a function app that runs on an App Service Plan. You can put the schedule expression in an app setting and set this property to the app setting name wrapped in % signs, as in this example: "%ScheduleAppSetting%".

function.json	Description
property	
runOnStartup	If <code>true</code> , the function is invoked when the runtime starts. For example, the runtime starts when the function app wakes up after going idle due to inactivity, when the function app restarts due to function changes, and when the function app scales out. <i>Use with caution.</i> <code>runOnStartup</code> should rarely if ever be set to <code>true</code> , especially in production.
useMonitor	Set to <code>true</code> or <code>false</code> to indicate whether the schedule should be monitored. Schedule monitoring persists schedule occurrences to aid in ensuring the schedule is maintained correctly even when function app instances restart. If not set explicitly, the default is <code>true</code> for schedules that have a recurrence interval greater than or equal to 1 minute. For schedules that trigger more than once per minute, the default is <code>false</code> .

The following example shows a timer trigger binding in a `function.json` file and a C# script function that uses the binding. The function writes a log indicating whether this function invocation is due to a missed schedule occurrence. The [TimerInfo](#) object is passed into the function.

Here's the binding data in the `function.json` file:

JSON

```
{
  "schedule": "0 */5 * * * *",
  "name": "myTimer",
  "type": "timerTrigger",
  "direction": "in"
}
```

Here's the C# script code:

C#

```
public static void Run(TimerInfo myTimer, ILogger log)
{
    if (myTimer.IsPastDue)
    {
        log.LogInformation("Timer is running late!");
    }
    log.LogInformation($"C# Timer trigger function executed at:
{DateTime.Now}");
```

HTTP trigger

The following table explains the trigger configuration properties that you set in the `function.json` file:

function.json property	Description
<code>type</code>	Required - must be set to <code>httpTrigger</code> .
<code>direction</code>	Required - must be set to <code>in</code> .
<code>name</code>	Required - the variable name used in function code for the request or request body.
<code>authLevel</code>	Determines what keys, if any, need to be present on the request in order to invoke the function. For supported values, see Authorization level .
<code>methods</code>	An array of the HTTP methods to which the function responds. If not specified, the function responds to all HTTP methods. See customize the HTTP endpoint .
<code>route</code>	Defines the route template, controlling to which request URLs your function responds. The default value if none is provided is <code><functionname></code> . For more information, see customize the HTTP endpoint .
<code>webHookType</code>	<i>Supported only for the version 1.x runtime.</i> Configures the HTTP trigger to act as a webhook receiver for the specified provider. For supported values, see WebHook type .

The following example shows a trigger binding in a `function.json` file and a C# script function that uses the binding. The function looks for a `name` parameter either in the query string or the body of the HTTP request.

Here's the `function.json` file:

```
JSON

{
  "disabled": false,
  "bindings": [
    {
      "authLevel": "function",
      "name": "req",
      "type": "httpTrigger",
      "direction": "in",
      "methods": [
        "get",
        "post"
      ]
    },
  ]}
```

```

        {
            "name": "$return",
            "type": "http",
            "direction": "out"
        }
    ]
}

```

Here's C# script code that binds to `HttpRequest`:

C#

```

#r "Newtonsoft.Json"

using System.Net;
using Microsoft.AspNetCore.Mvc;
using Microsoft.Extensions.Primitives;
using Newtonsoft.Json;

public static async Task<IActionResult> Run(HttpContext req, ILogger log)
{
    log.LogInformation("C# HTTP trigger function processed a request.");

    string name = req.Query["name"];

    string requestBody = String.Empty;
    using (StreamReader streamReader = new StreamReader(req.Body))
    {
        requestBody = await streamReader.ReadToEndAsync();
    }
    dynamic data = JsonConvert.DeserializeObject(requestBody);
    name = name ?? data?.name;

    return name != null
        ? (ActionResult)new OkObjectResult($"Hello, {name}")
        : new BadRequestObjectResult("Please pass a name on the query string or in the request body");
}

```

You can bind to a custom object instead of `HttpRequest`. This object is created from the body of the request and parsed as JSON. Similarly, a type can be passed to the HTTP response output binding and returned as the response body, along with a `200` status code.

C#

```

using System.Net;
using System.Threading.Tasks;
using Microsoft.Extensions.Logging;

```

```

public static string Run(Person person, ILogger log)
{
    return person.Name != null
        ? (ActionResult)new OkObjectResult($"Hello, {person.Name}")
        : new BadRequestObjectResult("Please pass an instance of Person.");
}

public class Person {
    public string Name {get; set;}
}

```

HTTP output

The following table explains the binding configuration properties that you set in the `function.json` file.

Property	Description
<code>type</code>	Must be set to <code>http</code> .
<code>direction</code>	Must be set to <code>out</code> .
<code>name</code>	The variable name used in function code for the response, or <code>\$return</code> to use the return value.

Event Hubs trigger

The following table explains the trigger configuration properties that you set in the `function.json` file:

function.json	Description
property	
<code>type</code>	Must be set to <code>eventHubTrigger</code> . This property is set automatically when you create the trigger in the Azure portal.
<code>direction</code>	Must be set to <code>in</code> . This property is set automatically when you create the trigger in the Azure portal.
<code>name</code>	The name of the variable that represents the event item in function code.
<code>eventHubName</code>	Functions 2.x and higher. The name of the event hub. When the event hub name is also present in the connection string, that value overrides this property at runtime. Can be referenced via <code>app settings %eventHubName%</code> . In version 1.x, this property is named <code>path</code> .
<code>consumerGroup</code>	An optional property that sets the <code>consumer group</code> used to subscribe to

function.json	Description
property	events in the hub. If omitted, the <code>\$Default</code> consumer group is used.
connection	The name of an app setting or setting collection that specifies how to connect to Event Hubs. See Connections .

The following example shows an Event Hubs trigger binding in a `function.json` file and a C# script function that uses the binding. The function logs the message body of the Event Hubs trigger.

The following examples show Event Hubs binding data in the `function.json` file for Functions runtime version 2.x and later versions.

JSON

```
{
  "type": "eventHubTrigger",
  "name": "myEventHubMessage",
  "direction": "in",
  "eventHubName": "MyEventHub",
  "connection": "myEventHubReadConnectionAppSetting"
}
```

Here's the C# script code:

C#

```
using System;

public static void Run(string myEventHubMessage, TraceWriter log)
{
    log.Info($"C# function triggered to process a message:
{myEventHubMessage}");
}
```

To get access to event metadata in function code, bind to an `EventData` object. You can also access the same properties by using binding expressions in the method signature. The following example shows both ways to get the same data:

C#

```
#r "Microsoft.Azure.EventHubs"

using System.Text;
using System;
using Microsoft.ServiceBus.Messaging;
```

```

using Microsoft.Azure.EventHubs;

public void Run(EventData myEventHubMessage,
    DateTime enqueuedTimeUtc,
    Int64 sequenceNumber,
    string offset,
    TraceWriter log)
{
    log.Info($"Event: {Encoding.UTF8.GetString(myEventHubMessage.Body)}");
    log.Info($"EnqueuedTimeUtc={myEventHubMessage.SystemProperties.EnqueuedTimeUtc}");
    log.Info($"SequenceNumber={myEventHubMessage.SystemProperties.SequenceNumber}");
    log.Info($"Offset={myEventHubMessage.SystemProperties.Offset}");

    // Metadata accessed by using binding expressions
    log.Info($"EnqueuedTimeUtc={enqueuedTimeUtc}");
    log.Info($"SequenceNumber={sequenceNumber}");
    log.Info($"Offset={offset}");
}

```

To receive events in a batch, make `string` or `EventData` an array:

C#

```

public static void Run(string[] eventHubMessages, TraceWriter log)
{
    foreach (var message in eventHubMessages)
    {
        log.Info($"C# function triggered to process a message: {message}");
    }
}

```

Event Hubs output

The following table explains the binding configuration properties that you set in the `function.json` file.

function.json property	Description
<code>type</code>	Must be set to <code>eventHub</code> .
<code>direction</code>	Must be set to <code>out</code> . This parameter is set automatically when you create the binding in the Azure portal.
<code>name</code>	The variable name used in function code that represents the event.

function.json	Description
eventHubName	Functions 2.x and higher. The name of the event hub. When the event hub name is also present in the connection string, that value overrides this property at runtime. In Functions 1.x, this property is named <code>path</code> .
connection	The name of an app setting or setting collection that specifies how to connect to Event Hubs. To learn more, see Connections .

The following example shows an event hub trigger binding in a `function.json` file and a C# script function that uses the binding. The function writes a message to an event hub.

The following examples show Event Hubs binding data in the `function.json` file for Functions runtime version 2.x and later versions.

JSON

```
{
  "type": "eventHub",
  "name": "outputEventHubMessage",
  "eventHubName": "myeventhub",
  "connection": "MyEventHubSendAppSetting",
  "direction": "out"
}
```

Here's C# script code that creates one message:

C#

```
using System;
using Microsoft.Extensions.Logging;

public static void Run(TimerInfo myTimer, out string outputEventHubMessage,
ILogger log)
{
    String msg = $"TimerTriggerCSharp1 executed at: {DateTime.Now}";
    log.LogInformation(msg);
    outputEventHubMessage = msg;
}
```

Here's C# script code that creates multiple messages:

C#

```
public static void Run(TimerInfo myTimer, ICollector<string>
outputEventHubMessage, ILogger log)
{
    string message = $"Message created at: {DateTime.Now}";
```

```

        log.LogInformation(message);
        outputEventHubMessage.Add("1 " + message);
        outputEventHubMessage.Add("2 " + message);
    }

```

Event Grid trigger

The following table explains the binding configuration properties for C# script that you set in the `function.json` file. There are no constructor parameters or properties to set in the `EventGridTrigger` attribute.

function.json	Description
property	
<code>type</code>	Required - must be set to <code>eventGridTrigger</code> .
<code>direction</code>	Required - must be set to <code>in</code> .
<code>name</code>	Required - the variable name used in function code for the parameter that receives the event data.

The following example shows an Event Grid trigger defined in the `function.json` file.

Here's the binding data in the `function.json` file:

JSON

```
{
  "bindings": [
    {
      "type": "eventGridTrigger",
      "name": "eventGridEvent",
      "direction": "in"
    }
  ],
  "disabled": false
}
```

Here's an example of a C# script function that uses an `EventGridEvent` binding parameter:

C#

```
#r "Azure.Messaging.EventGrid"
using Azure.Messaging.EventGrid;
using Microsoft.Extensions.Logging;
```

```
public static void Run(EventGridEvent eventGridEvent, ILogger log)
{
    log.LogInformation(eventGridEvent.Data.ToString());
}
```

Here's an example of a C# script function that uses a `JObject` binding parameter:

C#

```
#r "Newtonsoft.Json"

using Newtonsoft.Json;
using Newtonsoft.Json.Linq;

public static void Run(JObject eventGridEvent, TraceWriter log)
{
    log.Info(eventGridEvent.ToString(Formatting.Indented));
}
```

Event Grid output

The following table explains the binding configuration properties for C# script that you set in the `function.json` file.

function.json property	Description
<code>type</code>	Must be set to <code>eventGrid</code> .
<code>direction</code>	Must be set to <code>out</code> . This parameter is set automatically when you create the binding in the Azure portal.
<code>name</code>	The variable name used in function code that represents the event.
<code>topicEndpointUri</code>	The name of an app setting that contains the URI for the custom topic, such as <code>MyTopicEndpointUri</code> .
<code>topicKeySetting</code>	The name of an app setting that contains an access key for the custom topic.

The following example shows the Event Grid output binding data in the `function.json` file.

JSON

```
{
    "type": "eventGrid",
    "name": "outputEvent",
    "topicEndpointUri": "MyEventGridTopicUriSetting",
```

```
    "topicKeySetting": "MyEventGridTopicKeySetting",
    "direction": "out"
}
```

Here's C# script code that creates one event:

```
C#  
  
#r "Microsoft.Azure.EventGrid"  
using System;  
using Microsoft.Azure.EventGrid.Models;  
using Microsoft.Extensions.Logging;  
  
public static void Run(TimerInfo myTimer, out EventGridEvent outputEvent,  
ILogger log)  
{  
    outputEvent = new EventGridEvent("message-id", "subject-name", "event-  
data", "event-type", DateTime.UtcNow, "1.0");  
}
```

Here's C# script code that creates multiple events:

```
C#  
  
#r "Microsoft.Azure.EventGrid"  
using System;  
using Microsoft.Azure.EventGrid.Models;  
using Microsoft.Extensions.Logging;  
  
public static void Run(TimerInfo myTimer, ICollector<EventGridEvent>  
outputEvent, ILogger log)  
{  
    outputEvent.Add(new EventGridEvent("message-id-1", "subject-name",  
"event-data", "event-type", DateTime.UtcNow, "1.0"));  
    outputEvent.Add(new EventGridEvent("message-id-2", "subject-name",  
"event-data", "event-type", DateTime.UtcNow, "1.0"));  
}
```

Service Bus trigger

The following table explains the binding configuration properties that you set in the *function.json* file.

function.json property	Description
type	Must be set to <code>serviceBusTrigger</code> . This property is set automatically when you create the trigger in the Azure portal.

function.json	Description
property	
direction	Must be set to <code>in</code> . This property is set automatically when you create the trigger in the Azure portal.
name	The name of the variable that represents the queue or topic message in function code.
queueName	Name of the queue to monitor. Set only if monitoring a queue, not for a topic.
topicName	Name of the topic to monitor. Set only if monitoring a topic, not for a queue.
subscriptionName	Name of the subscription to monitor. Set only if monitoring a topic, not for a queue.
connection	The name of an app setting or setting collection that specifies how to connect to Service Bus. See Connections .
accessRights	Access rights for the connection string. Available values are <code>manage</code> and <code>listen</code> . The default is <code>manage</code> , which indicates that the <code>connection</code> has the Manage permission. If you use a connection string that does not have the Manage permission, set <code>accessRights</code> to "listen". Otherwise, the Functions runtime might fail trying to do operations that require manage rights. In Azure Functions version 2.x and higher, this property is not available because the latest version of the Service Bus SDK doesn't support manage operations.
isSessionsEnabled	<code>true</code> if connecting to a session-aware queue or subscription. <code>false</code> otherwise, which is the default value.
autoComplete	<code>true</code> when the trigger should automatically call <code>complete</code> after processing, or if the function code will manually call <code>complete</code> .
	Setting to <code>false</code> is only supported in C#.
	If set to <code>true</code> , the trigger completes the message automatically if the function execution completes successfully, and abandons the message otherwise.
	When set to <code>false</code> , you are responsible for calling MessageReceiver methods to complete, abandon, or deadletter the message. If an exception is thrown (and none of the <code>MessageReceiver</code> methods are called), then the lock remains. Once the lock expires, the message is re-queued with the <code>DeliveryCount</code> incremented and the lock is automatically renewed.
	This property is available only in Azure Functions 2.x and higher.

The following example shows a Service Bus trigger binding in a *function.json* file and a C# script function that uses the binding. The function reads message metadata and logs a Service Bus queue message.

Here's the binding data in the *function.json* file:

JSON

```
{  
  "bindings": [  
    {  
      "queueName": "testqueue",  
      "connection": "MyServiceBusConnection",  
      "name": "myQueueItem",  
      "type": "serviceBusTrigger",  
      "direction": "in"  
    }  
,  
  {"disabled": false  
}
```

Here's the C# script code:

C#

```
using System;  
  
public static void Run(string myQueueItem,  
    Int32 deliveryCount,  
    DateTime enqueuedTimeUtc,  
    string messageId,  
    TraceWriter log)  
{  
    log.Info($"C# ServiceBus queue trigger function processed message:  
{myQueueItem}");  
  
    log.Info($"EnqueuedTimeUtc={enqueuedTimeUtc}");  
    log.Info($"DeliveryCount={deliveryCount}");  
    log.Info($"MessageId={messageId}");  
}
```

Service Bus output

The following table explains the binding configuration properties that you set in the *function.json* file.

function.json	Description
property	
type	Must be set to <code>serviceBus</code> . This property is set automatically when you create the trigger in the Azure portal.
direction	Must be set to <code>out</code> . This property is set automatically when you create the trigger in the Azure portal.
name	The name of the variable that represents the queue or topic message in function code. Set to "\$return" to reference the function return value.
queueName	Name of the queue. Set only if sending queue messages, not for a topic.
topicName	Name of the topic. Set only if sending topic messages, not for a queue.
connection	The name of an app setting or setting collection that specifies how to connect to Service Bus. See Connections .
accessRights (v1 only)	Access rights for the connection string. Available values are <code>manage</code> and <code>listen</code> . The default is <code>manage</code> , which indicates that the <code>connection</code> has the Manage permission. If you use a connection string that does not have the Manage permission, set <code>accessRights</code> to "listen". Otherwise, the Functions runtime might fail trying to do operations that require manage rights. In Azure Functions version 2.x and higher, this property is not available because the latest version of the Service Bus SDK doesn't support manage operations.

The following example shows a Service Bus output binding in a `function.json` file and a C# script function that uses the binding. The function uses a timer trigger to send a queue message every 15 seconds.

Here's the binding data in the `function.json` file:

JSON

```
{
  "bindings": [
    {
      "schedule": "0/15 * * * *",
      "name": "myTimer",
      "runsOnStartup": true,
      "type": "timerTrigger",
      "direction": "in"
    },
    {
      "name": "outputSbQueue",
      "type": "serviceBus",
      "queueName": "testqueue",
      "connection": "MyServiceBusConnection",
      "direction": "out"
    }
  ]
}
```

```
  ],
  "disabled": false
}
```

Here's C# script code that creates a single message:

```
C#

public static void Run(TimerInfo myTimer, ILogger log, out string
outputSbQueue)
{
    string message = $"Service Bus queue message created at:
{DateTime.Now}";
    log.LogInformation(message);
    outputSbQueue = message;
}
```

Here's C# script code that creates multiple messages:

```
C#

public static async Task Run(TimerInfo myTimer, ILogger log,
IAsyncCollector<string> outputSbQueue)
{
    string message = $"Service Bus queue messages created at:
{DateTime.Now}";
    log.LogInformation(message);
    await outputSbQueue.AddAsync("1 " + message);
    await outputSbQueue.AddAsync("2 " + message);
}
```

Azure Cosmos DB v2 trigger

This section outlines support for the [version 4.x+ of the extension](#) only.

The following table explains the binding configuration properties that you set in the `function.json` file.

function.json property	Description
<code>type</code>	Must be set to <code>cosmosDBTrigger</code> .
<code>direction</code>	Must be set to <code>in</code> . This parameter is set automatically when you create the trigger in the Azure portal.
<code>name</code>	The variable name used in function code that represents the list of documents with changes.

function.json property	Description
connection	The name of an app setting or setting collection that specifies how to connect to the Azure Cosmos DB account being monitored. For more information, see Connections .
databaseName	The name of the Azure Cosmos DB database with the container being monitored.
containerName	The name of the container being monitored.
leaseConnection	(Optional) The name of an app setting or setting container that specifies how to connect to the Azure Cosmos DB account that holds the lease container. When not set, the <code>connection</code> value is used. This parameter is automatically set when the binding is created in the portal. The connection string for the leases container must have write permissions.
leaseDatabaseName	(Optional) The name of the database that holds the container used to store leases. When not set, the value of the <code>databaseName</code> setting is used.
leaseContainerName	(Optional) The name of the container used to store leases. When not set, the value <code>leases</code> is used.
createLeaseContainerIfNotExists	(Optional) When set to <code>true</code> , the leases container is automatically created when it doesn't already exist. The default value is <code>false</code> . When using Azure AD identities if you set the value to <code>true</code> , creating containers is not an allowed operation and your Function won't be able to start.
leasesContainerThroughput	(Optional) Defines the number of Request Units to assign when the leases container is created. This setting is only used when <code>createLeaseContainerIfNotExists</code> is set to <code>true</code> . This parameter is automatically set when the binding is created using the portal.
leaseContainerPrefix	(Optional) When set, the value is added as a prefix to the leases created in the Lease container for this function. Using a prefix allows two separate Azure Functions to share the same Lease container by using different prefixes.
feedPollDelay	(Optional) The time (in milliseconds) for the delay between polling a partition for new changes on the feed, after all current changes are drained. Default is 5,000 milliseconds, or 5 seconds.
leaseAcquireInterval	(Optional) When set, it defines, in milliseconds, the interval to kick off a task to compute if partitions are distributed evenly

function.json property	Description
	among known host instances. Default is 13000 (13 seconds).
leaseExpirationInterval	(Optional) When set, it defines, in milliseconds, the interval for which the lease is taken on a lease representing a partition. If the lease is not renewed within this interval, it will cause it to expire and ownership of the partition will move to another instance. Default is 60000 (60 seconds).
leaseRenewInterval	(Optional) When set, it defines, in milliseconds, the renew interval for all leases for partitions currently held by an instance. Default is 17000 (17 seconds).
maxItemsPerInvocation	(Optional) When set, this property sets the maximum number of items received per Function call. If operations in the monitored container are performed through stored procedures, transaction scope is preserved when reading items from the change feed. As a result, the number of items received could be higher than the specified value so that the items changed by the same transaction are returned as part of one atomic batch.
startFromBeginning	(Optional) This option tells the Trigger to read changes from the beginning of the container's change history instead of starting at the current time. Reading from the beginning only works the first time the trigger starts, as in subsequent runs, the checkpoints are already stored. Setting this option to <code>true</code> when there are leases already created has no effect.
startFromTime	(Optional) Gets or sets the date and time from which to initialize the change feed read operation. The recommended format is ISO 8601 with the UTC designator, such as <code>2021-02-16T14:19:29Z</code> . This is only used to set the initial trigger state. After the trigger has a lease state, changing this value has no effect.
preferredLocations	(Optional) Defines preferred locations (regions) for geo-replicated database accounts in the Azure Cosmos DB service. Values should be comma-separated. For example, "East US,South Central US,North Europe".

The following example shows an Azure Cosmos DB trigger binding in a `function.json` file and a [C# script function](#) that uses the binding. The function writes log messages when Azure Cosmos DB records are added or modified.

Here's the binding data in the `function.json` file:

JSON

```
{
    "type": "cosmosDBTrigger",
    "name": "documents",
    "direction": "in",
    "leaseContainerName": "leases",
    "connection": "<connection-app-setting>",
    "databaseName": "Tasks",
    "containerName": "Items",
    "createLeaseContainerIfNotExists": true
}
```

Here's the C# script code:

C#

```
using System;
using System.Collections.Generic;
using Microsoft.Extensions.Logging;

// Customize the model with your own desired properties
public class ToDoItem
{
    public string id { get; set; }
    public string Description { get; set; }
}

public static void Run(IReadOnlyList<ToDoItem> documents, ILogger log)
{
    log.LogInformation("Documents modified " + documents.Count);
    log.LogInformation("First document Id " + documents[0].id);
}
```

Azure Cosmos DB v2 input

This section outlines support for the [version 4.x+ of the extension](#) only.

The following table explains the binding configuration properties that you set in the `function.json` file.

function.json property	Description
type	Must be set to <code>cosmosDB</code> .
direction	Must be set to <code>in</code> .
name	The variable name used in function code that represents the list of documents with changes.

function.json property	Description
connection	The name of an app setting or setting container that specifies how to connect to the Azure Cosmos DB account being monitored. For more information, see Connections .
databaseName	The name of the Azure Cosmos DB database with the container being monitored.
containerName	The name of the container being monitored.
partitionKey	Specifies the partition key value for the lookup. May include binding parameters. It is required for lookups in partitioned containers.
id	The ID of the document to retrieve. This property supports binding expressions . Don't set both the <code>id</code> and <code>sqlQuery</code> properties. If you don't set either one, the entire container is retrieved.
sqlQuery	An Azure Cosmos DB SQL query used for retrieving multiple documents. The property supports runtime bindings, as in this example: <code>SELECT * FROM c WHERE c.departmentId = {departmentId}</code> . Don't set both the <code>id</code> and <code>sqlQuery</code> properties. If you don't set either one, the entire container is retrieved.
preferredLocations	(Optional) Defines preferred locations (regions) for geo-replicated database accounts in the Azure Cosmos DB service. Values should be comma-separated. For example, <code>East US,South Central US,North Europe</code> .

This section contains the following examples:

- [Queue trigger, look up ID from string](#)
- [Queue trigger, get multiple docs, using SqlQuery](#)
- [HTTP trigger, look up ID from query string](#)
- [HTTP trigger, look up ID from route data](#)
- [HTTP trigger, get multiple docs, using SqlQuery](#)
- [HTTP trigger, get multiple docs, using DocumentClient](#)

The HTTP trigger examples refer to a simple `ToDoItem` type:

C#

```
namespace CosmosDBSamplesV2
{
    public class ToDoItem
    {
        public string Id { get; set; }
        public string Description { get; set; }
```

```
    }  
}
```

Queue trigger, look up ID from string

The following example shows an Azure Cosmos DB input binding in a *function.json* file and a C# script function that uses the binding. The function reads a single document and updates the document's text value.

Here's the binding data in the *function.json* file:

JSON

```
{  
  "name": "inputDocument",  
  "type": "cosmosDB",  
  "databaseName": "MyDatabase",  
  "collectionName": "MyCollection",  
  "id" : "{queueTrigger}",  
  "partitionKey": "{partition key value}",  
  "connectionStringSetting": "MyAccount_COSMOSDB",  
  "direction": "in"  
}
```

Here's the C# script code:

C#

```
using System;  
  
// Change input document contents using Azure Cosmos DB input binding  
public static void Run(string myQueueItem, dynamic inputDocument)  
{  
    inputDocument.text = "This has changed.";  
}
```

Queue trigger, get multiple docs, using SqlQuery

The following example shows an Azure Cosmos DB input binding in a *function.json* file and a C# script function that uses the binding. The function retrieves multiple documents specified by a SQL query, using a queue trigger to customize the query parameters.

The queue trigger provides a parameter `departmentId`. A queue message of `{ "departmentId" : "Finance" }` would return all records for the finance department.

Here's the binding data in the *function.json* file:

JSON

```
{  
    "name": "documents",  
    "type": "cosmosDB",  
    "direction": "in",  
    "databaseName": "MyDb",  
    "collectionName": "MyCollection",  
    "sqlQuery": "SELECT * from c where c.departmentId = {departmentId}",  
    "connectionStringSetting": "CosmosDBConnection"  
}
```

Here's the C# script code:

C#

```
public static void Run(QueuePayload myQueueItem, IEnumerable<dynamic>  
documents)  
{  
    foreach (var doc in documents)  
    {  
        // operate on each document  
    }  
}  
  
public class QueuePayload  
{  
    public string departmentId { get; set; }  
}
```

HTTP trigger, look up ID from query string

The following example shows a C# script function that retrieves a single document. The function is triggered by an HTTP request that uses a query string to specify the ID and partition key value to look up. That ID and partition key value are used to retrieve a `ToDoItem` document from the specified database and collection.

Here's the *function.json* file:

JSON

```
{  
    "bindings": [  
        {  
            "authLevel": "anonymous",  
            "name": "req",  
            "type": "httpTrigger",  
            "direction": "in",  
            "method": "get",  
            "route": "GetItem/  
            "id": "  
            "partitionKey": "  
            "query": "  
            "host": "https://  
            "hostName": "myapp",  
            "port": 3001  
        }  
    ]  
}
```

```

    "type": "httpTrigger",
    "direction": "in",
    "methods": [
        "get",
        "post"
    ],
},
{
    "name": "$return",
    "type": "http",
    "direction": "out"
},
{
    "type": "cosmosDB",
    "name": "ToDoItem",
    "databaseName": "ToDoItems",
    "collectionName": "Items",
    "connectionStringSetting": "CosmosDBConnection",
    "direction": "in",
    "Id": "{Query.id}",
    "PartitionKey" : "{Query.partitionKeyValue}"
}
],
"disabled": false
}

```

Here's the C# script code:

```

C#

using System.Net;
using Microsoft.Extensions.Logging;

public static HttpResponseMessage Run(HttpRequestMessage req, ToDoItem
ToDoItem, ILogger log)
{
    log.LogInformation("C# HTTP trigger function processed a request.");

    if (ToDoItem == null)
    {
        log.LogInformation($"ToDo item not found");
    }
    else
    {
        log.LogInformation($"Found ToDo item, Description=
{ToDoItem.Description}");
    }
    return req.CreateResponse(HttpStatusCode.OK);
}

```

HTTP trigger, look up ID from route data

The following example shows a C# script function that retrieves a single document. The function is triggered by an HTTP request that uses route data to specify the ID and partition key value to look up. That ID and partition key value are used to retrieve a `ToDoItem` document from the specified database and collection.

Here's the `function.json` file:

```
JSON

{
  "bindings": [
    {
      "authLevel": "anonymous",
      "name": "req",
      "type": "httpTrigger",
      "direction": "in",
      "methods": [
        "get",
        "post"
      ],
      "route": "todoitems/{partitionKeyValue}/{id}"
    },
    {
      "name": "$return",
      "type": "http",
      "direction": "out"
    },
    {
      "type": "cosmosDB",
      "name": "ToDoItem",
      "databaseName": "ToDoItems",
      "collectionName": "Items",
      "connectionStringSetting": "CosmosDBConnection",
      "direction": "in",
      "id": "{id}",
      "partitionKey": "{partitionKeyValue}"
    }
  ],
  "disabled": false
}
```

Here's the C# script code:

```
C#

using System.Net;
using Microsoft.Extensions.Logging;

public static HttpResponseMessage Run(HttpRequestMessage req, ToDoItem
  toItem, ILogger log)
{
```

```

    log.LogInformation("C# HTTP trigger function processed a request.");

    if (ToDoItem == null)
    {
        log.LogInformation($"ToDo item not found");
    }
    else
    {
        log.LogInformation($"Found ToDo item, Description=
{ToDoItem.Description}");
    }
    return req.CreateResponse(HttpStatusCode.OK);
}

```

HTTP trigger, get multiple docs, using SqlQuery

The following example shows a C# script function that retrieves a list of documents. The function is triggered by an HTTP request. The query is specified in the `SqlQuery` attribute property.

Here's the `function.json` file:

JSON

```
{
  "bindings": [
    {
      "authLevel": "anonymous",
      "name": "req",
      "type": "httpTrigger",
      "direction": "in",
      "methods": [
        "get",
        "post"
      ]
    },
    {
      "name": "$return",
      "type": "http",
      "direction": "out"
    },
    {
      "type": "cosmosDB",
      "name": "ToDoItems",
      "databaseName": "ToDoItems",
      "collectionName": "Items",
      "connectionStringSetting": "CosmosDBConnection",
      "direction": "in",
      "sqlQuery": "SELECT top 2 * FROM c order by c._ts desc"
    }
  ],
}
```

```
        "disabled": false
    }
```

Here's the C# script code:

C#

```
using System.Net;
using Microsoft.Extensions.Logging;

public static HttpResponseMessage Run(HttpContext req,
IEnumerable<ToDoItem> ToDoItems, ILogger log)
{
    log.LogInformation("C# HTTP trigger function processed a request.");

    foreach (ToDoItem ToDoItem in ToDoItems)
    {
        log.LogInformation(ToDoItem.Description);
    }
    return req.CreateResponse(HttpStatusCode.OK);
}
```

HTTP trigger, get multiple docs, using DocumentClient

The following example shows a C# script function that retrieves a list of documents. The function is triggered by an HTTP request. The code uses a `DocumentClient` instance provided by the Azure Cosmos DB binding to read a list of documents. The `DocumentClient` instance could also be used for write operations.

Here's the `function.json` file:

JSON

```
{
  "bindings": [
    {
      "authLevel": "anonymous",
      "name": "req",
      "type": "httpTrigger",
      "direction": "in",
      "methods": [
        "get",
        "post"
      ]
    },
    {
      "name": "$return",
      "type": "http",
      "direction": "out"
    }
  ]
}
```

```

},
{
  "type": "cosmosDB",
  "name": "client",
  "databaseName": "ToDoItems",
  "collectionName": "Items",
  "connectionStringSetting": "CosmosDBConnection",
  "direction": "inout"
}
],
"disabled": false
}

```

Here's the C# script code:

C#

```

#r "Microsoft.Azure.Documents.Client"

using System.Net;
using Microsoft.Azure.Documents.Client;
using Microsoft.Azure.Documents.Linq;
using Microsoft.Extensions.Logging;

public static async Task<HttpResponseMessage> Run(HttpRequestMessage req,
DocumentClient client, ILogger log)
{
    log.LogInformation("C# HTTP trigger function processed a request.");

    Uri collectionUri = UriFactory.CreateDocumentCollectionUri("ToDoItems",
"Items");
    string searchterm = req.GetQueryNameValuePairs()
        .FirstOrDefault(q => string.Compare(q.Key, "searchterm", true) == 0)
        .Value;

    if (searchterm == null)
    {
        return req.CreateResponse(HttpStatusCode.NotFound);
    }

    log.LogInformation($"Searching for word: {searchterm} using Uri:
{collectionUri.ToString()}");
    IDocumentQuery<ToDoItem> query = client.CreateDocumentQuery<ToDoItem>
(collectionUri)
    .Where(p => p.Description.Contains(searchterm))
    .AsDocumentQuery();

    while (query.HasMoreResults)
    {
        foreach (ToDoItem result in await query.ExecuteNextAsync())
        {
            log.LogInformation(result.Description);
        }
    }
}

```

```

    }
    return req.CreateResponse(HttpStatusCode.OK);
}

```

Azure Cosmos DB v2 output

This section outlines support for the [version 4.x+ of the extension](#) only.

The following table explains the binding configuration properties that you set in the `function.json` file.

function.json property	Description
<code>connection</code>	The name of an app setting or setting collection that specifies how to connect to the Azure Cosmos DB account being monitored. For more information, see Connections .
<code>databaseName</code>	The name of the Azure Cosmos DB database with the container being monitored.
<code>containerName</code>	The name of the container being monitored.
<code>createIfNotExists</code>	A boolean value to indicate whether the container is created when it doesn't exist. The default is <i>false</i> because new containers are created with reserved throughput, which has cost implications. For more information, see the pricing page .
<code>partitionKey</code>	When <code>createIfNotExists</code> is true, it defines the partition key path for the created container. May include binding parameters.
<code>containerThroughput</code>	When <code>createIfNotExists</code> is true, it defines the throughput of the created container.
<code>preferredLocations</code>	(Optional) Defines preferred locations (regions) for geo-replicated database accounts in the Azure Cosmos DB service. Values should be comma-separated. For example, <code>East US,South Central US,North Europe</code> .

This section contains the following examples:

- [Queue trigger, write one doc](#)
- [Queue trigger, write docs using IAsyncCollector](#)

Queue trigger, write one doc

The following example shows an Azure Cosmos DB output binding in a *function.json* file and a [C# script function](#) that uses the binding. The function uses a queue input binding for a queue that receives JSON in the following format:

JSON

```
{  
    "name": "John Henry",  
    "employeeId": "123456",  
    "address": "A town nearby"  
}
```

The function creates Azure Cosmos DB documents in the following format for each record:

JSON

```
{  
    "id": "John Henry-123456",  
    "name": "John Henry",  
    "employeeId": "123456",  
    "address": "A town nearby"  
}
```

Here's the binding data in the *function.json* file:

JSON

```
{  
    "name": "employeeDocument",  
    "type": "cosmosDB",  
    "databaseName": "MyDatabase",  
    "collectionName": "MyCollection",  
    "createIfNotExists": true,  
    "connectionStringSetting": "MyAccount_COSMOSDB",  
    "direction": "out"  
}
```

Here's the C# script code:

C#

```
#r "Newtonsoft.Json"  
  
using Microsoft.Azure.WebJobs.Host;  
using Newtonsoft.Json.Linq;  
using Microsoft.Extensions.Logging;
```

```

    public static void Run(string myQueueItem, out object employeeDocument,
ILogger log)
{
    log.LogInformation($"C# Queue trigger function processed:
{myQueueItem}");

    dynamic employee = JObject.Parse(myQueueItem);

    employeeDocument = new {
        id = employee.name + "-" + employee.employeeId,
        name = employee.name,
        employeeId = employee.employeeId,
        address = employee.address
    };
}

```

Queue trigger, write docs using IAsyncCollector

To create multiple documents, you can bind to `ICollector<T>` or `IAsyncCollector<T>` where `T` is one of the supported types.

This example refers to a simple `ToDoItem` type:

C#

```

namespace CosmosDBSamplesV2
{
    public class ToDoItem
    {
        public string id { get; set; }
        public string Description { get; set; }
    }
}

```

Here's the function.json file:

JSON

```
{
  "bindings": [
    {
      "name": "ToDoItemsIn",
      "type": "queueTrigger",
      "direction": "in",
      "queueName": "todoqueueforwritemulti",
      "connectionStringSetting": "AzureWebJobsStorage"
    },
    {
      "type": "cosmosDB",

```

```

        "name": "ToDoItemsOut",
        "databaseName": "ToDoItems",
        "collectionName": "Items",
        "connectionStringSetting": "CosmosDBConnection",
        "direction": "out"
    }
],
"disabled": false
}

```

Here's the C# script code:

```
C#
using System;
using Microsoft.Extensions.Logging;

public static async Task Run(ToDoItem[] ToDoItemsIn,
IAsyncCollector<ToDoItem> ToDoItemsOut, ILogger log)
{
    log.LogInformation($"C# Queue trigger function processed
{ToDoItemsIn?.Length} items");

    foreach (ToDoItem ToDoItem in ToDoItemsIn)
    {
        log.LogInformation($"Description={ToDoItem.Description}");
        await ToDoItemsOut.AddAsync(ToDoItem);
    }
}
```

Azure Cosmos DB v1 trigger

The following example shows an Azure Cosmos DB trigger binding in a *function.json* file and a [C# script function](#) that uses the binding. The function writes log messages when Azure Cosmos DB records are modified.

Here's the binding data in the *function.json* file:

JSON

```
{
    "type": "cosmosDBTrigger",
    "name": "documents",
    "direction": "in",
    "leaseCollectionName": "leases",
    "connectionStringSetting": "<connection-app-setting>",
    "databaseName": "Tasks",
    "collectionName": "Items",
```

```
        "createLeaseCollectionIfNotExists": true  
    }  
}
```

Here's the C# script code:

```
C#  
  
#r "Microsoft.Azure.Documents.Client"  
  
using System;  
using Microsoft.Azure.Documents;  
using System.Collections.Generic;  
  
public static void Run(IReadOnlyList<Document> documents, TraceWriter log)  
{  
    log.Info("Documents modified " + documents.Count);  
    log.Info("First document Id " + documents[0].Id);  
}
```

Azure Cosmos DB v1 input

This section contains the following examples:

- Queue trigger, look up ID from string
- Queue trigger, get multiple docs, using SqlQuery
- HTTP trigger, look up ID from query string
- HTTP trigger, look up ID from route data
- HTTP trigger, get multiple docs, using SqlQuery
- HTTP trigger, get multiple docs, using DocumentClient

The HTTP trigger examples refer to a simple `ToDoItem` type:

```
C#  
  
namespace CosmosDBSamplesV1  
{  
    public class ToDoItem  
    {  
        public string Id { get; set; }  
        public string Description { get; set; }  
    }  
}
```

Queue trigger, look up ID from string

The following example shows an Azure Cosmos DB input binding in a *function.json* file and a [C# script function](#) that uses the binding. The function reads a single document and updates the document's text value.

Here's the binding data in the *function.json* file:

```
JSON

{
    "name": "inputDocument",
    "type": "documentDB",
    "databaseName": "MyDatabase",
    "collectionName": "MyCollection",
    "id": "{queueTrigger}",
    "partitionKey": "{partition key value}",
    "connection": "MyAccount_COSMOSDB",
    "direction": "in"
}
```

Here's the C# script code:

```
C#

using System;

// Change input document contents using Azure Cosmos DB input binding
public static void Run(string myQueueItem, dynamic inputDocument)
{
    inputDocument.text = "This has changed.";
}
```

Queue trigger, get multiple docs, using SqlQuery

The following example shows an Azure Cosmos DB input binding in a *function.json* file and a [C# script function](#) that uses the binding. The function retrieves multiple documents specified by a SQL query, using a queue trigger to customize the query parameters.

The queue trigger provides a parameter `departmentId`. A queue message of `{ "departmentId" : "Finance" }` would return all records for the finance department.

Here's the binding data in the *function.json* file:

```
JSON

{
    "name": "documents",
```

```
"type": "documentdb",
"direction": "in",
"databaseName": "MyDb",
"collectionName": "MyCollection",
"sqlQuery": "SELECT * from c where c.departmentId = {departmentId}",
"connection": "CosmosDBConnection"
}
```

Here's the C# script code:

C#

```
public static void Run(QueuePayload myQueueItem, IEnumerable<dynamic>
documents)
{
    foreach (var doc in documents)
    {
        // operate on each document
    }
}

public class QueuePayload
{
    public string departmentId { get; set; }
}
```

HTTP trigger, look up ID from query string

The following example shows a [C# script function](#) that retrieves a single document. The function is triggered by an HTTP request that uses a query string to specify the ID to look up. That ID is used to retrieve a `ToDoItem` document from the specified database and collection.

Here's the `function.json` file:

JSON

```
{
  "bindings": [
    {
      "authLevel": "anonymous",
      "name": "req",
      "type": "httpTrigger",
      "direction": "in",
      "methods": [
        "get",
        "post"
      ]
    },
    {
      "name": "myDatabase",
      "type": "cosmosDB",
      "direction": "out",
      "databaseName": "MyDb",
      "collectionName": "MyCollection"
    }
  ],
  "triggers": []
}
```

```
{
  "name": "$return",
  "type": "http",
  "direction": "out"
},
{
  "type": "documentDB",
  "name": "ToDoItem",
  "databaseName": "ToDoItems",
  "collectionName": "Items",
  "connection": "CosmosDBConnection",
  "direction": "in",
  "Id": "{Query.id}"
}
],
"disabled": true
}
```

Here's the C# script code:

```
C#
using System.Net;

public static HttpResponseMessage Run(HttpRequestMessage req, ToDoItem
ToDoItem, TraceWriter log)
{
    log.Info("C# HTTP trigger function processed a request.");

    if (ToDoItem == null)
    {
        log.Info($"ToDo item not found");
    }
    else
    {
        log.Info($"Found ToDo item, Description={ToDoItem.Description}");
    }
    return req.CreateResponse(HttpStatusCode.OK);
}
```

HTTP trigger, look up ID from route data

The following example shows a [C# script function](#) that retrieves a single document. The function is triggered by an HTTP request that uses route data to specify the ID to look up. That ID is used to retrieve a `ToDoItem` document from the specified database and collection.

Here's the `function.json` file:

JSON

```
{  
  "bindings": [  
    {  
      "authLevel": "anonymous",  
      "name": "req",  
      "type": "httpTrigger",  
      "direction": "in",  
      "methods": [  
        "get",  
        "post"  
      ],  
      "route": "todoitems/{id}"  
    },  
    {  
      "name": "$return",  
      "type": "http",  
      "direction": "out"  
    },  
    {  
      "type": "documentDB",  
      "name": "ToDoItem",  
      "databaseName": "ToDoItems",  
      "collectionName": "Items",  
      "connection": "CosmosDBConnection",  
      "direction": "in",  
      "Id": "{id}"  
    }  
  ],  
  "disabled": false  
}
```

Here's the C# script code:

C#

```
using System.Net;  
  
public static HttpResponseMessage Run(HttpRequestMessage req, ToDoItem  
toDoItem, TraceWriter log)  
{  
    log.Info("C# HTTP trigger function processed a request.");  
  
    if (toDoItem == null)  
    {  
        log.Info($"ToDo item not found");  
    }  
    else  
    {  
        log.Info($"Found ToDo item, Description={toDoItem.Description}");  
    }  
}
```

```
        return req.CreateResponse(HttpStatusCode.OK);
    }
```

HTTP trigger, get multiple docs, using SqlQuery

The following example shows a [C# script function](#) that retrieves a list of documents. The function is triggered by an HTTP request. The query is specified in the `SqlQuery` attribute property.

Here's the `function.json` file:

JSON

```
{
  "bindings": [
    {
      "authLevel": "anonymous",
      "name": "req",
      "type": "httpTrigger",
      "direction": "in",
      "methods": [
        "get",
        "post"
      ]
    },
    {
      "name": "$return",
      "type": "http",
      "direction": "out"
    },
    {
      "type": "documentDB",
      "name": "ToDoItems",
      "databaseName": "ToDoItems",
      "collectionName": "Items",
      "connection": "CosmosDBConnection",
      "direction": "in",
      "sqlQuery": "SELECT top 2 * FROM c ORDER BY c._ts DESC"
    }
  ],
  "disabled": false
}
```

Here's the C# script code:

C#

```
using System.Net;
```

```

public static HttpResponseMessage Run(HttpRequestMessage req,
IEnumerable<ToDoItem> ToDoItems, TraceWriter log)
{
    log.Info("C# HTTP trigger function processed a request.");

    foreach (ToDoItem ToDoItem in ToDoItems)
    {
        log.Info(ToDoItem.Description);
    }
    return req.CreateResponse(HttpStatusCode.OK);
}

```

HTTP trigger, get multiple docs, using DocumentClient

The following example shows a [C# script function](#) that retrieves a list of documents. The function is triggered by an HTTP request. The code uses a `DocumentClient` instance provided by the Azure Cosmos DB binding to read a list of documents. The `DocumentClient` instance could also be used for write operations.

Here's the `function.json` file:

JSON

```
{
  "bindings": [
    {
      "authLevel": "anonymous",
      "name": "req",
      "type": "httpTrigger",
      "direction": "in",
      "methods": [
        "get",
        "post"
      ]
    },
    {
      "name": "$return",
      "type": "http",
      "direction": "out"
    },
    {
      "type": "documentDB",
      "name": "client",
      "databaseName": "ToDoItems",
      "collectionName": "Items",
      "connection": "CosmosDBConnection",
      "direction": "inout"
    }
  ],
}
```

```
        "disabled": false
    }
```

Here's the C# script code:

```
C#  
  
#r "Microsoft.Azure.Documents.Client"  
  
using System.Net;  
using Microsoft.Azure.Documents.Client;  
using Microsoft.Azure.Documents.Linq;  
  
public static async Task<HttpResponseMessage> Run(HttpRequestMessage req,  
DocumentClient client, TraceWriter log)  
{  
    log.Info("C# HTTP trigger function processed a request.");  
  
    Uri collectionUri = UriFactory.CreateDocumentCollectionUri("ToDoItems",  
"Items");  
    string searchterm = req.GetQueryNameValuePairs()  
        .FirstOrDefault(q => string.Compare(q.Key, "searchterm", true) == 0)  
        .Value;  
  
    if (searchterm == null)  
    {  
        return req.CreateResponse(HttpStatusCode.NotFound);  
    }  
  
    log.Info($"Searching for word: {searchterm} using Uri:  
{collectionUri.ToString()}");  
    IDocumentQuery<ToDoItem> query = client.CreateDocumentQuery<ToDoItem>(  
collectionUri)  
        .Where(p => p.Description.Contains(searchterm))  
        .AsDocumentQuery();  
  
    while (query.HasMoreResults)  
    {  
        foreach (ToDoItem result in await query.ExecuteNextAsync())  
        {  
            log.Info(result.Description);  
        }  
    }  
    return req.CreateResponse(HttpStatusCode.OK);  
}
```

Azure Cosmos DB v1 output

This section contains the following examples:

- Queue trigger, write one doc

- Queue trigger, write docs using `IAsyncCollector`

Queue trigger, write one doc

The following example shows an Azure Cosmos DB output binding in a `function.json` file and a [C# script function](#) that uses the binding. The function uses a queue input binding for a queue that receives JSON in the following format:

JSON

```
{
  "name": "John Henry",
  "employeeId": "123456",
  "address": "A town nearby"
}
```

The function creates Azure Cosmos DB documents in the following format for each record:

JSON

```
{
  "id": "John Henry-123456",
  "name": "John Henry",
  "employeeId": "123456",
  "address": "A town nearby"
}
```

Here's the binding data in the `function.json` file:

JSON

```
{
  "name": "employeeDocument",
  "type": "documentDB",
  "databaseName": "MyDatabase",
  "collectionName": "MyCollection",
  "createIfNotExists": true,
  "connection": "MyAccount_COSMOSDB",
  "direction": "out"
}
```

Here's the C# script code:

C#

```

#r "Newtonsoft.Json"

using Microsoft.Azure.WebJobs.Host;
using Newtonsoft.Json.Linq;

public static void Run(string myQueueItem, out object employeeDocument,
TraceWriter log)
{
    log.Info($"C# Queue trigger function processed: {myQueueItem}");

    dynamic employee = JObject.Parse(myQueueItem);

    employeeDocument = new {
        id = employee.name + "-" + employee.employeeId,
        name = employee.name,
        employeeId = employee.employeeId,
        address = employee.address
    };
}

```

Queue trigger, write docs using IAsyncCollector

To create multiple documents, you can bind to `ICollector<T>` or `IAsyncCollector<T>` where `T` is one of the supported types.

This example refers to a simple `ToDoItem` type:

C#

```

namespace CosmosDBSamplesV1
{
    public class ToDoItem
    {
        public string Id { get; set; }
        public string Description { get; set; }
    }
}

```

Here's the function.json file:

JSON

```
{
  "bindings": [
    {
      "name": "ToDoItemsIn",
      "type": "queueTrigger",
      "direction": "in",
      "queueName": "todoqueueforwritemulti",
      "connection": "AzureWebJobsStorage"
    }
  ]
}
```

```

        "connection": "AzureWebJobsStorage"
    },
    {
        "type": "documentDB",
        "name": "ToDoItemsOut",
        "databaseName": "ToDoItems",
        "collectionName": "Items",
        "connection": "CosmosDBConnection",
        "direction": "out"
    }
],
"disabled": false
}

```

Here's the C# script code:

C#

```

using System;

public static async Task Run(ToDoItem[] ToDoItemsIn,
    IAsyncCollector<ToDoItem> ToDoItemsOut, TraceWriter log)
{
    log.Info($"C# Queue trigger function processed {ToDoItemsIn?.Length} items");

    foreach (ToDoItem ToDoItem in ToDoItemsIn)
    {
        log.Info($"Description={ToDoItem.Description}");
        await ToDoItemsOut.AddAsync(ToDoItem);
    }
}

```

Azure SQL trigger

More samples for the Azure SQL trigger are available in the [GitHub repository](#).

The example refers to a `ToDoItem` class and a corresponding database table:

C#

```

namespace AzureSQL.ToDo
{
    public class ToDoItem
    {
        public Guid Id { get; set; }
        public int? order { get; set; }
        public string title { get; set; }
        public string url { get; set; }
        public bool? completed { get; set; }
    }
}

```

```
    }  
}
```

SQL

```
CREATE TABLE dbo.ToDo (  
    [Id] UNIQUEIDENTIFIER PRIMARY KEY,  
    [order] INT NULL,  
    [title] NVARCHAR(200) NOT NULL,  
    [url] NVARCHAR(200) NOT NULL,  
    [completed] BIT NOT NULL  
);
```

Change tracking is enabled on the database and on the table:

SQL

```
ALTER DATABASE [SampleDatabase]  
SET CHANGE_TRACKING = ON  
(CHANGE_RETENTION = 2 DAYS, AUTO_CLEANUP = ON);  
  
ALTER TABLE [dbo].[ToDo]  
ENABLE CHANGE_TRACKING;
```

The SQL trigger binds to a `IReadOnlyList<SqlChange<T>>`, a list of `SqlChange` objects each with two properties:

- **Item:** the item that was changed. The type of the item should follow the table schema as seen in the `ToDoItem` class.
- **Operation:** a value from `SqlChangeOperation` enum. The possible values are `Insert`, `Update`, and `Delete`.

The following example shows a SQL trigger in a function.json file and a [C# script function](#) that is invoked when there are changes to the `ToDo` table:

The following is binding data in the function.json file:

JSON

```
{  
    "name": "todoChanges",  
    "type": "sqlTrigger",  
    "direction": "in",  
    "tableName": "dbo.ToDo",  
    "connectionStringSetting": "SqlConnectionString"  
}
```

The following is the C# script function:

```
C#  
  
#r "Newtonsoft.Json"  
  
using System.Net;  
using Microsoft.AspNetCore.Mvc;  
using Microsoft.Extensions.Primitives;  
using Newtonsoft.Json;  
  
public static void Run(IReadOnlyList<SqlChange<ToDoItem>> todoChanges,  
ILogger log)  
{  
    log.LogInformation($"C# SQL trigger function processed a request.");  
  
    foreach (SqlChange<ToDoItem> change in todoChanges)  
    {  
        ToDoItem ToDoItem = change.Item;  
        log.LogInformation($"Change operation: {change.Operation}");  
        log.LogInformation($"Id: {ToDoItem.Id}, Title: {ToDoItem.title},  
Url: {ToDoItem.url}, Completed: {ToDoItem.completed}");  
    }  
}
```

Azure SQL input

More samples for the Azure SQL input binding are available in the [GitHub repository](#).

This section contains the following examples:

- [HTTP trigger, get row by ID from query string](#)
- [HTTP trigger, delete rows](#)

The examples refer to a `ToDoItem` class and a corresponding database table:

```
C#  
  
namespace AzureSQL.ToDo  
{  
    public class ToDoItem  
    {  
        public Guid Id { get; set; }  
        public int? order { get; set; }  
        public string title { get; set; }  
        public string url { get; set; }  
        public bool? completed { get; set; }  
    }  
}
```

SQL

```
CREATE TABLE dbo.ToDo (
    [Id] UNIQUEIDENTIFIER PRIMARY KEY,
    [order] INT NULL,
    [title] NVARCHAR(200) NOT NULL,
    [url] NVARCHAR(200) NOT NULL,
    [completed] BIT NOT NULL
);
```

HTTP trigger, get row by ID from query string

The following example shows an Azure SQL input binding in a *function.json* file and a [C# script function](#) that uses the binding. The function is triggered by an HTTP request that uses a query string to specify the ID. That ID is used to retrieve a `ToDoItem` record with the specified query.

ⓘ Note

The HTTP query string parameter is case-sensitive.

Here's the binding data in the *function.json* file:

JSON

```
{
  "authLevel": "anonymous",
  "type": "httpTrigger",
  "direction": "in",
  "name": "req",
  "methods": [
    "get"
  ],
  {
    "type": "http",
    "direction": "out",
    "name": "res"
  },
  {
    "name": "todoItem",
    "type": "sql",
    "direction": "in",
    "commandText": "select [Id], [order], [title], [url], [completed] from dbo.ToDo where Id = @Id",
    "commandType": "Text",
    "parameters": "@Id = {Query.id}",
  }
}
```

```
        "connectionStringSetting": "SqlConnectionString"
    }
```

Here's the C# script code:

C#

```
#r "Newtonsoft.Json"

using System.Net;
using Microsoft.AspNetCore.Mvc;
using Microsoft.Extensions.Primitives;
using Newtonsoft.Json;
using System.Collections.Generic;

public static IActionResult Run(HttpContext req, ILogger log,
IEnumerable<ToDoItem> todoItem)
{
    return new OkObjectResult(todoItem);
}
```

HTTP trigger, delete rows

The following example shows an Azure SQL input binding in a `function.json` file and a [C# script function](#) that uses the binding to execute a stored procedure with input from the HTTP request query parameter. In this example, the stored procedure deletes a single record or all records depending on the value of the parameter.

The stored procedure `dbo.DeleteToDo` must be created on the SQL database.

SQL

```
CREATE PROCEDURE [dbo].[DeleteToDo]
@Id NVARCHAR(100)
AS
DECLARE @UID UNIQUEIDENTIFIER = TRY_CAST(@ID AS UNIQUEIDENTIFIER)
IF @UID IS NOT NULL AND @Id != ''
BEGIN
    DELETE FROM dbo.ToDo WHERE Id = @UID
END
ELSE
BEGIN
    DELETE FROM dbo.ToDo WHERE @ID = ''
END

SELECT [Id], [order], [title], [url], [completed] FROM dbo.ToDo
GO
```

Here's the binding data in the *function.json* file:

JSON

```
{  
    "authLevel": "anonymous",  
    "type": "httpTrigger",  
    "direction": "in",  
    "name": "req",  
    "methods": [  
        "get"  
    ]  
},  
{  
    "type": "http",  
    "direction": "out",  
    "name": "res"  
},  
{  
    "name": "todoItems",  
    "type": "sql",  
    "direction": "in",  
    "commandText": "DeleteToDo",  
    "commandType": "StoredProcedure",  
    "parameters": "@Id = {Query.id}",  
    "connectionStringSetting": "SqlConnectionString"  
}
```

C#

```
using System;  
using System.Collections.Generic;  
using Microsoft.AspNetCore.Mvc;  
using Microsoft.Azure.WebJobs;  
using Microsoft.Azure.WebJobs.Extensions.Http;  
using Microsoft.AspNetCore.Http;  
using Microsoft.Extensions.Logging;  
  
namespace AzureSQL.ToDo  
{  
    public static class DeleteToDo  
    {  
        // delete all items or a specific item from querystring  
        // returns remaining items  
        // uses input binding with a stored procedure DeleteToDo to delete  
        items and return remaining items  
        [FunctionName("DeleteToDo")]  
        public static IActionResult Run(  
            [HttpTrigger(AuthorizationLevel.Anonymous, "delete", Route =  
"DeleteFunction")] HttpRequest req,  
            ILogger log,  
            [Sql(commandText: "DeleteToDo", commandType:  
System.Data.CommandType.StoredProcedure,
```

```

        parameters: "@Id={Query.id}", connectionStringSetting:
"SqlConnectionString")]
    IEnumerable<ToDoItem> ToDoItems)
{
    return new OkObjectResult(ToDoItems);
}
}
}

```

Here's the C# script code:

```

C#

#r "Newtonsoft.Json"

using System.Net;
using Microsoft.AspNetCore.Mvc;
using Microsoft.Extensions.Primitives;
using Newtonsoft.Json;
using System.Collections.Generic;

public static IActionResult Run(HttpContext req, ILogger log,
IEnumerable<ToDoItem> todoItems)
{
    return new OkObjectResult(todoItems);
}

```

Azure SQL output

More samples for the Azure SQL output binding are available in the [GitHub repository](#).

This section contains the following examples:

- [HTTP trigger, write records to a table](#)
- [HTTP trigger, write to two tables](#)

The examples refer to a `ToDoItem` class and a corresponding database table:

```

C#

namespace AzureSQL.ToDo
{
    public class ToDoItem
    {
        public Guid Id { get; set; }
        public int? Order { get; set; }
        public string Title { get; set; }
        public string Url { get; set; }
    }
}

```

```
        public bool? completed { get; set; }  
    }  
}
```

SQL

```
CREATE TABLE dbo.ToDo (  
    [Id] UNIQUEIDENTIFIER PRIMARY KEY,  
    [order] INT NULL,  
    [title] NVARCHAR(200) NOT NULL,  
    [url] NVARCHAR(200) NOT NULL,  
    [completed] BIT NOT NULL  
);
```

HTTP trigger, write records to a table

The following example shows a SQL output binding in a function.json file and a [C# script function](#) that adds records to a table, using data provided in an HTTP POST request as a JSON body.

The following is binding data in the function.json file:

JSON

```
{  
    "authLevel": "anonymous",  
    "type": "httpTrigger",  
    "direction": "in",  
    "name": "req",  
    "methods": [  
        "post"  
    ]  
},  
{  
    "type": "http",  
    "direction": "out",  
    "name": "res"  
},  
{  
    "name": "todoItem",  
    "type": "sql",  
    "direction": "out",  
    "commandText": "dbo.ToDo",  
    "connectionStringSetting": "SqlConnectionString"  
}
```

The following is sample C# script code:

C#

```
#r "Newtonsoft.Json"

using System.Net;
using Microsoft.AspNetCore.Mvc;
using Microsoft.Extensions.Primitives;
using Newtonsoft.Json;

public static IActionResult Run(HttpContext req, ILogger log, out ToDoItem todoItem)
{
    log.LogInformation("C# HTTP trigger function processed a request.");

    string requestBody = new StreamReader(req.Body).ReadToEnd();
    todoItem = JsonConvert.DeserializeObject<ToDoItem>(requestBody);

    return new OkObjectResult(todoItem);
}
```

HTTP trigger, write to two tables

The following example shows a SQL output binding in a function.json file and a [C# script function](#) that adds records to a database in two different tables (`dbo.ToDo` and `dbo.RequestLog`), using data provided in an HTTP POST request as a JSON body and multiple output bindings.

The second table, `dbo.RequestLog`, corresponds to the following definition:

SQL

```
CREATE TABLE dbo.RequestLog (
    Id int identity(1,1) primary key,
    RequestTimeStamp datetime2 not null,
    ItemCount int not null
)
```

The following is binding data in the function.json file:

JSON

```
{
    "authLevel": "anonymous",
    "type": "httpTrigger",
    "direction": "in",
    "name": "req",
    "methods": [
        "post"
    ]}
```

```

        ],
    },
    {
        "type": "http",
        "direction": "out",
        "name": "res"
    },
    {
        "name": "todoItem",
        "type": "sql",
        "direction": "out",
        "commandText": "dbo.ToDo",
        "connectionStringSetting": "SqlConnectionString"
    },
    {
        "name": "requestLog",
        "type": "sql",
        "direction": "out",
        "commandText": "dbo.RequestLog",
        "connectionStringSetting": "SqlConnectionString"
    }
}

```

The following is sample C# script code:

C#

```

#r "Newtonsoft.Json"

using System.Net;
using Microsoft.AspNetCore.Mvc;
using Microsoft.Extensions.Primitives;
using Newtonsoft.Json;

public static IActionResult Run(HttpContext req, ILogger log, out ToDoItem
todoItem, out RequestLog requestLog)
{
    log.LogInformation("C# HTTP trigger function processed a request.");

    string requestBody = new StreamReader(req.Body).ReadToEnd();
    todoItem = JsonConvert.DeserializeObject<ToDoItem>(requestBody);

    requestLog = new RequestLog();
    requestLog.RequestTimeStamp = DateTime.Now;
    requestLog.ItemCount = 1;

    return new OkObjectResult(todoItem);
}

public class RequestLog {
    public DateTime RequestTimeStamp { get; set; }
    public int ItemCount { get; set; }
}

```

RabbitMQ output

The following example shows a RabbitMQ output binding in a *function.json* file and a [C# script function](#) that uses the binding. The function reads in the message from an HTTP trigger and outputs it to the RabbitMQ queue.

Here's the binding data in the *function.json* file:

```
JSON

{
  "bindings": [
    {
      "type": "httpTrigger",
      "direction": "in",
      "authLevel": "function",
      "name": "input",
      "methods": [
        "get",
        "post"
      ]
    },
    {
      "type": "rabbitMQ",
      "name": "outputMessage",
      "queueName": "outputQueue",
      "connectionStringSetting": "rabbitMQConnectionStringAppSetting",
      "direction": "out"
    }
  ]
}
```

Here's the C# script code:

```
C#

using System;
using Microsoft.Extensions.Logging;

public static void Run(string input, out string outputMessage, ILogger log)
{
    log.LogInformation(input);
    outputMessage = input;
}
```

SendGrid output

The following example shows a SendGrid output binding in a *function.json* file and a [C# script function](#) that uses the binding.

Here's the binding data in the *function.json* file:

JSON

```
{  
  "bindings": [  
    {  
      "type": "queueTrigger",  
      "name": "mymsg",  
      "queueName": "myqueue",  
      "connection": "AzureWebJobsStorage",  
      "direction": "in"  
    },  
    {  
      "type": "sendGrid",  
      "name": "$return",  
      "direction": "out",  
      "apiKey": "SendGridAPIKeyAsAppSetting",  
      "from": "{FromEmail}",  
      "to": "{ToEmail}"  
    }  
  ]  
}
```

Here's the C# script code:

C#

```
#r "SendGrid"  
  
using System;  
using SendGrid.Helpers.Mail;  
using Microsoft.Azure.WebJobs.Host;  
  
public static SendGridMessage Run(Message mymsg, ILogger log)  
{  
    SendGridMessage message = new SendGridMessage()  
    {  
        Subject = $"{mymsg.Subject}"  
    };  
  
    message.AddContent("text/plain", $"{mymsg.Content}");  
  
    return message;  
}  
public class Message  
{  
    public string ToEmail { get; set; }  
    public string FromEmail { get; set; }  
}
```

```
    public string Subject { get; set; }
    public string Content { get; set; }
}
```

SignalR trigger

Here's example binding data in the *function.json* file:

JSON

```
{
  "type": "signalRTrigger",
  "name": "invocation",
  "hubName": "SignalRTTest",
  "category": "messages",
  "event": "SendMessage",
  "parameterNames": [
    "message"
  ],
  "direction": "in"
}
```

And, here's the code:

C#

```
#r "Microsoft.Azure.WebJobs.Extensions.SignalRService"
using System;
using Microsoft.Azure.WebJobs.Extensions.SignalRService;
using Microsoft.Extensions.Logging;

public static void Run(InvocationContext invocation, string message, ILogger logger)
{
    logger.LogInformation($"Receive {message} from
{invocationContext.ConnectionId}.");
}
```

SignalR input

The following example shows a SignalR connection info input binding in a *function.json* file and a [C# Script function](#) that uses the binding to return the connection information.

Here's binding data in the *function.json* file:

Example *function.json*:

JSON

```
{  
    "type": "signalRConnectionInfo",  
    "name": "connectionInfo",  
    "hubName": "chat",  
    "connectionStringSetting": "<name of setting containing SignalR Service  
connection string>",  
    "direction": "in"  
}
```

Here's the C# Script code:

C#

```
#r "Microsoft.Azure.WebJobs.Extensions.SignalRService"  
using Microsoft.Azure.WebJobs.Extensions.SignalRService;  
  
public static SignalRConnectionInfo Run(WebRequest req,  
SignalRConnectionInfo connectionInfo)  
{  
    return connectionInfo;  
}
```

You can set the `userId` property of the binding to the value from either header using a [binding expression](#): `{headers.x-ms-client-principal-id}` or `{headers.x-ms-client-principal-name}`.

Example function.json:

JSON

```
{  
    "type": "signalRConnectionInfo",  
    "name": "connectionInfo",  
    "hubName": "chat",  
    "userId": "{headers.x-ms-client-principal-id}",  
    "connectionStringSetting": "<name of setting containing SignalR Service  
connection string>",  
    "direction": "in"  
}
```

Here's the C# Script code:

C#

```
#r "Microsoft.Azure.WebJobs.Extensions.SignalRService"  
using Microsoft.Azure.WebJobs.Extensions.SignalRService;
```

```
public static SignalRConnectionInfo Run(HttpRequest req,
SignalRConnectionInfo connectionInfo)
{
    // connectionInfo contains an access key token with a name identifier
    // claim set to the authenticated user
    return connectionInfo;
}
```

SignalR output

Here's binding data in the *function.json* file:

Example *function.json*:

JSON

```
{
    "type": "signalR",
    "name": "signalRMessages",
    "hubName": "<hub_name>",
    "connectionStringSetting": "<name of setting containing SignalR Service
connection string>",
    "direction": "out"
}
```

Here's the C# Script code:

C#

```
#r "Microsoft.Azure.WebJobs.Extensions.SignalRService"
using Microsoft.Azure.WebJobs.Extensions.SignalRService;

public static Task Run(
    object message,
    IAsyncCollector<SignalRMessage> signalRMessages)
{
    return signalRMessages.AddAsync(
        new SignalRMessage
        {
            Target = "newMessage",
            Arguments = new [] { message }
        });
}
```

You can send a message only to connections that have been authenticated to a user by setting the *user ID* in the SignalR message.

Example function.json:

JSON

```
{  
  "type": "signalR",  
  "name": "signalRMessages",  
  "hubName": "<hub_name>",  
  "connectionStringSetting": "<name of setting containing SignalR Service  
connection string>",  
  "direction": "out"  
}
```

Here's the C# script code:

C#

```
#r "Microsoft.Azure.WebJobs.Extensions.SignalRService"  
using Microsoft.Azure.WebJobs.Extensions.SignalRService;  
  
public static Task Run(  
    object message,  
    IAsyncCollector<SignalRMessage> signalRMessages)  
{  
    return signalRMessages.AddAsync(  
        new SignalRMessage  
        {  
            // the message will only be sent to this user ID  
            UserId = "userId1",  
            Target = "newMessage",  
            Arguments = new [] { message }  
        });  
}
```

You can send a message only to connections that have been added to a group by setting the *group name* in the SignalR message.

Example function.json:

JSON

```
{  
  "type": "signalR",  
  "name": "signalRMessages",  
  "hubName": "<hub_name>",  
  "connectionStringSetting": "<name of setting containing SignalR Service  
connection string>",  
  "direction": "out"  
}
```

Here's the C# Script code:

```
C#  
  
#r "Microsoft.Azure.WebJobs.Extensions.SignalRService"  
using Microsoft.Azure.WebJobs.Extensions.SignalRService;  
  
public static Task Run(  
    object message,  
    IAsyncCollector<SignalRMessage> signalRMessages)  
{  
    return signalRMessages.AddAsync(  
        new SignalRMessage  
        {  
            // the message will be sent to the group with this name  
            GroupName = "myGroup",  
            Target = "newMessage",  
            Arguments = new [] { message }  
        });  
}
```

SignalR Service allows users or connections to be added to groups. Messages can then be sent to a group. You can use the `SignalR` output binding to manage groups.

The following example adds a user to a group.

Example `function.json`

```
JSON  
  
{  
    "type": "signalR",  
    "name": "signalRGroupActions",  
    "connectionStringSetting": "<name of setting containing SignalR Service connection string>",  
    "hubName": "chat",  
    "direction": "out"  
}
```

`Run.csx`

```
C#  
  
#r "Microsoft.Azure.WebJobs.Extensions.SignalRService"  
using Microsoft.Azure.WebJobs.Extensions.SignalRService;  
  
public static Task Run(  
    HttpRequest req,  
    ClaimsPrincipal claimsPrincipal,  
    IAsyncCollector<SignalRGroupAction> signalRGroupActions)
```

```
{
    var userIdClaim = claimsPrincipal.FindFirst(ClaimTypes.NameIdentifier);
    return signalRGroupActions.AddAsync(
        new SignalRGroupAction
    {
        UserId = userIdClaim.Value,
        GroupName = "myGroup",
        Action = GroupAction.Add
    });
}
```

The following example removes a user from a group.

Example *function.json*

JSON

```
{
    "type": "signalR",
    "name": "signalRGroupActions",
    "connectionStringSetting": "<name of setting containing SignalR Service connection string>",
    "hubName": "chat",
    "direction": "out"
}
```

Run.csx

C#

```
#r "Microsoft.Azure.WebJobs.Extensions.SignalRService"
using Microsoft.Azure.WebJobs.Extensions.SignalRService;

public static Task Run(
    HttpRequest req,
    ClaimsPrincipal claimsPrincipal,
    IAsyncCollector<SignalRGroupAction> signalRGroupActions)
{
    var userIdClaim = claimsPrincipal.FindFirst(ClaimTypes.NameIdentifier);
    return signalRGroupActions.AddAsync(
        new SignalRGroupAction
    {
        UserId = userIdClaim.Value,
        GroupName = "myGroup",
        Action = GroupAction.Remove
    });
}
```

Twilio output

The following example shows a Twilio output binding in a `function.json` file and a [C# script function](#) that uses the binding. The function uses an `out` parameter to send a text message.

Here's binding data in the `function.json` file:

Example `function.json`:

```
JSON

{
  "type": "twilioSms",
  "name": "message",
  "accountSidSetting": "TwilioAccountSid",
  "authTokenSetting": "TwilioAuthToken",
  "from": "+1425XXXXXXX",
  "direction": "out",
  "body": "Azure Functions Testing"
}
```

Here's C# script code:

```
C#

#r "Newtonsoft.Json"
#r "Twilio"
#r "Microsoft.Azure.WebJobs.Extensions.Twilio"

using System;
using Microsoft.Extensions.Logging;
using Newtonsoft.Json;
using Microsoft.Azure.WebJobs.Extensions.Twilio;
using Twilio.Rest.Api.V2010.Account;
using Twilio.Types;

public static void Run(string myQueueItem, out CreateMessageOptions message,
ILogger log)
{
    log.LogInformation($"C# Queue trigger function processed:
{myQueueItem}");

    // In this example the queue item is a JSON string representing an order
    // that contains the name of a
    // customer and a mobile number to send text updates to.
    dynamic order = JsonConvert.DeserializeObject(myQueueItem);
    string msg = "Hello " + order.name + ", thank you for your order.';

    // You must initialize the CreateMessageOptions variable with the "To"
    // phone number.
    message = new CreateMessageOptions(new PhoneNumber("+1704XXXXXXX"));
}
```

```
// A dynamic message can be set instead of the body in the output
binding. In this example, we use
// the order information to personalize a text message.
message.Body = msg;
}
```

You can't use out parameters in asynchronous code. Here's an asynchronous C# script code example:

C#

```
#r "Newtonsoft.Json"
#r "Twilio"
#r "Microsoft.Azure.WebJobs.Extensions.Twilio"

using System;
using Microsoft.Extensions.Logging;
using Newtonsoft.Json;
using Microsoft.Azure.WebJobs.Extensions.Twilio;
using Twilio.Rest.Api.V2010.Account;
using Twilio.Types;

public static async Task Run(string myQueueItem,
IAsyncCollector<CreateMessageOptions> message, ILogger log)
{
    log.LogInformation($"C# Queue trigger function processed:
{myQueueItem}");

    // In this example the queue item is a JSON string representing an order
    // that contains the name of a
    // customer and a mobile number to send text updates to.
    dynamic order = JsonConvert.DeserializeObject(myQueueItem);
    string msg = "Hello " + order.name + ", thank you for your order.";

    // You must initialize the CreateMessageOptions variable with the "To"
    // phone number.
    CreateMessageOptions smsText = new CreateMessageOptions(new
    PhoneNumber("+1704XXXXXXX"));

    // A dynamic message can be set instead of the body in the output
    // binding. In this example, we use
    // the order information to personalize a text message.
    smsText.Body = msg;

    await message.AddAsync(smsText);
}
```

Warmup trigger

The following example shows a warmup trigger in a `function.json` file and a [C# script function](#) that runs on each new instance when it's added to your app.

Not supported for version 1.x of the Functions runtime.

Here's the `function.json` file:

JSON

```
{  
  "bindings": [  
    {  
      "type": "warmupTrigger",  
      "direction": "in",  
      "name": "warmupContext"  
    }  
  ]  
}
```

C#

```
public static void Run(WarmupContext warmupContext, ILogger log)  
{  
    log.LogInformation("Function App instance is warm.");  
}
```

Differences between the isolated worker model and the in-process model for .NET on Azure Functions

Article • 06/17/2024

There are two execution models for .NET functions:

 Expand table

Execution model	Description
Isolated worker model	Your function code runs in a separate .NET worker process. Use with supported versions of .NET and .NET Framework . To learn more, see Develop .NET isolated worker process functions .
In-process model	Your function code runs in the same process as the Functions host process. Supports only Long Term Support (LTS) versions of .NET . To learn more, see Develop .NET class library functions .

Important

[Support will end for the in-process model on November 10, 2026](#). We highly recommend that you [migrate your apps to the isolated worker model](#) for full support.

This article describes the current state of the functional and behavioral differences between the two models. To migrate from the in-process model to the isolated worker model, see [Migrate .NET apps from the in-process model to the isolated worker model](#).

Execution model comparison table

Use the following table to compare feature and functional differences between the two models:

 Expand table

Feature/behavior	Isolated worker model	In-process model ³
Supported .NET versions	Long Term Support (LTS) versions, Standard Term Support (STS) versions, .NET Framework	Long Term Support (LTS) versions, ending with .NET 8

Feature/behavior	Isolated worker model	In-process model ³
Core packages	Microsoft.Azure.Functions.Worker Microsoft.Azure.Functions.Worker.Sdk	Microsoft.NET.Sdk.Functions
Binding extension packages	Microsoft.Azure.Functions.Worker.Extensions.*	Microsoft.Azure.WebJobs.Extensions.*
Durable Functions	Supported	Supported
Model types exposed by bindings	Simple types JSON serializable types Arrays/enumerations Service SDK types⁴	Simple types JSON serializable types Arrays/enumerations Service SDK types ⁴
HTTP trigger model types	HttpRequestData / HttpResponseData HttpRequest / IActionResult (using ASP.NET Core integration) ⁵	HttpRequest / IActionResult HttpRequestMessage / HttpResponseMessage
Output binding interactions	Return values in an expanded model with: - single or multiple outputs - arrays of outputs	Return values (single output only), <code>out</code> parameters, IAsyncCollector
Imperative bindings ¹	Not supported - instead work with SDK types directly	Supported
Dependency injection	Supported (improved model consistent with .NET ecosystem)	Supported
Middleware	Supported	Not supported
Logging	ILogger<T>/ILogger obtained from FunctionContext or via dependency injection	ILogger passed to the function ILogger<T> via dependency injection
Application Insights dependencies	Supported	Supported
Cancellation tokens	Supported	Supported
Cold start times ²	Configurable optimizations	Optimized
ReadyToRun	Supported	Supported
[Flex Consumption]	Supported	Not supported

¹ When you need to interact with a service using parameters determined at runtime, using the corresponding service SDKs directly is recommended over using imperative bindings. The SDKs are less verbose, cover more scenarios, and have advantages for error handling and debugging purposes. This recommendation applies to both models.

² Cold start times could be additionally impacted on Windows when using some preview versions of .NET due to just-in-time loading of preview frameworks. This impact applies to both the in-process and out-of-process models but can be noticeable when comparing across different versions. This delay for preview versions isn't present on Linux plans.

³ C# Script functions also run in-process and use the same libraries as in-process class library functions. For more information, see the [Azure Functions C# script \(.csx\) developer reference](#).

⁴ Service SDK types include types from the [Azure SDK for .NET](#) such as `BlobClient`.

⁵ ASP.NET Core types are not supported for .NET Framework.

Supported versions

Versions of the Functions runtime support specific versions of .NET. To learn more about Functions versions, see [Azure Functions runtime versions overview](#). Version support also depends on whether your functions run in-process or isolated worker process.

Note

To learn how to change the Functions runtime version used by your function app, see [view and update the current runtime version](#).

The following table shows the highest level of .NET or .NET Framework that can be used with a specific version of Functions.

 [Expand table](#)

Functions runtime version	Isolated worker model	In-process model ⁵
Functions 4.x ¹	.NET 8.0 .NET 6.0 ² .NET Framework 4.8 ³	.NET 8.0 .NET 6.0 ²
Functions 1.x ⁴	n/a	.NET Framework 4.8

¹ .NET 7 was previously supported on the isolated worker model but reached the [end of official support](#) on May 14, 2024.

² .NET 6 reaches the [end of official support](#) on November 12, 2024.

³ The build process also requires the [.NET SDK](#).

⁴ Support ends for version 1.x of the Azure Functions runtime on September 14, 2026. For more information, see [this support announcement](#). For continued full support, you should [migrate your apps to version 4.x](#).

⁵ Support ends for the in-process model on November 10, 2026. For more information, see [this support announcement](#). For continued full support, you should [migrate your apps to the isolated worker model](#).

For the latest news about Azure Functions releases, including the removal of specific older minor versions, monitor [Azure App Service announcements](#).

Azure Functions Node.js developer guide

Article • 02/28/2024

This guide is an introduction to developing Azure Functions using JavaScript or TypeScript. The article assumes that you have already read the [Azure Functions developer guide](#).

ⓘ Important

The content of this article changes based on your choice of the Node.js programming model in the selector at the top of this page. The version you choose should match the version of the [@azure/functions](#) npm package you are using in your app. If you do not have that package listed in your `package.json`, the default is v3. Learn more about the differences between v3 and v4 in the [migration guide](#).

As a Node.js developer, you might also be interested in one of the following articles:

 Expand table

Getting started	Concepts	Guided learning
<ul style="list-style-type: none">Node.js function using Visual Studio CodeNode.js function with terminal/command promptNode.js function using the Azure portal	<ul style="list-style-type: none">Developer guideHosting optionsPerformance considerations	<ul style="list-style-type: none">Create serverless applicationsRefactor Node.js and Express APIs to Serverless APIs

Considerations

- The Node.js programming model shouldn't be confused with the Azure Functions runtime:
 - **Programming model:** Defines how you author your code and is specific to JavaScript and TypeScript.
 - **Runtime:** Defines underlying behavior of Azure Functions and is shared across all languages.
- The version of the programming model is strictly tied to the version of the [@azure/functions](#) npm package. It's versioned independently of the **runtime**.

Both the runtime and the programming model use the number 4 as their latest major version, but that's a coincidence.

- You can't mix the v3 and v4 programming models in the same function app. As soon as you register one v4 function in your app, any v3 functions registered in *function.json* files are ignored.

Supported versions

The following table shows each version of the Node.js programming model along with its supported versions of the Azure Functions runtime and Node.js.

[\[+\] Expand table](#)

Programming Model Version ↗	Support Level	Functions Runtime Version	Node.js Version ↗	Description
4.x	GA	4.25+	20.x, 18.x	Supports a flexible file structure and code-centric approach to triggers and bindings.
3.x	GA	4.x	20.x, 18.x, 16.x, 14.x	Requires a specific file structure with your triggers and bindings declared in a "function.json" file
2.x	n/a	3.x	14.x, 12.x, 10.x	Reached end of support on December 13, 2022. See Functions Versions for more info.
1.x	n/a	2.x	10.x, 8.x	Reached end of support on December 13, 2022. See Functions Versions for more info.

Folder structure

JavaScript

The recommended folder structure for a JavaScript project looks like the following example:

```
<project_root>
| - .vscode/
| - node_modules/
| - src/
| | - functions/
| | | - myFirstFunction.js
| | | - mySecondFunction.js
| - test/
| | - functions/
| | | - myFirstFunction.test.js
| | | - mySecondFunction.test.js
| - .funcignore
| - host.json
| - local.settings.json
| - package.json
```

The main project folder, `<project_root>`, can contain the following files:

- **.vscode/**: (Optional) Contains the stored Visual Studio Code configuration. To learn more, see [Visual Studio Code settings](#).
- **src/functions/**: The default location for all functions and their related triggers and bindings.
- **test/**: (Optional) Contains the test cases of your function app.
- **.funcignore**: (Optional) Declares files that shouldn't get published to Azure. Usually, this file contains `.vscode/` to ignore your editor setting, `test/` to ignore test cases, and `local.settings.json` to prevent local app settings being published.
- **host.json**: Contains configuration options that affect all functions in a function app instance. This file does get published to Azure. Not all options are supported when running locally. To learn more, see [host.json](#).
- **local.settings.json**: Used to store app settings and connection strings when it's running locally. This file doesn't get published to Azure. To learn more, see [local.settings.file](#).
- **package.json**: Contains configuration options like a list of package dependencies, the main entrypoint, and scripts.

Registering a function

The programming model loads your functions based on the `main` field in your `package.json`. You can set the `main` field to a single file or multiple files by using a [glob pattern](#). The following table shows example values for the `main` field:

[] Expand table

Example	Description
<code>src/index.js</code>	Register functions from a single root file.
<code>src/functions/*.js</code>	Register each function from its own file.
<code>src/{index.js,functions/*.js}</code>	A combination where you register each function from its own file, but you still have a root file for general app-level code.

In order to register a function, you must import the `app` object from the `@azure/functions` npm module and call the method specific to your trigger type. The first argument when registering a function is the function name. The second argument is an `options` object specifying configuration for your trigger, your handler, and any other inputs or outputs. In some cases where trigger configuration isn't necessary, you can pass the handler directly as the second argument instead of an `options` object.

Registering a function can be done from any file in your project, as long as that file is loaded (directly or indirectly) based on the `main` field in your `package.json` file. The function should be registered at a global scope because you can't register functions once executions have started.

The following example is a simple function that logs that it was triggered and responds with `Hello, world!`:

JavaScript

```
const { app } = require('@azure/functions');

app.http('helloWorld1', {
    methods: ['POST', 'GET'],
    handler: async (request, context) => {
        context.log('Http function was triggered.');
        return { body: 'Hello, world!' };
    }
});
```

Inputs and outputs

Your function is required to have exactly one primary input called the trigger. It may also have secondary inputs, a primary output called the return output, and/or secondary outputs. Inputs and outputs are also referred to as [bindings](#) outside the context of the Node.js programming model. Before v4 of the model, these bindings were configured in `function.json` files.

Trigger input

The trigger is the only required input or output. For most trigger types, you register a function by using a method on the `app` object named after the trigger type. You can specify configuration specific to the trigger directly on the `options` argument. For example, an HTTP trigger allows you to specify a route. During execution, the value corresponding to this trigger is passed in as the first argument to your handler.

JavaScript

```
const { app } = require('@azure/functions');

app.http('helloWorld1', {
    route: 'hello/world',
    handler: async (request, context) => {
        ...
    }
});
```

Return output

The return output is optional, and in some cases configured by default. For example, an HTTP trigger registered with `app.http` is configured to return an HTTP response output automatically. For most output types, you specify the return configuration on the `options` argument with the help of the `output` object exported from the `@azure/functions` module. During execution, you set this output by returning it from your handler.

The following example uses a [timer trigger](#) and a [storage queue output](#):

JavaScript

JavaScript

```
const { app, output } = require('@azure/functions');

app.timer('timerTrigger1', {
    schedule: '0 */5 * * * *',
    return: output.storageQueue({
        connection: 'storage_APPSETTING',
        ...
    }),
    handler: (myTimer, context) => {
        return { hello: 'world' }
    }
});
```

Extra inputs and outputs

In addition to the trigger and return, you may specify extra inputs or outputs on the `options` argument when registering a function. The `input` and `output` objects exported from the `@azure/functions` module provide type-specific methods to help construct the configuration. During execution, you get or set the values with `context.extraInputs.get` or `context.extraOutputs.set`, passing in the original configuration object as the first argument.

The following example is a function triggered by a `storage queue`, with an extra `storage blob input` that is copied to an extra `storage blob output`. The queue message should be the name of a file and replaces `{queueTrigger}` as the blob name to be copied, with the help of a [binding expression](#).

JavaScript

```
const { app, input, output } = require('@azure/functions');

const blobInput = input.storageBlob({
    connection: 'storage_APPSETTING',
    path: 'helloworld/{queueTrigger}',
});

const blobOutput = output.storageBlob({
    connection: 'storage_APPSETTING',
    path: 'helloworld/{queueTrigger}-copy',
});
```

```
app.storageQueue('copyBlob1', {
    queueName: 'copyblobqueue',
    connection: 'storage_APPSETTING',
    extraInputs: [blobInput],
    extraOutputs: [blobOutput],
    handler: (queueItem, context) => {
        const blobInputValue = context.extraInputs.get(blobInput);
        context.extraOutputs.set(blobOutput, blobInputValue);
    }
});
```

Generic inputs and outputs

The `app`, `trigger`, `input`, and `output` objects exported by the `@azure/functions` module provide type-specific methods for most types. For all the types that aren't supported, a `generic` method is provided to allow you to manually specify the configuration. The `generic` method can also be used if you want to change the default settings provided by a type-specific method.

The following example is a simple HTTP triggered function using generic methods instead of type-specific methods.

JavaScript

```
JavaScript

const { app, output, trigger } = require('@azure/functions');

app.generic('helloWorld1', {
    trigger: trigger.generic({
        type: 'httpTrigger',
        methods: ['GET', 'POST']
    }),
    return: output.generic({
        type: 'http'
    }),
    handler: async (request, context) => {
        context.log(`Http function processed request for url
        ${request.url}`);
        return { body: `Hello, world!` };
    }
});
```

Invocation context

Each invocation of your function is passed an invocation `context` object, with information about your invocation and methods used for logging. In the v4 model, the `context` object is typically the second argument passed to your handler.

The `InvocationContext` class has the following properties:

[+] Expand table

Property	Description
<code>invocationId</code>	The ID of the current function invocation.
<code>functionName</code>	The name of the function.
<code>extraInputs</code>	Used to get the values of extra inputs. For more information, see extra inputs and outputs .
<code>extraOutputs</code>	Used to set the values of extra outputs. For more information, see extra inputs and outputs .
<code>retryContext</code>	See retry context .
<code>traceContext</code>	The context for distributed tracing. For more information, see Trace Context ↗ .
<code>triggerMetadata</code>	Metadata about the trigger input for this invocation, not including the value itself. For example, an event hub trigger has an <code>enqueuedTimeUtc</code> property.
<code>options</code>	The options used when registering the function, after they've been validated and with defaults explicitly specified.

Retry context

The `retryContext` object has the following properties:

[+] Expand table

Property	Description
<code>retryCount</code>	A number representing the current retry attempt.
<code>maxRetryCount</code>	Maximum number of times an execution is retried. A value of <code>-1</code> means to retry indefinitely.
<code>exception</code>	Exception that caused the retry.

For more information, see [retry-policies](#).

Logging

In Azure Functions, it's recommended to use `context.log()` to write logs. Azure Functions integrates with Azure Application Insights to better capture your function app logs. Application Insights, part of Azure Monitor, provides facilities for collection, visual rendering, and analysis of both application logs and your trace outputs. To learn more, see [monitoring Azure Functions](#).

ⓘ Note

If you use the alternative Node.js `console.log` method, those logs are tracked at the app-level and will *not* be associated with any specific function. It is *highly recommended* to use `context` for logging instead of `console` so that all logs are associated with a specific function.

The following example writes a log at the default "information" level, including the invocation ID:

```
JavaScript
JavaScript
context.log(`Something has happened. Invocation ID:
"${context.invocationId}"`);
```

Log levels

In addition to the default `context.log` method, the following methods are available that let you write logs at specific levels:

[+] [Expand table](#)

Method	Description
<code>context.trace()</code>	Writes a trace-level event to the logs.
<code>context.debug()</code>	Writes a debug-level event to the logs.

Method	Description
<code>context.info()</code>	Writes an information-level event to the logs.
<code>context.warn()</code>	Writes a warning-level event to the logs.
<code>context.error()</code>	Writes an error-level event to the logs.

Configure log level

Azure Functions lets you define the threshold level to be used when tracking and viewing logs. To set the threshold, use the `logging.logLevel` property in the `host.json` file. This property lets you define a default level applied to all functions, or a threshold for each individual function. To learn more, see [How to configure monitoring for Azure Functions](#).

HTTP triggers

HTTP and webhook triggers use `HttpRequest` and `HttpResponse` objects to represent HTTP messages. The classes represent a subset of the [fetch standard](#), using Node.js's [undici](#) package.

HTTP Request

The request can be accessed as the first argument to your handler for an HTTP triggered function.

JavaScript

JavaScript

```
async (request, context) => {
    context.log(`Http function processed request for url
    ${request.url}`);
}
```

The `HttpRequest` object has the following properties:

[+] [Expand table](#)

Property	Type	Description
<code>method</code>	<code>string</code>	HTTP request method used to invoke this function.
<code>url</code>	<code>string</code>	Request URL.
<code>headers</code>	<code>Headers</code> ↗	HTTP request headers.
<code>query</code>	<code>URLSearchParams</code> ↗	Query string parameter keys and values from the URL.
<code>params</code>	<code>Record<string, string></code>	Route parameter keys and values.
<code>user</code>	<code>HttpRequestUser</code> <code>null</code>	Object representing logged-in user, either through Functions authentication, SWA Authentication, or null when no such user is logged in.
<code>body</code>	<code>ReadableStream</code> <code>null</code> ↗	Body as a readable stream.
<code>bodyUsed</code>	<code>boolean</code>	A boolean indicating if the body is already read.

In order to access a request or response's body, the following methods can be used:

[+] [Expand table](#)

Method	Return Type
<code>arrayBuffer()</code>	<code>Promise<ArrayBuffer></code> ↗
<code>blob()</code>	<code>Promise<Blob></code> ↗
<code>formData()</code>	<code>Promise<FormData></code> ↗
<code>json()</code>	<code>Promise<unknown></code>
<code>text()</code>	<code>Promise<string></code>

ⓘ Note

The body functions can be run only once; subsequent calls will resolve with empty strings/ArrayBuffers.

HTTP Response

The response can be set in several ways:

- As a simple interface with type `HttpServletResponseInit`: This option is the most concise way of returning responses.

JavaScript

```
return { body: `Hello, world!` };
```

The `HttpServletResponseInit` interface has the following properties:

[+] Expand table

Property	Type	Description
<code>body</code>	<code>BodyInit</code> (optional)	HTTP response body as one of <code>ArrayBuffer</code> , <code>AsyncIterable<Uint8Array></code> , <code>Blob</code> , <code>FormData</code> , <code>Iterable<Uint8Array></code> , <code>NodeJS.ArrayBufferView</code> , <code>URLSearchParams</code> , <code>null</code> , or <code>string</code> .
<code>jsonBody</code>	<code>any</code> (optional)	A JSON-serializable HTTP Response body. If set, the <code>HttpServletResponseInit.body</code> property is ignored in favor of this property.
<code>status</code>	<code>number</code> (optional)	HTTP response status code. If not set, defaults to <code>200</code> .
<code>headers</code>	<code>HeadersInit</code> (optional)	HTTP response headers.
<code>cookies</code>	<code>Cookie[]</code> (optional)	HTTP response cookies.

- As a class with type `HttpServletResponse`: This option provides helper methods for reading and modifying various parts of the response like the headers.

JavaScript

```
const response = new HttpServletResponse({ body: `Hello, world!` });
response.headers.set('content-type', 'application/json');
return response;
```

The `HttpResponse` class accepts an optional `HttpResponseInit` as an argument to its constructor and has the following properties:

[+] Expand table

Property	Type	Description
<code>status</code>	<code>number</code>	HTTP response status code.
<code>headers</code>	<code>Headers</code> ↗	HTTP response headers.
<code>cookies</code>	<code>Cookie[]</code>	HTTP response cookies.
<code>body</code>	<code>ReadableStream null</code> ↗	Body as a readable stream.
<code>bodyUsed</code>	<code>boolean</code>	A boolean indicating if the body has been read from already.

HTTP streams

HTTP streams is a feature that makes it easier to process large data, stream OpenAI responses, deliver dynamic content, and support other core HTTP scenarios. It lets you stream requests to and responses from HTTP endpoints in your Node.js function app. Use HTTP streams in scenarios where your app requires real-time exchange and interaction between client and server over HTTP. You can also use HTTP streams to get the best performance and reliability for your apps when using HTTP.

The existing `HttpRequest` and `HttpResponse` types in programming model v4 already support various ways of handling the message body, including as a stream.

Prerequisites

- The [@azure/functions npm package](#) ↗ version 4.3.0 or later.
- [Azure Functions runtime](#) version 4.28 or later.
- [Azure Functions Core Tools](#) version 4.0.5530 or a later version, which contains the correct runtime version.

Enable streams

Use these steps to enable HTTP streams in your function app in Azure and in your local projects:

1. If you plan to stream large amounts of data, modify the `FUNCTIONS_REQUEST_BODY_SIZE_LIMIT` setting in Azure. The default maximum body size allowed is `104857600`, which limits your requests to a size of ~100 MB.
2. For local development, also add `FUNCTIONS_REQUEST_BODY_SIZE_LIMIT` to the [local.settings.json file](#).
3. Add the following code to your app in any file included by your [main field](#).

```
JavaScript
```

```
JavaScript
```

```
const { app } = require('@azure/functions');

app.setup({ enableHttpStream: true });
```

Stream examples

This example shows an HTTP triggered function that receives data via an HTTP POST request, and the function streams this data to a specified output file:

```
JavaScript
```

```
JavaScript
```

```
const { app } = require('@azure/functions');
const { createWriteStream } = require('fs');
const { Writable } = require('stream');

app.http('httpTriggerStreamRequest', {
    methods: ['POST'],
    authLevel: 'anonymous',
    handler: async (request, context) => {
        const writeStream = createWriteStream('<output file path>');
        await request.body.pipeTo(Writable.toWeb(writeStream));

        return { body: 'Done!' };
    },
});
```

This example shows an HTTP triggered function that streams a file's content as the response to incoming HTTP GET requests:

JavaScript

JavaScript

```
const { app } = require('@azure/functions');
const { createReadStream } = require('fs');

app.http('httpTriggerStreamResponse', {
    methods: ['GET'],
    authLevel: 'anonymous',
    handler: async (request, context) => {
        const body = createReadStream('<input file path>');

        return { body };
    },
});
```

For a ready-to-run sample app using streams, check out this example on [GitHub](#).

Stream considerations

- Use `request.body` to obtain the maximum benefit from using streams. You can still continue to use methods like `request.text()`, which always return the body as a string.

Hooks

Use a hook to execute code at different points in the Azure Functions lifecycle. Hooks are executed in the order they're registered and can be registered from any file in your app. There are currently two scopes of hooks, "app" level and "invocation" level.

Invocation hooks

Invocation hooks are executed once per invocation of your function, either before in a `preInvocation` hook or after in a `postInvocation` hook. By default your hook executes for all trigger types, but you can also filter by type. The following example shows how to register an invocation hook and filter by trigger type:

JavaScript

JavaScript

```

const { app } = require('@azure/functions');

app.hook.preInvocation((context) => {
    if (context.invocationContext.options.trigger.type ===
'httpTrigger') {
        context.invocationContext.log(
            `preInvocation hook executed for http function
${context.invocationContext.functionName}`
        );
    }
});

app.hook.postInvocation((context) => {
    if (context.invocationContext.options.trigger.type ===
'httpTrigger') {
        context.invocationContext.log(
            `postInvocation hook executed for http function
${context.invocationContext.functionName}`
        );
    }
});

```

The first argument to the hook handler is a context object specific to that hook type.

The `PreInvocationContext` object has the following properties:

[+] Expand table

Property	Description
<code>inputs</code>	The arguments passed to the invocation.
<code>functionHandler</code>	The function handler for the invocation. Changes to this value affect the function itself.
<code>invocationContext</code>	The <code>invocation context</code> object passed to the function.
<code>hookData</code>	The recommended place to store and share data between hooks in the same scope. You should use a unique property name so that it doesn't conflict with other hooks' data.

The `PostInvocationContext` object has the following properties:

[+] Expand table

Property	Description
<code>inputs</code>	The arguments passed to the invocation.

Property	Description
<code>result</code>	The result of the function. Changes to this value affect the overall result of the function.
<code>error</code>	The error thrown by the function, or null/undefined if there's no error. Changes to this value affect the overall result of the function.
<code>invocationContext</code>	The invocation context object passed to the function.
<code>hookData</code>	The recommended place to store and share data between hooks in the same scope. You should use a unique property name so that it doesn't conflict with other hooks' data.

App hooks

App hooks are executed once per instance of your app, either during startup in an `appStart` hook or during termination in an `appTerminate` hook. App terminate hooks have a limited time to execute and don't execute in all scenarios.

The Azure Functions runtime currently [doesn't support](#) context logging outside of an invocation. Use the Application Insights [npm package](#) to log data during app level hooks.

The following example registers app hooks:

JavaScript

```
const { app } = require('@azure/functions');

app.hook.appStart((context) => {
    // add your logic here
});

app.hook.appTerminate((context) => {
    // add your logic here
});
```

The first argument to the hook handler is a context object specific to that hook type.

The `AppStartContext` object has the following properties:

[+] [Expand table](#)

Property	Description
<code>hookData</code>	The recommended place to store and share data between hooks in the same scope. You should use a unique property name so that it doesn't conflict with other hooks' data.

The `AppTerminateContext` object has the following properties:

[+] Expand table

Property	Description
<code>hookData</code>	The recommended place to store and share data between hooks in the same scope. You should use a unique property name so that it doesn't conflict with other hooks' data.

Scaling and concurrency

By default, Azure Functions automatically monitors the load on your application and creates more host instances for Node.js as needed. Azure Functions uses built-in (not user configurable) thresholds for different trigger types to decide when to add instances, such as the age of messages and queue size for QueueTrigger. For more information, see [How the Consumption and Premium plans work](#).

This scaling behavior is sufficient for many Node.js applications. For CPU-bound applications, you can improve performance further by using multiple language worker processes. You can increase the number of worker processes per host from the default of 1 up to a max of 10 by using the `FUNCTIONS_WORKER_PROCESS_COUNT` application setting. Azure Functions then tries to evenly distribute simultaneous function invocations across these workers. This behavior makes it less likely that a CPU-intensive function blocks other functions from running. The setting applies to each host that Azure Functions creates when scaling out your application to meet demand.

⚠ Warning

Use the `FUNCTIONS_WORKER_PROCESS_COUNT` setting with caution. Multiple processes running in the same instance can lead to unpredictable behavior and increase function load times. If you use this setting, it's *highly recommended* to offset these downsides by [running from a package file](#).

Node version

You can see the current version that the runtime is using by logging `process.version` from any function. See [supported versions](#) for a list of Node.js versions supported by each programming model.

Setting the Node version

The way that you upgrade your Node.js version depends on the OS on which your function app runs.

Windows

When running on Windows, the Node.js version is set by the [WEBSITE_NODE_DEFAULT_VERSION](#) application setting. This setting can be updated either by using the Azure CLI or in the Azure portal.

For more information about Node.js versions, see [Supported versions](#).

Before upgrading your Node.js version, make sure your function app is running on the latest version of the Azure Functions runtime. If you need to upgrade your runtime version, see [Migrate apps from Azure Functions version 3.x to version 4.x](#).

Azure CLI

Run the Azure CLI `az functionapp config appsettings set` command to update the Node.js version for your function app running on Windows:

```
Azure CLI  
az functionapp config appsettings set --settings  
WEBSITE_NODE_DEFAULT_VERSION=~20 \  
--name <FUNCTION_APP_NAME> --resource-group <RESOURCE_GROUP_NAME>
```

This sets the [WEBSITE_NODE_DEFAULT_VERSION](#) application setting the supported LTS version of `~20`.

After changes are made, your function app restarts. To learn more about Functions support for Node.js, see [Language runtime support policy](#).

Environment variables

Environment variables can be useful for operational secrets (connection strings, keys, endpoints, etc.) or environmental settings such as profiling variables. You can add environment variables in both your local and cloud environments and access them through `process.env` in your function code.

The following example logs the `WEBSITE_SITE_NAME` environment variable:

```
JavaScript
```

```
JavaScript
```

```
async function timerTrigger1(myTimer, context) {
    context.log(`WEBSITE_SITE_NAME:
${process.env["WEBSITE_SITE_NAME"]}`);
}
```

In local development environment

When you run locally, your functions project includes a [local.settings.json file](#), where you store your environment variables in the `Values` object.

```
JSON
```

```
{
  "IsEncrypted": false,
  "Values": {
    "AzureWebJobsStorage": "",
    "FUNCTIONS_WORKER_RUNTIME": "node",
    "CUSTOM_ENV_VAR_1": "hello",
    "CUSTOM_ENV_VAR_2": "world"
  }
}
```

In Azure cloud environment

When you run in Azure, the function app lets you set and use [Application settings](#), such as service connection strings, and exposes these settings as environment variables during execution.

There are several ways that you can add, update, and delete function app settings:

- In the Azure portal.
- By using the Azure CLI.

- By using Azure PowerShell.

Changes to function app settings require your function app to be restarted.

Worker environment variables

There are several Functions environment variables specific to Node.js:

languageWorkers_node_arguments

This setting allows you to specify custom arguments when starting your Node.js process. It's most often used locally to start the worker in debug mode, but can also be used in Azure if you need custom arguments.

⚠ Warning

If possible, avoid using `languageWorkers_node_arguments` in Azure because it can have a negative effect on cold start times. Rather than using pre-warmed workers, the runtime has to start a new worker from scratch with your custom arguments.

logging(LogLevel)_Worker

This setting adjusts the default log level for Node.js-specific worker logs. By default, only warning or error logs are shown, but you can set it to `information` or `debug` to help diagnose issues with the Node.js worker. For more information, see [configuring log levels](#).

ECMAScript modules (preview)

ⓘ Note

As ECMAScript modules are currently a preview feature in Node.js 14 or higher in Azure Functions.

[ECMAScript modules](#) (ES modules) are the new official standard module system for Node.js. So far, the code samples in this article use the CommonJS syntax. When running Azure Functions in Node.js 14 or higher, you can choose to write your functions using ES modules syntax.

To use ES modules in a function, change its filename to use a `.mjs` extension. The following `index.mjs` file example is an HTTP triggered function that uses ES modules syntax to import the `uuid` library and return a value.

```
JavaScript
```

```
JavaScript

import { v4 as uuidv4 } from 'uuid';

async function httpTrigger1(request, context) {
    return { body: uuidv4() };
}

app.http('httpTrigger1', {
    methods: ['GET', 'POST'],
    handler: httpTrigger1
});
```

Local debugging

It's recommended to use VS Code for local debugging, which starts your Node.js process in debug mode automatically and attaches to the process for you. For more information, see [run the function locally](#).

If you're using a different tool for debugging or want to start your Node.js process in debug mode manually, add `"languageWorkers_node_arguments": "--inspect"` under `Values` in your `local.settings.json`. The `--inspect` argument tells Node.js to listen for a debug client, on port 9229 by default. For more information, see the [Node.js debugging guide](#).

Recommendations

This section describes several impactful patterns for Node.js apps that we recommend you follow.

Choose single-vCPU App Service plans

When you create a function app that uses the App Service plan, we recommend that you select a single-vCPU plan rather than a plan with multiple vCPUs. Today, Functions runs Node.js functions more efficiently on single-vCPU VMs, and using larger VMs doesn't

produce the expected performance improvements. When necessary, you can manually scale out by adding more single-vCPU VM instances, or you can enable autoscale. For more information, see [Scale instance count manually or automatically](#).

Run from a package file

When you develop Azure Functions in the serverless hosting model, cold starts are a reality. *Cold start* refers to the first time your function app starts after a period of inactivity, taking longer to start up. For Node.js apps with large dependency trees in particular, cold start can be significant. To speed up the cold start process, [run your functions as a package file](#) when possible. Many deployment methods use this model by default, but if you're experiencing large cold starts you should check to make sure you're running this way.

Use a single static client

When you use a service-specific client in an Azure Functions application, don't create a new client with every function invocation because you can hit connection limits. Instead, create a single, static client in the global scope. For more information, see [managing connections in Azure Functions](#).

Use `async` and `await`

When writing Azure Functions in Node.js, you should write code using the `async` and `await` keywords. Writing code using `async` and `await` instead of callbacks or `.then` and `.catch` with Promises helps avoid two common problems:

- Throwing uncaught exceptions that [crash the Node.js process](#), potentially affecting the execution of other functions.
- Unexpected behavior, such as missing logs from `context.log`, caused by asynchronous calls that aren't properly awaited.

In the following example, the asynchronous method `fs.readFile` is invoked with an error-first callback function as its second parameter. This code causes both of the issues previously mentioned. An exception that isn't explicitly caught in the correct scope can crash the entire process (issue #1). Returning without ensuring the callback finishes means the http response will sometimes have an empty body (issue #2).

JavaScript

JavaScript

```
// DO NOT USE THIS CODE
const { app } = require('@azure/functions');
const fs = require('fs');

app.http('httpTriggerBadAsync', {
    methods: ['GET', 'POST'],
    authLevel: 'anonymous',
    handler: async (request, context) => {
        let fileData;
        fs.readFile('./helloWorld.txt', (err, data) => {
            if (err) {
                context.error(err);
                // BUG #1: This will result in an uncaught exception
                that crashes the entire process
                throw err;
            }
            fileData = data;
        });
        // BUG #2: fileData is not guaranteed to be set before the
        invocation ends
        return { body: fileData };
    },
});
```

Use the `async` and `await` keywords to help avoid both of these issues. Most APIs in the Node.js ecosystem have been converted to support promises in some form. For example, starting in v14, Node.js provides an `fs/promises` API to replace the `fs` callback API.

In the following example, any unhandled exceptions thrown during the function execution only fail the individual invocation that raised the exception. The `await` keyword means that steps following `readFile` only execute after it's complete.

JavaScript

JavaScript

```
// Recommended pattern
const { app } = require('@azure/functions');
const fs = require('fs/promises');

app.http('httpTriggerGoodAsync', {
    methods: ['GET', 'POST'],
    authLevel: 'anonymous',
    handler: async (request, context) => {
        try {
            const fileData = await fs.readFile('./helloWorld.txt');
            return { body: fileData };
        }
    }
});
```

```
        } catch (err) {
            context.error(err);
            // This rethrown exception will only fail the individual
            invocation, instead of crashing the whole process
            throw err;
        }
    },
});
```

Troubleshoot

Azure Functions Node.js developer guide

Article • 02/28/2024

This guide is an introduction to developing Azure Functions using JavaScript or TypeScript. The article assumes that you have already read the [Azure Functions developer guide](#).

ⓘ Important

The content of this article changes based on your choice of the Node.js programming model in the selector at the top of this page. The version you choose should match the version of the [@azure/functions](#) npm package you are using in your app. If you do not have that package listed in your `package.json`, the default is v3. Learn more about the differences between v3 and v4 in the [migration guide](#).

As a Node.js developer, you might also be interested in one of the following articles:

 Expand table

Getting started	Concepts	Guided learning
<ul style="list-style-type: none">Node.js function using Visual Studio CodeNode.js function with terminal/command promptNode.js function using the Azure portal	<ul style="list-style-type: none">Developer guideHosting optionsPerformance considerations	<ul style="list-style-type: none">Create serverless applicationsRefactor Node.js and Express APIs to Serverless APIs

Considerations

- The Node.js programming model shouldn't be confused with the Azure Functions runtime:
 - **Programming model:** Defines how you author your code and is specific to JavaScript and TypeScript.
 - **Runtime:** Defines underlying behavior of Azure Functions and is shared across all languages.
- The version of the programming model is strictly tied to the version of the [@azure/functions](#) npm package. It's versioned independently of the **runtime**.

Both the runtime and the programming model use the number 4 as their latest major version, but that's a coincidence.

- You can't mix the v3 and v4 programming models in the same function app. As soon as you register one v4 function in your app, any v3 functions registered in `function.json` files are ignored.

Supported versions

The following table shows each version of the Node.js programming model along with its supported versions of the Azure Functions runtime and Node.js.

[\[+\] Expand table](#)

Programming Model Version ↗	Support Level	Functions Runtime Version	Node.js Version ↗	Description
4.x	GA	4.25+	20.x, 18.x	Supports a flexible file structure and code-centric approach to triggers and bindings.
3.x	GA	4.x	20.x, 18.x, 16.x, 14.x	Requires a specific file structure with your triggers and bindings declared in a "function.json" file
2.x	n/a	3.x	14.x, 12.x, 10.x	Reached end of support on December 13, 2022. See Functions Versions for more info.
1.x	n/a	2.x	10.x, 8.x	Reached end of support on December 13, 2022. See Functions Versions for more info.

Folder structure

TypeScript

The recommended folder structure for a TypeScript project looks like the following example:

```
<project_root>
| - .vscode/
| - dist/
| - node_modules/
| - src/
| | - functions/
| | | - myFirstFunction.ts
| | | - mySecondFunction.ts
| - test/
| | - functions/
| | | - myFirstFunction.test.ts
| | | - mySecondFunction.test.ts
| - .funcignore
| - host.json
| - local.settings.json
| - package.json
| - tsconfig.json
```

The main project folder, `<project_root>`, can contain the following files:

- **.vscode/**: (Optional) Contains the stored Visual Studio Code configuration. To learn more, see [Visual Studio Code settings](#).
- **dist/**: Contains the compiled JavaScript code after you run a build. The name of this folder can be configured in your "tsconfig.json" file.
- **src/functions/**: The default location for all functions and their related triggers and bindings.
- **test/**: (Optional) Contains the test cases of your function app.
- **.funcignore**: (Optional) Declares files that shouldn't get published to Azure. Usually, this file contains `.vscode/` to ignore your editor setting, `test/` to ignore test cases, and `local.settings.json` to prevent local app settings being published.
- **host.json**: Contains configuration options that affect all functions in a function app instance. This file does get published to Azure. Not all options are supported when running locally. To learn more, see [host.json](#).
- **local.settings.json**: Used to store app settings and connection strings when it's running locally. This file doesn't get published to Azure. To learn more, see [local.settings.file](#).
- **package.json**: Contains configuration options like a list of package dependencies, the main entrypoint, and scripts.
- **tsconfig.json**: Contains TypeScript compiler options like the output directory.

Registering a function

The programming model loads your functions based on the `main` field in your `package.json`. You can set the `main` field to a single file or multiple files by using a [glob pattern](#). The following table shows example values for the `main` field:

TypeScript	 Expand table
Example	Description
<code>dist/src/index.js</code>	Register functions from a single root file.
<code>dist/src/functions/*.js</code>	Register each function from its own file.
<code>dist/src/{index.js,functions/*.js}</code>	A combination where you register each function from its own file, but you still have a root file for general app-level code.

In order to register a function, you must import the `app` object from the `@azure/functions` npm module and call the method specific to your trigger type. The first argument when registering a function is the function name. The second argument is an `options` object specifying configuration for your trigger, your handler, and any other inputs or outputs. In some cases where trigger configuration isn't necessary, you can pass the handler directly as the second argument instead of an `options` object.

Registering a function can be done from any file in your project, as long as that file is loaded (directly or indirectly) based on the `main` field in your `package.json` file. The function should be registered at a global scope because you can't register functions once executions have started.

The following example is a simple function that logs that it was triggered and responds with `Hello, world!`:

TypeScript
<pre>import { app, HttpRequest, HttpResponseInit, InvocationContext } from "@azure/functions"; async function helloWorld1(request: HttpRequest, context: InvocationContext): Promise<HttpResponseInit> { context.log('Http function was triggered.');</pre>

```
        return { body: 'Hello, world!' };

};

app.http('helloWorld1', {
    methods: ['GET', 'POST'],
    handler: helloWorld1
});
```

Inputs and outputs

Your function is required to have exactly one primary input called the trigger. It may also have secondary inputs, a primary output called the return output, and/or secondary outputs. Inputs and outputs are also referred to as [bindings](#) outside the context of the Node.js programming model. Before v4 of the model, these bindings were configured in `function.json` files.

Trigger input

The trigger is the only required input or output. For most trigger types, you register a function by using a method on the `app` object named after the trigger type. You can specify configuration specific to the trigger directly on the `options` argument. For example, an HTTP trigger allows you to specify a route. During execution, the value corresponding to this trigger is passed in as the first argument to your handler.

TypeScript

```
TypeScript

import { app, HttpRequest, HttpResponseInit, InvocationContext } from
"@azure/functions";

async function helloWorld1(request: HttpRequest, context:
InvocationContext): Promise<HttpResponseInit> {
    ...
};

app.http('helloWorld1', {
    route: 'hello/world',
    handler: helloWorld1
});
```

Return output

The return output is optional, and in some cases configured by default. For example, an HTTP trigger registered with `app.http` is configured to return an HTTP response output automatically. For most output types, you specify the return configuration on the `options` argument with the help of the `output` object exported from the `@azure/functions` module. During execution, you set this output by returning it from your handler.

The following example uses a [timer trigger](#) and a [storage queue output](#):

TypeScript

```
TypeScript

import { app, InvocationContext, Timer, output } from
"@azure/functions";

async function timerTrigger1(myTimer: Timer, context:
InvocationContext): Promise<any> {
    return { hello: 'world' }
}

app.timer('timerTrigger1', {
    schedule: '0 */5 * * *',
    return: output.storageQueue({
        connection: 'storage_APPSETTING',
        ...
    }),
    handler: timerTrigger1
});
```

Extra inputs and outputs

In addition to the trigger and return, you may specify extra inputs or outputs on the `options` argument when registering a function. The `input` and `output` objects exported from the `@azure/functions` module provide type-specific methods to help construct the configuration. During execution, you get or set the values with `context.extraInputs.get` or `context.extraOutputs.set`, passing in the original configuration object as the first argument.

The following example is a function triggered by a [storage queue](#), with an extra [storage blob input](#) that is copied to an extra [storage blob output](#). The queue message should be the name of a file and replaces `{queueTrigger}` as the blob name to be copied, with the help of a [binding expression](#).

TypeScript

TypeScript

```
import { app, InvocationContext, input, output } from
"@azure/functions";

const blobInput = input.storageBlob({
    connection: 'storage_APPSETTING',
    path: 'helloworld/{queueTrigger}',
});

const blobOutput = output.storageBlob({
    connection: 'storage_APPSETTING',
    path: 'helloworld/{queueTrigger}-copy',
});

async function copyBlob1(queueItem: unknown, context:
InvocationContext): Promise<void> {
    const blobInputValue = context.extraInputs.get(blobInput);
    context.extraOutputs.set(blobOutput, blobInputValue);
}

app.storageQueue('copyBlob1', {
    queueName: 'copyblobqueue',
    connection: 'storage_APPSETTING',
    extraInputs: [blobInput],
    extraOutputs: [blobOutput],
    handler: copyBlob1
});
```

Generic inputs and outputs

The `app`, `trigger`, `input`, and `output` objects exported by the `@azure/functions` module provide type-specific methods for most types. For all the types that aren't supported, a `generic` method is provided to allow you to manually specify the configuration. The `generic` method can also be used if you want to change the default settings provided by a type-specific method.

The following example is a simple HTTP triggered function using generic methods instead of type-specific methods.

TypeScript

TypeScript

```

import { app, InvocationContext, HttpRequest, HttpResponseInit, output,
trigger } from "@azure/functions";

async function helloWorld1(request: HttpRequest, context:
InvocationContext): Promise<HttpResponseInit> {
    context.log(`Http function processed request for url
"${request.url}"`);

    return { body: `Hello, world!` };
}

app.generic('helloWorld1', {
    trigger: trigger.generic({
        type: 'httpTrigger',
        methods: ['GET', 'POST']
    }),
    return: output.generic({
        type: 'http'
    }),
    handler: helloWorld1
});

```

Invocation context

Each invocation of your function is passed an invocation `context` object, with information about your invocation and methods used for logging. In the v4 model, the `context` object is typically the second argument passed to your handler.

The `InvocationContext` class has the following properties:

[] [Expand table](#)

Property	Description
<code>invocationId</code>	The ID of the current function invocation.
<code>functionName</code>	The name of the function.
<code>extraInputs</code>	Used to get the values of extra inputs. For more information, see extra inputs and outputs .
<code>extraOutputs</code>	Used to set the values of extra outputs. For more information, see extra inputs and outputs .
<code>retryContext</code>	See retry context .
<code>traceContext</code>	The context for distributed tracing. For more information, see Trace Context .

Property	Description
<code>triggerMetadata</code>	Metadata about the trigger input for this invocation, not including the value itself. For example, an event hub trigger has an <code>enqueuedTimeUtc</code> property.
<code>options</code>	The options used when registering the function, after they've been validated and with defaults explicitly specified.

Retry context

The `retryContext` object has the following properties:

[+] [Expand table](#)

Property	Description
<code>retryCount</code>	A number representing the current retry attempt.
<code>maxRetryCount</code>	Maximum number of times an execution is retried. A value of <code>-1</code> means to retry indefinitely.
<code>exception</code>	Exception that caused the retry.

For more information, see [retry-policies](#).

Logging

In Azure Functions, it's recommended to use `context.log()` to write logs. Azure Functions integrates with Azure Application Insights to better capture your function app logs. Application Insights, part of Azure Monitor, provides facilities for collection, visual rendering, and analysis of both application logs and your trace outputs. To learn more, see [monitoring Azure Functions](#).

ⓘ Note

If you use the alternative Node.js `console.log` method, those logs are tracked at the app-level and will *not* be associated with any specific function. It is *highly recommended* to use `context` for logging instead of `console` so that all logs are associated with a specific function.

The following example writes a log at the default "information" level, including the invocation ID:

TypeScript

TypeScript

```
context.log(`Something has happened. Invocation ID:  
"${context.invocationId}"`);
```

Log levels

In addition to the default `context.log` method, the following methods are available that let you write logs at specific levels:

[+] Expand table

Method	Description
<code>context.trace()</code>	Writes a trace-level event to the logs.
<code>context.debug()</code>	Writes a debug-level event to the logs.
<code>context.info()</code>	Writes an information-level event to the logs.
<code>context.warn()</code>	Writes a warning-level event to the logs.
<code>context.error()</code>	Writes an error-level event to the logs.

Configure log level

Azure Functions lets you define the threshold level to be used when tracking and viewing logs. To set the threshold, use the `logging.level` property in the `host.json` file. This property lets you define a default level applied to all functions, or a threshold for each individual function. To learn more, see [How to configure monitoring for Azure Functions](#).

HTTP triggers

HTTP and webhook triggers use `HttpRequest` and `HttpResponse` objects to represent HTTP messages. The classes represent a subset of the [fetch standard](#), using Node.js's [undici](#) package.

HTTP Request

The request can be accessed as the first argument to your handler for an HTTP triggered function.

TypeScript

```
async function helloWorld1(request: HttpRequest, context: InvocationContext): Promise<HttpResponseInit> {
    context.log(`Http function processed request for url
"${request.url}"`);
```

The `HttpRequest` object has the following properties:

[+] Expand table

Property	Type	Description
<code>method</code>	<code>string</code>	HTTP request method used to invoke this function.
<code>url</code>	<code>string</code>	Request URL.
<code>headers</code>	<code>Headers</code> ↗	HTTP request headers.
<code>query</code>	<code>URLSearchParams</code> ↗	Query string parameter keys and values from the URL.
<code>params</code>	<code>Record<string, string></code>	Route parameter keys and values.
<code>user</code>	<code>HttpRequestUser null</code>	Object representing logged-in user, either through Functions authentication, SWA Authentication, or null when no such user is logged in.
<code>body</code>	<code>ReadableStream null</code> ↗	Body as a readable stream.
<code>bodyUsed</code>	<code>boolean</code>	A boolean indicating if the body is already read.

In order to access a request or response's body, the following methods can be used:

[+] Expand table

Method	Return Type
<code>arrayBuffer()</code>	<code>Promise<ArrayBuffer></code> ↗
<code>blob()</code>	<code>Promise<Blob></code> ↗

Method	Return Type
<code>formData()</code>	<code>Promise<FormData></code>
<code>json()</code>	<code>Promise<unknown></code>
<code>text()</code>	<code>Promise<string></code>

ⓘ Note

The body functions can be run only once; subsequent calls will resolve with empty strings/ArrayBuffers.

HTTP Response

The response can be set in several ways:

- As a simple interface with type `HttpServletResponseInit`: This option is the most concise way of returning responses.

TypeScript

```
TypeScript

return { body: `Hello, world!` };
```

The `HttpServletResponseInit` interface has the following properties:

[] [Expand table](#)

Property	Type	Description
<code>body</code>	<code>BodyInit</code> (optional)	HTTP response body as one of <code>ArrayBuffer</code> , <code>AsyncIterable<Uint8Array></code> , <code>Blob</code> , <code>FormData</code> , <code>Iterable<Uint8Array></code> , <code>NodeJS.ArrayBufferView</code> , <code>URLSearchParams</code> , <code>null</code> , or <code>string</code> .
<code>jsonBody</code>	<code>any</code> (optional)	A JSON-serializable HTTP Response body. If set, the <code>HttpServletResponseInit.body</code> property is ignored in favor of this property.
<code>status</code>	<code>number</code> (optional)	HTTP response status code. If not set, defaults to <code>200</code> .

Property	Type	Description
<code>headers</code>	<code>HeadersInit</code> ↗	HTTP response headers. (optional)
<code>cookies</code>	<code>Cookie[]</code>	HTTP response cookies. (optional)

- As a class with type `HttpResponse`: This option provides helper methods for reading and modifying various parts of the response like the headers.

TypeScript

```
const response = new HttpResponse({ body: `Hello, world!` });
response.headers.set('content-type', 'application/json');
return response;
```

The `HttpResponse` class accepts an optional `HttpResponseInit` as an argument to its constructor and has the following properties:

[+] Expand table

Property	Type	Description
<code>status</code>	<code>number</code>	HTTP response status code.
<code>headers</code>	<code>Headers</code> ↗	HTTP response headers.
<code>cookies</code>	<code>Cookie[]</code>	HTTP response cookies.
<code>body</code>	<code>ReadableStream null</code> ↗	Body as a readable stream.
<code>bodyUsed</code>	<code>boolean</code>	A boolean indicating if the body has been read from already.

HTTP streams

HTTP streams is a feature that makes it easier to process large data, stream OpenAI responses, deliver dynamic content, and support other core HTTP scenarios. It lets you stream requests to and responses from HTTP endpoints in your Node.js function app. Use HTTP streams in scenarios where your app requires real-time exchange and

interaction between client and server over HTTP. You can also use HTTP streams to get the best performance and reliability for your apps when using HTTP.

The existing `HttpRequest` and `HttpResponse` types in programming model v4 already support various ways of handling the message body, including as a stream.

Prerequisites

- The [@azure/functions npm package](#) version 4.3.0 or later.
- [Azure Functions runtime](#) version 4.28 or later.
- [Azure Functions Core Tools](#) version 4.0.5530 or a later version, which contains the correct runtime version.

Enable streams

Use these steps to enable HTTP streams in your function app in Azure and in your local projects:

1. If you plan to stream large amounts of data, modify the `FUNCTIONS_REQUEST_BODY_SIZE_LIMIT` setting in Azure. The default maximum body size allowed is `104857600`, which limits your requests to a size of ~100 MB.
2. For local development, also add `FUNCTIONS_REQUEST_BODY_SIZE_LIMIT` to the [local.settings.json file](#).
3. Add the following code to your app in any file included by your [main field](#).

```
TypeScript

TypeScript
import { app } from '@azure/functions';
app.setup({ enableHttpStream: true });
```

Stream examples

This example shows an HTTP triggered function that receives data via an HTTP POST request, and the function streams this data to a specified output file:

```
TypeScript
```

TypeScript

```
import { app, HttpRequest, HttpResponseInit, InvocationContext } from
'@azure/functions';
import { createWriteStream } from 'fs';
import { Writable } from 'stream';

export async function httpTriggerStreamRequest(
    request: HttpRequest,
    context: InvocationContext
): Promise<HttpResponseInit> {
    const writeStream = createWriteStream('<output file path>');
    await request.body.pipeTo(Writable.toWeb(writeStream));

    return { body: 'Done!' };
}

app.http('httpTriggerStreamRequest', {
    methods: ['POST'],
    authLevel: 'anonymous',
    handler: httpTriggerStreamRequest,
});
```

This example shows an HTTP triggered function that streams a file's content as the response to incoming HTTP GET requests:

TypeScript

```
import { app, HttpRequest, HttpResponseInit, InvocationContext } from
'@azure/functions';
import { createReadStream } from 'fs';

export async function httpTriggerStreamResponse(
    request: HttpRequest,
    context: InvocationContext
): Promise<HttpResponseInit> {
    const body = createReadStream('<input file path>');

    return { body };
}

app.http('httpTriggerStreamResponse', {
    methods: ['GET'],
    authLevel: 'anonymous',
    handler: httpTriggerStreamResponse,
});
```

For a ready-to-run sample app using streams, check out this example on [GitHub](#).

Stream considerations

- Use `request.body` to obtain the maximum benefit from using streams. You can still continue to use methods like `request.text()`, which always return the body as a string.

Hooks

Use a hook to execute code at different points in the Azure Functions lifecycle. Hooks are executed in the order they're registered and can be registered from any file in your app. There are currently two scopes of hooks, "app" level and "invocation" level.

Invocation hooks

Invocation hooks are executed once per invocation of your function, either before in a `preInvocation` hook or after in a `postInvocation` hook. By default your hook executes for all trigger types, but you can also filter by type. The following example shows how to register an invocation hook and filter by trigger type:

TypeScript

```
TypeScript

import { app, PostInvocationContext, PreInvocationContext } from
'@azure/functions';

app.hook.preInvocation((context: PreInvocationContext) => {
    if (context.invocationContext.options.trigger.type ===
'httpTrigger') {
        context.invocationContext.log(
            `preInvocation hook executed for http function
${context.invocationContext.functionName}`
        );
    }
});

app.hook.postInvocation((context: PostInvocationContext) => {
    if (context.invocationContext.options.trigger.type ===
'httpTrigger') {
        context.invocationContext.log(
            `postInvocation hook executed for http function
${context.invocationContext.functionName}`
        );
}
```

```
    }  
});
```

The first argument to the hook handler is a context object specific to that hook type.

The `PreInvocationContext` object has the following properties:

[+] [Expand table](#)

Property	Description
<code>inputs</code>	The arguments passed to the invocation.
<code>functionHandler</code>	The function handler for the invocation. Changes to this value affect the function itself.
<code>invocationContext</code>	The invocation context object passed to the function.
<code>hookData</code>	The recommended place to store and share data between hooks in the same scope. You should use a unique property name so that it doesn't conflict with other hooks' data.

The `PostInvocationContext` object has the following properties:

[+] [Expand table](#)

Property	Description
<code>inputs</code>	The arguments passed to the invocation.
<code>result</code>	The result of the function. Changes to this value affect the overall result of the function.
<code>error</code>	The error thrown by the function, or null/undefined if there's no error. Changes to this value affect the overall result of the function.
<code>invocationContext</code>	The invocation context object passed to the function.
<code>hookData</code>	The recommended place to store and share data between hooks in the same scope. You should use a unique property name so that it doesn't conflict with other hooks' data.

App hooks

App hooks are executed once per instance of your app, either during startup in an `appStart` hook or during termination in an `appTerminate` hook. App terminate hooks

have a limited time to execute and don't execute in all scenarios.

The Azure Functions runtime currently [doesn't support](#) context logging outside of an invocation. Use the Application Insights [npm package](#) to log data during app level hooks.

The following example registers app hooks:

TypeScript

```
import { app, AppStartContext, AppTerminateContext } from '@azure/functions';

app.hook.appStart((context: AppStartContext) => {
    // add your logic here
});

app.hook.appTerminate((context: AppTerminateContext) => {
    // add your logic here
});
```

The first argument to the hook handler is a context object specific to that hook type.

The `AppStartContext` object has the following properties:

[+] [Expand table](#)

Property	Description
<code>hookData</code>	The recommended place to store and share data between hooks in the same scope. You should use a unique property name so that it doesn't conflict with other hooks' data.

The `AppTerminateContext` object has the following properties:

[+] [Expand table](#)

Property	Description
<code>hookData</code>	The recommended place to store and share data between hooks in the same scope. You should use a unique property name so that it doesn't conflict with other hooks' data.

Scaling and concurrency

By default, Azure Functions automatically monitors the load on your application and creates more host instances for Node.js as needed. Azure Functions uses built-in (not user configurable) thresholds for different trigger types to decide when to add instances, such as the age of messages and queue size for QueueTrigger. For more information, see [How the Consumption and Premium plans work](#).

This scaling behavior is sufficient for many Node.js applications. For CPU-bound applications, you can improve performance further by using multiple language worker processes. You can increase the number of worker processes per host from the default of 1 up to a max of 10 by using the `FUNCTIONS_WORKER_PROCESS_COUNT` application setting. Azure Functions then tries to evenly distribute simultaneous function invocations across these workers. This behavior makes it less likely that a CPU-intensive function blocks other functions from running. The setting applies to each host that Azure Functions creates when scaling out your application to meet demand.

⚠ Warning

Use the `FUNCTIONS_WORKER_PROCESS_COUNT` setting with caution. Multiple processes running in the same instance can lead to unpredictable behavior and increase function load times. If you use this setting, it's *highly recommended* to offset these downsides by [running from a package file](#).

Node version

You can see the current version that the runtime is using by logging `process.version` from any function. See [supported versions](#) for a list of Node.js versions supported by each programming model.

Setting the Node version

The way that you upgrade your Node.js version depends on the OS on which your function app runs.

Windows

When running on Windows, the Node.js version is set by the `WEBSITE_NODE_DEFAULT_VERSION` application setting. This setting can be updated

either by using the Azure CLI or in the Azure portal.

For more information about Node.js versions, see [Supported versions](#).

Before upgrading your Node.js version, make sure your function app is running on the latest version of the Azure Functions runtime. If you need to upgrade your runtime version, see [Migrate apps from Azure Functions version 3.x to version 4.x](#).

Azure CLI

Run the Azure CLI `az functionapp config appsettings set` command to update the Node.js version for your function app running on Windows:

Azure CLI

```
az functionapp config appsettings set --settings  
WEBSITE_NODE_DEFAULT_VERSION=~20 \  
--name <FUNCTION_APP_NAME> --resource-group <RESOURCE_GROUP_NAME>
```

This sets the `WEBSITE_NODE_DEFAULT_VERSION` application setting the supported LTS version of `~20`.

After changes are made, your function app restarts. To learn more about Functions support for Node.js, see [Language runtime support policy](#).

Environment variables

Environment variables can be useful for operational secrets (connection strings, keys, endpoints, etc.) or environmental settings such as profiling variables. You can add environment variables in both your local and cloud environments and access them through `process.env` in your function code.

The following example logs the `WEBSITE_SITE_NAME` environment variable:

TypeScript

TypeScript

```
async function timerTrigger1(myTimer: Timer, context:  
InvocationContext): Promise<void> {  
    context.log(`WEBSITE_SITE_NAME:
```

```
    ${process.env[ "WEBSITE_SITE_NAME" ]} );
}
```

In local development environment

When you run locally, your functions project includes a [local.settings.json file](#), where you store your environment variables in the `Values` object.

JSON

```
{
  "IsEncrypted": false,
  "Values": {
    "AzureWebJobsStorage": "",
    "FUNCTIONS_WORKER_RUNTIME": "node",
    "CUSTOM_ENV_VAR_1": "hello",
    "CUSTOM_ENV_VAR_2": "world"
  }
}
```

In Azure cloud environment

When you run in Azure, the function app lets you set and use [Application settings](#), such as service connection strings, and exposes these settings as environment variables during execution.

There are several ways that you can add, update, and delete function app settings:

- [In the Azure portal](#).
- [By using the Azure CLI](#).
- [By using Azure PowerShell](#).

Changes to function app settings require your function app to be restarted.

Worker environment variables

There are several Functions environment variables specific to Node.js:

languageWorkers_node_arguments

This setting allows you to specify custom arguments when starting your Node.js process. It's most often used locally to start the worker in debug mode, but can also be used in Azure if you need custom arguments.

⚠️ Warning

If possible, avoid using `languageWorkers__node__arguments` in Azure because it can have a negative effect on cold start times. Rather than using pre-warmed workers, the runtime has to start a new worker from scratch with your custom arguments.

logging(LogLevel.Worker)

This setting adjusts the default log level for Node.js-specific worker logs. By default, only warning or error logs are shown, but you can set it to `information` or `debug` to help diagnose issues with the Node.js worker. For more information, see [configuring log levels](#).

ECMAScript modules (preview)

ⓘ Note

As ECMAScript modules are currently a preview feature in Node.js 14 or higher in Azure Functions.

[ECMAScript modules](#) (ES modules) are the new official standard module system for Node.js. So far, the code samples in this article use the CommonJS syntax. When running Azure Functions in Node.js 14 or higher, you can choose to write your functions using ES modules syntax.

To use ES modules in a function, change its filename to use a `.mjs` extension. The following `index.mjs` file example is an HTTP triggered function that uses ES modules syntax to import the `uuid` library and return a value.

TypeScript

TypeScript

```
import { app, HttpRequest, HttpResponseInit, InvocationContext } from
"@azure/functions";
import { v4 as uuidv4 } from 'uuid';

async function httpTrigger1(request: HttpRequest, context:
InvocationContext): Promise<HttpResponseInit> {
    return { body: uuidv4() };
};
```

```
app.http('httpTrigger1', {
    methods: ['GET', 'POST'],
    handler: httpTrigger1
});
```

Local debugging

It's recommended to use VS Code for local debugging, which starts your Node.js process in debug mode automatically and attaches to the process for you. For more information, see [run the function locally](#).

If you're using a different tool for debugging or want to start your Node.js process in debug mode manually, add `"languageWorkers__node__arguments": "--inspect"` under `Values` in your [local.settings.json](#). The `--inspect` argument tells Node.js to listen for a debug client, on port 9229 by default. For more information, see the [Node.js debugging guide](#).

Recommendations

This section describes several impactful patterns for Node.js apps that we recommend you follow.

Choose single-vCPU App Service plans

When you create a function app that uses the App Service plan, we recommend that you select a single-vCPU plan rather than a plan with multiple vCPUs. Today, Functions runs Node.js functions more efficiently on single-vCPU VMs, and using larger VMs doesn't produce the expected performance improvements. When necessary, you can manually scale out by adding more single-vCPU VM instances, or you can enable autoscale. For more information, see [Scale instance count manually or automatically](#).

Run from a package file

When you develop Azure Functions in the serverless hosting model, cold starts are a reality. *Cold start* refers to the first time your function app starts after a period of inactivity, taking longer to start up. For Node.js apps with large dependency trees in particular, cold start can be significant. To speed up the cold start process, [run your functions as a package file](#) when possible. Many deployment methods use this model by

default, but if you're experiencing large cold starts you should check to make sure you're running this way.

Use a single static client

When you use a service-specific client in an Azure Functions application, don't create a new client with every function invocation because you can hit connection limits. Instead, create a single, static client in the global scope. For more information, see [managing connections in Azure Functions](#).

Use `async` and `await`

When writing Azure Functions in Node.js, you should write code using the `async` and `await` keywords. Writing code using `async` and `await` instead of callbacks or `.then` and `.catch` with Promises helps avoid two common problems:

- Throwing uncaught exceptions that [crash the Node.js process ↗](#), potentially affecting the execution of other functions.
- Unexpected behavior, such as missing logs from `context.log`, caused by asynchronous calls that aren't properly awaited.

In the following example, the asynchronous method `fs.readFile` is invoked with an error-first callback function as its second parameter. This code causes both of the issues previously mentioned. An exception that isn't explicitly caught in the correct scope can crash the entire process (issue #1). Returning without ensuring the callback finishes means the http response will sometimes have an empty body (issue #2).

TypeScript

```
TypeScript

// DO NOT USE THIS CODE
import { app, HttpRequest, HttpResponseInit, InvocationContext } from
  '@azure/functions';
import * as fs from 'fs';

export async function httpTriggerBadAsync(request: HttpRequest, context: InvocationContext): Promise<HttpResponseInit> {
  let fileData: Buffer;
  fs.readFile('./helloWorld.txt', (err, data) => {
    if (err) {
      context.error(err);
      // BUG #1: This will result in an uncaught exception that
      crashes the entire process
      throw err;
    }
    fileData = data;
  })
  return {
    status: 200,
    body: fileData,
  };
}
```

```

        }
        fileData = data;
    });
    // BUG #2: fileData is not guaranteed to be set before the
    invocation ends
    return { body: fileData };
}

app.http('httpTriggerBadAsync', {
    methods: ['GET', 'POST'],
    authLevel: 'anonymous',
    handler: httpTriggerBadAsync,
});

```

Use the `async` and `await` keywords to help avoid both of these issues. Most APIs in the Node.js ecosystem have been converted to support promises in some form. For example, starting in v14, Node.js provides an `fs/promises` API to replace the `fs` callback API.

In the following example, any unhandled exceptions thrown during the function execution only fail the individual invocation that raised the exception. The `await` keyword means that steps following `readFile` only execute after it's complete.

TypeScript

```

TypeScript

// Recommended pattern
import { app, HttpRequest, HttpResponseInit, InvocationContext } from
'@azure/functions';
import * as fs from 'fs/promises';

export async function httpTriggerGoodAsync(
    request: HttpRequest,
    context: InvocationContext
): Promise<HttpResponseInit> {
    try {
        const fileData = await fs.readFile('./helloWorld.txt');
        return { body: fileData };
    } catch (err) {
        context.error(err);
        // This rethrown exception will only fail the individual
        invocation, instead of crashing the whole process
        throw err;
    }
}

app.http('httpTriggerGoodAsync', {
    methods: ['GET', 'POST'],
}

```

```
    authLevel: 'anonymous',
    handler: httpTriggerGoodAsync,
});
```

Azure Functions Java developer guide

Article • 01/31/2024

This guide contains detailed information to help you succeed developing Azure Functions using Java.

As a Java developer, if you're new to Azure Functions, consider first reading one of the following articles:

[+] Expand table

Getting started	Concepts	Scenarios/samples
<ul style="list-style-type: none">Java function using Visual Studio CodeJava/Maven function with terminal/command promptJava function using GradleJava function using EclipseJava function using IntelliJ IDEA	<ul style="list-style-type: none">Developer guideHosting optionsPerformance considerations	<ul style="list-style-type: none">Java samples with different triggersEvent Hubs trigger and Azure Cosmos DB output bindingDependency injection samples ↗

Java function basics

A Java function is a `public` method, decorated with the annotation `@FunctionName`. This method defines the entry for a Java function, and must be unique in a particular package. The package can have multiple classes with multiple public methods annotated with `@FunctionName`. A single package is deployed to a function app in Azure. In Azure, the function app provides the deployment, execution, and management context for your individual Java functions.

Programming model

The concepts of [triggers and bindings](#) are fundamental to Azure Functions. Triggers start the execution of your code. Bindings give you a way to pass data to and return data from a function, without having to write custom data access code.

Create Java functions

To make it easier to create Java functions, there are Maven-based tooling and archetypes that use predefined Java templates to help you create projects with a specific function trigger.

Maven-based tooling

The following developer environments have Azure Functions tooling that lets you create Java function projects:

- [Visual Studio Code ↗](#)
- [Eclipse](#)
- [IntelliJ](#)

These articles show you how to create your first functions using your IDE of choice.

Project scaffolding

If you prefer command line development from the Terminal, the simplest way to scaffold Java-based function projects is to use [Apache Maven](#) archetypes. The Java Maven archetype for Azure Functions is published under the following *groupId:artifactId:com.microsoft.azure:azure-functions-archetype* ↗.

The following command generates a new Java function project using this archetype:

```
Bash
mvn archetype:generate \
-DarchetypeGroupId=com.microsoft.azure \
-DarchetypeArtifactId=azure-functions-archetype
```

To get started using this archetype, see the [Java quickstart](#).

Folder structure

Here's the folder structure of an Azure Functions Java project:

```
FunctionsProject
| - src
```

```
| | - main
| | | - java
| | | | - FunctionApp
| | | | | - MyFirstFunction.java
| | | | | - MySecondFunction.java
| - target
| | - azure-functions
| | | - FunctionApp
| | | | - FunctionApp.jar
| | | | - host.json
| | | | | - MyFirstFunction
| | | | | | - function.json
| | | | | - MySecondFunction
| | | | | | - function.json
| | | | - bin
| | | | - lib
| - pom.xml
```

You can use a shared [host.json](#) file to configure the function app. Each function has its own code file (.java) and binding configuration file (function.json).

You can put more than one function in a project. Avoid putting your functions into separate jars. The `FunctionApp` in the target directory is what gets deployed to your function app in Azure.

Triggers and annotations

Functions are invoked by a trigger, such as an HTTP request, a timer, or an update to data. Your function needs to process that trigger, and any other inputs, to produce one or more outputs.

Use the Java annotations included in the [com.microsoft.azure.functions.annotation.*](#) package to bind input and outputs to your methods. For more information, see the [Java reference docs](#).

Important

You must configure an Azure Storage account in your [local.settings.json](#) to run Azure Blob storage, Azure Queue storage, or Azure Table storage triggers locally.

Example:

Java

```
public class Function {
    public String echo(@HttpTrigger(name = "req",
```

```
        methods = {HttpMethod.POST}, authLevel =
AuthorizationLevel.ANONYMOUS)
    String req, ExecutionContext context) {
    return String.format(req);
}
}
```

Here's the generated corresponding `function.json` by the [azure-functions-maven-plugin](#):

JSON

```
{
  "scriptFile": "azure-functions-example.jar",
  "entryPoint": "com.example.Function.echo",
  "bindings": [
    {
      "type": "httpTrigger",
      "name": "req",
      "direction": "in",
      "authLevel": "anonymous",
      "methods": [ "GET", "POST" ]
    },
    {
      "type": "http",
      "name": "$return",
      "direction": "out"
    }
  ]
}
```

Java versions

The version of Java on which your app runs in Azure is specified in the pom.xml file. The Maven archetype currently generates a pom.xml for Java 8, which you can change before publishing. The Java version in pom.xml should match the version on which you've locally developed and tested your app.

Supported versions

The following table shows current supported Java versions for each major version of the Functions runtime, by operating system:

[] [Expand table](#)

Functions version	Java versions (Windows)	Java versions (Linux)
4.x	17	21 (Preview)
	11	17
	8	11
		8
3.x	11	11
	8	8
2.x	8	n/a

Unless you specify a Java version for your deployment, the Maven archetype defaults to Java 8 during deployment to Azure.

Specify the deployment version

You can control the version of Java targeted by the Maven archetype by using the `-DjavaVersion` parameter. The value of this parameter can be either `8`, `11`, `17` or `21`.

The Maven archetype generates a pom.xml that targets the specified Java version. The following elements in pom.xml indicate the Java version to use:

[\[+\] Expand table](#)

Element	Java 8 value	Java 11 value	Java 17 value	Java 21 value (Preview, Linux)	Description
<code>Java.version</code>	1.8	11	17	21	Version of Java used by the maven-compiler-plugin.
<code>JavaVersion</code>	8	11	17	21	Java version hosted by the function app in Azure.

The following examples show the settings for Java 8 in the relevant sections of the pom.xml file:

`Java.version`

XML

```
<properties>
    <project.build.sourceEncoding>UTF-8</project.build.sourceEncoding>
    <java.version>1.8</java.version>

    <azure.functions.maven.plugin.version>1.6.0</azure.functions.maven.plugin.v
```

```
rsion>

<azure.functions.java.library.version>1.3.1</azure.functions.java.library.version>
    <functionAppName>fabrikam-functions-20200718015742191</functionAppName>
    <stagingDirectory>${project.build.directory}/azure-
functions/${functionAppName}</stagingDirectory>
</properties>
```

JavaVersion

XML

```
<runtime>
    <!-- runtime os, could be windows, linux or docker-->
    <os>windows</os>
    <javaVersion>8</javaVersion>
    <!-- for docker function, please set the following parameters -->
    <!-- <image>[hub-user/]repo-name[:tag]</image> -->
    <!-- <serverId></serverId> -->
    <!-- <registryUrl></registryUrl> -->
</runtime>
```

ⓘ Important

You must have the JAVA_HOME environment variable set correctly to the JDK directory that is used during code compiling using Maven. Make sure that the version of the JDK is at least as high as the `Java.version` setting.

Specify the deployment OS

Maven also lets you specify the operating system on which your function app runs in Azure. Use the `os` element to choose the operating system.

[+] Expand table

Element	Windows	Linux	Docker
<code>os</code>	windows	linux	docker

The following example shows the operating system setting in the `runtime` section of the `pom.xml` file:

XML

```
<runtime>
    <!-- runtime os, could be windows, linux or docker-->
    <os>windows</os>
    <javaVersion>8</javaVersion>
    <!-- for docker function, please set the following parameters -->
    <!-- <image>[hub-user/]repo-name[:tag]</image> -->
    <!-- <serverId></serverId> -->
    <!-- <registryUrl></registryUrl> -->
</runtime>
```

JDK runtime availability and support

Microsoft and [Adoptium](#) builds of OpenJDK are provided and supported on Functions for Java 8 (Adoptium), Java 11, 17 and 21 (MSFT). These binaries are provided as a no-cost, multi-platform, production-ready distribution of the OpenJDK for Azure. They contain all the components for building and running Java SE applications.

For local development or testing, you can download the [Microsoft build of OpenJDK](#) or [Adoptium Temurin](#) binaries for free. [Azure support](#) for issues with the JDKs and function apps is available with a [qualified support plan](#).

If you would like to continue using the Zulu for Azure binaries on your Function app, [configure your app accordingly](#). You can continue to use the Azul binaries for your site. However, any security patches or improvements are only available in new versions of the OpenJDK. Because of this, you should eventually remove this configuration so that your apps use the latest available version of Java.

Customize JVM

Functions lets you customize the Java virtual machine (JVM) used to run your Java functions. The [following JVM options](#) are used by default:

- `-XX:+TieredCompilation`
- `-XX:TieredStopAtLevel=1`
- `-noverify`
- `-Djava.net.preferIPv4Stack=true`
- `-jar`

You can provide other arguments to the JVM by using one of the following application settings, depending on the plan type:

Plan type	Setting name	Comment
Consumption plan	languageWorkers_java_arguments	This setting does increase the cold start times for Java functions running in a Consumption plan.
Premium plan Dedicated plan	JAVA_OPTS	

The following sections show you how to add these settings. To learn more about working with application settings, see the [Work with application settings](#) section.

Azure portal

In the [Azure portal](#), use the [Application Settings tab](#) to add either the `languageWorkers_java_arguments` or the `JAVA_OPTS` setting.

Azure CLI

You can use the `az functionapp config appsettings set` command to add these settings, as shown in the following example for the `-Djava.awt.headless=true` option:

The screenshot shows the Azure CLI interface. A dropdown menu is open, showing the option "Consumption plan". Below it, the command line interface shows the following command:

```
az functionapp config appsettings set \
    --settings "languageWorkers_java_arguments=-
Djava.awt.headless=true" \
    --name <APP_NAME> --resource-group <RESOURCE_GROUP>
```

This example enables headless mode. Replace `<APP_NAME>` with the name of your function app, and `<RESOURCE_GROUP>` with the resource group.

Third-party libraries

Azure Functions supports the use of third-party libraries. By default, all dependencies specified in your project `pom.xml` file are automatically bundled during the [mvn package](#) goal. For libraries not specified as dependencies in the `pom.xml` file, place them in a `lib`

directory in the function's root directory. Dependencies placed in the `lib` directory are added to the system class loader at runtime.

The `com.microsoft.azure.functions:azure-functions-java-library` dependency is provided on the classpath by default, and doesn't need to be included in the `lib` directory. Also, [azure-functions-java-worker](#) adds dependencies listed [here](#) to the classpath.

Data type support

You can use Plain old Java objects (POJOs), types defined in `azure-functions-java-library`, or primitive data types such as String and Integer to bind to input or output bindings.

POJOs

For converting input data to POJO, [azure-functions-java-worker](#) uses the `gson` library. POJO types used as inputs to functions should be `public`.

Binary data

Bind binary inputs or outputs to `byte[]`, by setting the `dataType` field in your `function.json` to `binary`:

```
Java

@FunctionName("BlobTrigger")
@StorageAccount("AzureWebJobsStorage")
public void blobTrigger(
    @BlobTrigger(name = "content", path = "myblob/{fileName}", dataType
= "binary") byte[] content,
    @BindingName("fileName") String fileName,
    final ExecutionContext context
) {
    context.getLogger().info("Java Blob trigger function processed a
blob.\n Name: " + fileName + "\n Size: " + content.length + " Bytes");
}
```

If you expect null values, use `Optional<T>`.

Bindings

Input and output bindings provide a declarative way to connect to data from within your code. A function can have multiple input and output bindings.

Input binding example

Java

```
package com.example;

import com.microsoft.azure.functions.annotation.*;

public class Function {
    @FunctionName("echo")
    public static String echo(
        @HttpTrigger(name = "req", methods = { HttpMethod.PUT }, authLevel =
AuthorizationLevel.ANONYMOUS, route = "items/{id}") String inputReq,
        @TableInput(name = "item", tableName = "items", partitionKey =
"Example", rowKey = "{id}", connection = "AzureWebJobsStorage")
TestInputData inputData,
        @TableOutput(name = "myOutputTable", tableName = "Person",
connection = "AzureWebJobsStorage") OutputBinding<Person> testOutputData
    ) {
        testOutputData.setValue(new Person(httpbody + "Partition", httpbody
+ "Row", httpbody + "Name"));
        return "Hello, " + inputReq + " and " + inputData.getKey() + ".";
    }

    public static class TestInputData {
        public String getKey() { return this.rowKey; }
        private String rowKey;
    }
    public static class Person {
        public String partitionKey;
        public String rowKey;
        public String name;

        public Person(String p, String r, String n) {
            this.partitionKey = p;
            this.rowKey = r;
            this.name = n;
        }
    }
}
```

You invoke this function with an HTTP request.

- HTTP request payload is passed as a `String` for the argument `inputReq`.
- One entry is retrieved from Table storage, and is passed as `TestInputData` to the argument `inputData`.

To receive a batch of inputs, you can bind to `String[]`, `POJO[]`, `List<String>`, or `List<POJO>`.

Java

```
@FunctionName("ProcessIotMessages")
public void processIotMessages(
    @EventHubTrigger(name = "message", eventHubName =
"%AzureWebJobsEventHubPath%", connection = "AzureWebJobsEventHubSender",
cardinality = Cardinality.MANY) List<TestEventData> messages,
    final ExecutionContext context)
{
    context.getLogger().info("Java Event Hub trigger received messages.
Batch size: " + messages.size());
}

public class TestEventData {
    public String id;
}
```

This function gets triggered whenever there's new data in the configured event hub. Because the `cardinality` is set to `MANY`, the function receives a batch of messages from the event hub. `EventData` from event hub gets converted to `TestEventData` for the function execution.

Output binding example

You can bind an output binding to the return value by using `$return`.

Java

```
package com.example;

import com.microsoft.azure.functions.annotation.*;

public class Function {
    @FunctionName("copy")
    @StorageAccount("AzureWebJobsStorage")
    @BlobOutput(name = "$return", path = "samples-output-java/{name}")
    public static String copy(@BlobTrigger(name = "blob", path = "samples-
input-java/{name}") String content) {
        return content;
    }
}
```

If there are multiple output bindings, use the return value for only one of them.

To send multiple output values, use `OutputBinding<T>` defined in the `azure-functions-java-library` package.

Java

```
@FunctionName("QueueOutputPOJOList")
    public HttpResponseMessage QueueOutputPOJOList(@HttpTrigger(name =
"req", methods = { HttpMethod.GET,
                    HttpMethod.POST }, authLevel = AuthorizationLevel.ANONYMOUS)
HttpRequestMessage<Optional<String>> request,
        @QueueOutput(name = "itemsOut", queueName = "test-output-java-
pojo", connection = "AzureWebJobsStorage") OutputBinding<List<TestData>>
itemsOut,
        final ExecutionContext context) {
    context.getLogger().info("Java HTTP trigger processed a request.");

    String query = request.getQueryParameters().get("queueMessageId");
    String queueMessageId = request.getBody().orElse(query);
    itemsOut.setValue(new ArrayList<TestData>());
    if (queueMessageId != null) {
        TestData testData1 = new TestData();
        testData1.id = "msg1"+queueMessageId;
        TestData testData2 = new TestData();
        testData2.id = "msg2"+queueMessageId;

        itemsOut.getValue().add(testData1);
        itemsOut.getValue().add(testData2);

        return request.createResponseBuilder(HttpStatus.OK).body("Hello,
" + queueMessageId).build();
    } else {
        return
request.createResponseBuilder(HttpStatus.INTERNAL_SERVER_ERROR)
            .body("Did not find expected items in CosmosDB input
list").build();
    }
}

public static class TestData {
    public String id;
}
```

You invoke this function on an `HttpRequest` object. It writes multiple values to Queue storage.

HttpRequestMessage and HttpResponseMessage

These are defined in `azure-functions-java-library`. They're helper types to work with `HttpTrigger` functions.

[+] Expand table

Specialized type	Target	Typical usage
<code>HttpRequestMessage<T></code>	HTTP Trigger	Gets method, headers, or queries
<code>HttpResponseMessage</code>	HTTP Output Binding	Returns status other than 200

Metadata

Few triggers send [trigger metadata](#) along with input data. You can use annotation `@BindingName` to bind to trigger metadata.

Java

```
package com.example;

import java.util.Optional;
import com.microsoft.azure.functions.annotation.*;

public class Function {
    @FunctionName("metadata")
    public static String metadata(
        @HttpTrigger(name = "req", methods = { HttpMethod.GET,
HttpMethod.POST }, authLevel = AuthorizationLevel.ANONYMOUS)
Optional<String> body,
        @BindingName("name") String queryValue
    ) {
        return body.orElse(queryValue);
    }
}
```

In the preceding example, the `queryValue` is bound to the query string parameter `name` in the HTTP request URL, `http://{example.host}/api/metadata?name=test`. Here's another example, showing how to bind to `Id` from queue trigger metadata.

Java

```
@FunctionName("QueueTriggerMetadata")
public void QueueTriggerMetadata(
    @QueueTrigger(name = "message", queueName = "test-input-javametadata",
connection = "AzureWebJobsStorage") String
message,@BindingName("Id") String metadataId,
```

```
    @QueueOutput(name = "output", queueName = "test-output-java-metadata", connection = "AzureWebJobsStorage") OutputBinding<TestData> output,
        final ExecutionContext context
    ) {
    context.getLogger().info("Java Queue trigger function processed a message: " + message + " with metadataId:" + metadataId );
    TestData testData = new TestData();
    testData.id = metadataId;
    output.setValue(testData);
}
```

ⓘ Note

The name provided in the annotation needs to match the metadata property.

Execution context

`ExecutionContext`, defined in the `azure-functions-java-library`, contains helper methods to communicate with the functions runtime. For more information, see the [ExecutionContext reference article](#).

Logger

Use `getLogger`, defined in `ExecutionContext`, to write logs from function code.

Example:

Java

```
import com.microsoft.azure.functions.*;
import com.microsoft.azure.functions.annotation.*;

public class Function {
    public String echo(@HttpTrigger(name = "req", methods =
{HttpMethod.POST}, authLevel = AuthorizationLevel.ANONYMOUS) String req,
ExecutionContext context) {
        if (req.isEmpty()) {
            context.getLogger().warning("Empty request body received by
function " + context.getFunctionName() + " with invocation " +
context.getInvocationId());
        }
        return String.format(req);
    }
}
```

View logs and trace

You can use the Azure CLI to stream Java stdout and stderr logging, and other application logging.

Here's how to configure your function app to write application logging by using the Azure CLI:

Bash

Azure CLI

```
az webapp log config --name functionname --resource-group  
myResourceGroup --application-logging true
```

To stream logging output for your function app by using the Azure CLI, open a new command prompt, Bash, or Terminal session, and enter the following command:

Bash

Azure CLI

```
az webapp log tail --name webappname --resource-group myResourceGroup
```

The `az webapp log tail` command has options to filter output by using the `--provider` option.

To download the log files as a single ZIP file by using the Azure CLI, open a new command prompt, Bash, or Terminal session, and enter the following command:

Azure CLI

```
az webapp log download --resource-group resourcegroupname --name  
functionappname
```

You must have enabled file system logging in the Azure portal or the Azure CLI before running this command.

Environment variables

In Functions, [app settings](#), such as service connection strings, are exposed as environment variables during execution. You can access these settings by using, `System.getenv("AzureWebJobsStorage")`.

The following example gets the [application setting](#), with the key named `myAppSetting`:

Java

```
public class Function {
    public String echo(@HttpTrigger(name = "req", methods =
{HttpMethod.POST}, authLevel = AuthorizationLevel.ANONYMOUS) String req,
ExecutionContext context) {
        context.getLogger().info("My app setting value: "+
System.getenv("myAppSetting"));
        return String.format(req);
    }
}
```

Use dependency injection in Java Functions

Azure Functions Java supports the dependency injection (DI) software design pattern, which is a technique to achieve [Inversion of Control \(IoC\)](#) between classes and their dependencies. Java Azure Functions provides a hook to integrate with popular Dependency Injection frameworks in your Functions Apps. [Azure Functions Java SPI](#) contains an interface [FunctionInstanceInjector](#). By implementing this interface, you can return an instance of your function class and your functions will be invoked on this instance. This gives frameworks like [Spring](#), [Quarkus](#), Google Guice, Dagger, etc. the ability to create the function instance and register it into their IOC container. This means you can use those Dependency Injection frameworks to manage your functions naturally.

Note

Microsoft Azure Functions Java SPI Types ([azure-function-java-spi](#)) is a package that contains all SPI interfaces for third parties to interact with Microsoft Azure functions runtime.

Function instance injector for dependency injection

[azure-function-java-spi](#) contains an interface `FunctionInstanceInjector`

Java

```
package com.microsoft.azure.functions.spi.inject;

/**
 * The instance factory used by DI framework to initialize function
instance.

 *
 * @since 1.0.0
 */

public interface FunctionInstanceInjector {

    /**
     * This method is used by DI framework to initialize the function
instance. This method takes in the customer class and returns

     * an instance create by the DI framework, later customer functions will
be invoked on this instance.

     * @param functionClass the class that contains customer functions

     * @param <T> customer functions class type

     * @return the instance that will be invoked on by azure functions java
worker

     * @throws Exception any exception that is thrown by the DI framework
during instance creation

    */

    <T> T getInstance(Class<T> functionClass) throws Exception;
}
```

For more examples that use `FunctionInstanceInjector` to integrate with Dependency injection frameworks refer to [this](#) repository.

Azure Functions PowerShell developer guide

Article • 03/09/2023

This article provides details about how you write Azure Functions using PowerShell.

A PowerShell Azure function (function) is represented as a PowerShell script that executes when triggered. Each function script has a related `function.json` file that defines how the function behaves, such as how it's triggered and its input and output parameters. To learn more, see the [Triggers and binding article](#).

Like other kinds of functions, PowerShell script functions take in parameters that match the names of all the input bindings defined in the `function.json` file. A `TriggerMetadata` parameter is also passed that contains additional information on the trigger that started the function.

This article assumes that you have already read the [Azure Functions developer reference](#). You should have also completed the [Functions quickstart for PowerShell](#) to create your first PowerShell function.

Folder structure

The required folder structure for a PowerShell project looks like the following. This default can be changed. For more information, see the `scriptFile` section below.

```
PSFunctionApp
| - MyFirstFunction
| | - run.ps1
| | - function.json
| - MySecondFunction
| | - run.ps1
| | - function.json
| - Modules
| | - myFirstHelperModule
| | | - myFirstHelperModule.psd1
| | | - myFirstHelperModule.psm1
| | - mySecondHelperModule
| | | - mySecondHelperModule.psd1
| | | - mySecondHelperModule.psm1
| - local.settings.json
| - host.json
| - requirements.psd1
| - profile.ps1
```

```
| - extensions.csproj  
| - bin
```

At the root of the project, there's a shared `host.json` file that can be used to configure the function app. Each function has a folder with its own code file (`.ps1`) and binding configuration file (`function.json`). The name of the `function.json` file's parent directory is always the name of your function.

Certain bindings require the presence of an `extensions.csproj` file. Binding extensions, required in [version 2.x and later versions](#) of the Functions runtime, are defined in the `extensions.csproj` file, with the actual library files in the `bin` folder. When developing locally, you must [register binding extensions](#). When developing functions in the Azure portal, this registration is done for you.

In PowerShell Function Apps, you may optionally have a `profile.ps1` which runs when a function app starts to run (otherwise known as a [cold start](#)). For more information, see [PowerShell profile](#).

Defining a PowerShell script as a function

By default, the Functions runtime looks for your function in `run.ps1`, where `run.ps1` shares the same parent directory as its corresponding `function.json`.

Your script is passed a number of arguments on execution. To handle these parameters, add a `param` block to the top of your script as in the following example:

PowerShell

```
# $TriggerMetadata is optional here. If you don't need it, you can safely  
remove it from the param block  
param($MyFirstInputBinding, $MySecondInputBinding, $TriggerMetadata)
```

TriggerMetadata parameter

The `TriggerMetadata` parameter is used to supply additional information about the trigger. The additional metadata varies from binding to binding but they all contain a `sys` property that contains the following data:

PowerShell

```
$TriggerMetadata.sys
```

Property	Description	Type
UtcNow	When, in UTC, the function was triggered	DateTime
MethodName	The name of the Function that was triggered	string
RandGuid	a unique guid to this execution of the function	string

Every trigger type has a different set of metadata. For example, the `$TriggerMetadata` for `QueueTrigger` contains the `InsertionTime`, `Id`, `DequeueCount`, among other things. For more information on the queue trigger's metadata, go to the [official documentation for queue triggers](#). Check the documentation on the [triggers](#) you're working with to see what comes inside the trigger metadata.

Bindings

In PowerShell, [bindings](#) are configured and defined in a function's `function.json`. Functions interact with bindings a number of ways.

Reading trigger and input data

Trigger and input bindings are read as parameters passed to your function. Input bindings have a `direction` set to `in` in `function.json`. The `name` property defined in `function.json` is the name of the parameter, in the `param` block. Since PowerShell uses named parameters for binding, the order of the parameters doesn't matter. However, it's a best practice to follow the order of the bindings defined in the `function.json`.

PowerShell

```
param($MyFirstInputBinding, $MySecondInputBinding)
```

Writing output data

In Functions, an output binding has a `direction` set to `out` in the `function.json`. You can write to an output binding by using the `Push-OutputBinding` cmdlet, which is available to the Functions runtime. In all cases, the `name` property of the binding as defined in `function.json` corresponds to the `Name` parameter of the `Push-OutputBinding` cmdlet.

The following shows how to call `Push-OutputBinding` in your function script:

PowerShell

```
param($MyFirstInputBinding, $MySecondInputBinding)

Push-OutputBinding -Name myQueue -Value $myValue
```

You can also pass in a value for a specific binding through the pipeline.

PowerShell

```
param($MyFirstInputBinding, $MySecondInputBinding)

Produce-MyOutputValue | Push-OutputBinding -Name myQueue
```

`Push-OutputBinding` behaves differently based on the value specified for `-Name`:

- When the specified name cannot be resolved to a valid output binding, then an error is thrown.
- When the output binding accepts a collection of values, you can call `Push-OutputBinding` repeatedly to push multiple values.
- When the output binding only accepts a singleton value, calling `Push-OutputBinding` a second time raises an error.

Push-OutputBinding syntax

The following are valid parameters for calling `Push-OutputBinding`:

Name	Type	Position	Description
<code>-Name</code>	String	1	The name of the output binding you want to set.
<code>-Value</code>	Object	2	The value of the output binding you want to set, which is accepted from the pipeline <code>ByValue</code> .
<code>-</code> <code>Clobber</code>	SwitchParameter	Named	(Optional) When specified, forces the value to be set for a specified output binding.

The following common parameters are also supported:

- `Verbose`
- `Debug`
- `ErrorAction`
- `ErrorVariable`
- `WarningAction`

- `WarningVariable`
- `OutBuffer`
- `PipelineVariable`
- `OutVariable`

For more information, see [About CommonParameters](#).

Push-OutputBinding example: HTTP responses

An HTTP trigger returns a response using an output binding named `response`. In the following example, the output binding of `response` has the value of "output #1":

PowerShell

```
PS >Push-OutputBinding -Name response -Value ([HttpResponseContext]@{  
    StatusCode = [System.Net.HttpStatusCode]::OK  
    Body = "output #1"  
})
```

Because the output is to HTTP, which accepts a singleton value only, an error is thrown when `Push-OutputBinding` is called a second time.

PowerShell

```
PS >Push-OutputBinding -Name response -Value ([HttpResponseContext]@{  
    StatusCode = [System.Net.HttpStatusCode]::OK  
    Body = "output #2"  
})
```

For outputs that only accept singleton values, you can use the `-Clobber` parameter to override the old value instead of trying to add to a collection. The following example assumes that you have already added a value. By using `-Clobber`, the response from the following example overrides the existing value to return a value of "output #3":

PowerShell

```
PS >Push-OutputBinding -Name response -Value ([HttpResponseContext]@{  
    StatusCode = [System.Net.HttpStatusCode]::OK  
    Body = "output #3"  
}) -Clobber
```

Push-OutputBinding example: Queue output binding

`Push-OutputBinding` is used to send data to output bindings, such as an [Azure Queue storage output binding](#). In the following example, the message written to the queue has a value of "output #1":

PowerShell

```
PS >Push-OutputBinding -Name outQueue -Value "output #1"
```

The output binding for a Storage queue accepts multiple output values. In this case, calling the following example after the first writes to the queue a list with two items: "output #1" and "output #2".

PowerShell

```
PS >Push-OutputBinding -Name outQueue -Value "output #2"
```

The following example, when called after the previous two, adds two more values to the output collection:

PowerShell

```
PS >Push-OutputBinding -Name outQueue -Value @("output #3", "output #4")
```

When written to the queue, the message contains these four values: "output #1", "output #2", "output #3", and "output #4".

Get-OutputBinding cmdlet

You can use the `Get-OutputBinding` cmdlet to retrieve the values currently set for your output bindings. This cmdlet retrieves a hashtable that contains the names of the output bindings with their respective values.

The following is an example of using `Get-OutputBinding` to return current binding values:

PowerShell

```
Get-OutputBinding
```

Output

Name	Value
-----	-----

```
MyQueue  
MyOtherQueue
```

```
myData  
myData
```

`Get-OutputBinding` also contains a parameter called `-Name`, which can be used to filter the returned binding, as in the following example:

```
PowerShell
```

```
Get-OutputBinding -Name MyQ*
```

```
Output
```

Name	Value
-----	-----
MyQueue	myData

Wildcards (*) are supported in `Get-OutputBinding`.

Logging

Logging in PowerShell functions works like regular PowerShell logging. You can use the logging cmdlets to write to each output stream. Each cmdlet maps to a log level used by Functions.

Functions logging level	Logging cmdlet
Error	<code>Write-Error</code>
Warning	<code>Write-Warning</code>
Information	<code>Write-Information</code> <code>Write-Host</code> <code>Write-Output</code> Writes to the <code>Information</code> log level.
Debug	<code>Write-Debug</code>
Trace	<code>Write-Progress</code> <code>Write-Verbose</code>

In addition to these cmdlets, anything written to the pipeline is redirected to the `Information` log level and displayed with the default PowerShell formatting.

 **Important**

Using the `Write-Verbose` or `Write-Debug` cmdlets is not enough to see verbose and debug level logging. You must also configure the log level threshold, which declares what level of logs you actually care about. To learn more, see [Configure the function app log level](#).

Configure the function app log level

Azure Functions lets you define the threshold level to make it easy to control the way Functions writes to the logs. To set the threshold for all traces written to the console, use the `logging.logLevel.default` property in the [host.json file](#). This setting applies to all functions in your function app.

The following example sets the threshold to enable verbose logging for all functions, but sets the threshold to enable debug logging for a function named `MyFunction`:

JSON

```
{  
  "logging": {  
    "logLevel": {  
      "Function.MyFunction": "Debug",  
      "default": "Trace"  
    }  
  }  
}
```

For more information, see [host.json reference](#).

Viewing the logs

If your Function App is running in Azure, you can use Application Insights to monitor it. Read [monitoring Azure Functions](#) to learn more about viewing and querying function logs.

If you're running your Function App locally for development, logs default to the file system. To see the logs in the console, set the `AZURE_FUNCTIONS_ENVIRONMENT` environment variable to `Development` before starting the Function App.

Triggers and bindings types

There are a number of triggers and bindings available to you to use with your function app. The full list of triggers and bindings [can be found here](#).

All triggers and bindings are represented in code as a few real data types:

- Hashtable
- string
- byte[]
- int
- double
- HttpRequestContext
- HttpResponseMessage

The first five types in this list are standard .NET types. The last two are used only by the [HttpTrigger trigger](#).

Each binding parameter in your functions must be one of these types.

HTTP triggers and bindings

HTTP and webhook triggers and HTTP output bindings use request and response objects to represent the HTTP messaging.

Request object

The request object that's passed into the script is of the type `HttpRequestContext`, which has the following properties:

Property	Description	Type
<code>Body</code>	An object that contains the body of the request. <code>Body</code> is serialized into the best type based on the data. For example, if the data is JSON, it's passed in as a hashtable. If the data is a string, it's passed in as a string.	object
<code>Headers</code>	A dictionary that contains the request headers.	<code>Dictionary<string,string></code> *
<code>Method</code>	The HTTP method of the request.	string
<code>Params</code>	An object that contains the routing parameters of the request.	<code>Dictionary<string,string></code> *
<code>Query</code>	An object that contains the query parameters.	<code>Dictionary<string,string></code> *
<code>Uri</code>	The URL of the request.	string

* All `Dictionary<string,string>` keys are case-insensitive.

Response object

The response object that you should send back is of the type `HttpContext`, which has the following properties:

Property	Description	Type
<code>Body</code>	An object that contains the body of the response.	object
<code>ContentType</code>	A short hand for setting the content type for the response.	string
<code>Headers</code>	An object that contains the response headers.	Dictionary or Hashtable
<code>StatusCode</code>	The HTTP status code of the response.	string or int

Accessing the request and response

When you work with HTTP triggers, you can access the HTTP request the same way you would with any other input binding. It's in the `param` block.

Use an `HttpContext` object to return a response, as shown in the following:

`function.json`

JSON

```
{
  "bindings": [
    {
      "type": "httpTrigger",
      "direction": "in",
      "authLevel": "anonymous"
    },
    {
      "type": "http",
      "direction": "out",
      "name": "Response"
    }
  ]
}
```

`run.ps1`

PowerShell

```
param($req, $TriggerMetadata)

$name = $req.Query.Name

Push-OutputBinding -Name Response -Value ([HttpResponseContext]@{
    StatusCode = [System.Net.HttpStatusCode]::OK
    Body = "Hello $name!"
})
```

The result of invoking this function would be:

```
PS > irm http://localhost:5001?Name=Functions
Hello Functions!
```

Type-casting for triggers and bindings

For certain bindings like the blob binding, you're able to specify the type of the parameter.

For example, to have data from Blob storage supplied as a string, add the following type cast to my `param` block:

PowerShell

```
param([string] $myBlob)
```

PowerShell profile

In PowerShell, there's the concept of a PowerShell profile. If you're not familiar with PowerShell profiles, see [About profiles](#).

In PowerShell Functions, the profile script is executed once per PowerShell worker instance in the app when first deployed and after being idled ([cold start](#)). When concurrency is enabled by setting the `PSWorkerInProcConcurrencyUpperBound` value, the profile script is run for each runspace created.

When you create a function app using tools, such as Visual Studio Code and Azure Functions Core Tools, a default `profile.ps1` is created for you. The default profile is maintained [on the Core Tools GitHub repository](#) and contains:

- Automatic MSI authentication to Azure.

- The ability to turn on the Azure PowerShell `AzureRM` PowerShell aliases if you would like.

PowerShell versions

The following table shows the PowerShell versions available to each major version of the Functions runtime, and the .NET version required:

Functions version	PowerShell version	.NET version
4.x	PowerShell 7.2	.NET 6

You can see the current version by printing `$PSVersionTable` from any function.

To learn more about Azure Functions runtime support policy, please refer to this [article](#)

Running local on a specific version

Support for PowerShell 7.0 in Azure Functions has ended on 3 December 2022. To use PowerShell 7.2 when running locally, you need to add the setting

`"FUNCTIONS_WORKER_RUNTIME_VERSION" : "7.2"` to the `Values` array in the `local.setting.json` file in the project root. When running locally on PowerShell 7.2, your `local.settings.json` file looks like the following example:

```
JSON

{
  "IsEncrypted": false,
  "Values": {
    "AzureWebJobsStorage": "",
    "FUNCTIONS_WORKER_RUNTIME": "powershell",
    "FUNCTIONS_WORKER_RUNTIME_VERSION" : "7.2"
  }
}
```

ⓘ Note

In PowerShell Functions, the value "`~7`" for `FUNCTIONS_WORKER_RUNTIME_VERSION` refers to "`7.0.x`". We do not automatically upgrade PowerShell Function apps that have "`~7`" to "`7.2`". Going forward, for PowerShell Function Apps, we will require that apps specify both the major and minor version they want to target. Hence, it is necessary to mention "`7.2`" if you want to target "`7.2.x`"

Changing the PowerShell version

Support for PowerShell 7.0 in Azure Functions has ended on 3 December 2022. To upgrade your Function App to PowerShell 7.2, ensure the value of FUNCTIONS_EXTENSION_VERSION is set to ~4. To learn how to do this, see [View and update the current runtime version](#).

Use the following steps to change the PowerShell version used by your function app. You can do this either in the Azure portal or by using PowerShell.

Portal

1. In the [Azure portal](#), browse to your function app.
2. Under **Settings**, choose **Configuration**. In the **General settings** tab, locate the **PowerShell version**.

The screenshot shows the Azure Functions Configuration page for the 'AzureFunctions-PowerShell' function app. The 'General settings' tab is selected. In the 'Stack settings' section, the 'PowerShell Core Version' dropdown is open, showing three options: 'PowerShell 7.2' (selected), 'PowerShell 7.2', and 'PowerShell 7.0'. A red box highlights the 'Save' button at the top right of the configuration pane. Another red box highlights the 'General settings' tab. A third red box highlights the 'Configuration' link in the left sidebar under the 'Settings' category. A red arrow points from the 'PowerShell 7.2' option in the dropdown to the selected item.

3. Choose your desired **PowerShell Core version** and select **Save**. When warned about the pending restart choose **Continue**. The function app restarts on the chosen PowerShell version.

The function app restarts after the change is made to the configuration.

Dependency management

Functions lets you leverage [PowerShell gallery](#) for managing dependencies. With dependency management enabled, the requirements.psd1 file is used to automatically download required modules. You enable this behavior by setting the `managedDependency` property to `true` in the root of the [host.json file](#), as in the following example:

JSON

```
{  
    "managedDependency": {  
        "enabled": true  
    }  
}
```

When you create a new PowerShell functions project, dependency management is enabled by default, with the Azure [Az module](#) included. The maximum number of modules currently supported is 10. The supported syntax is `MajorNumber.*` or exact module version, as shown in the following requirements.psd1 example:

PowerShell

```
@{  
    Az = '1.*'  
   SqlServer = '21.1.18147'  
}
```

When you update the requirements.psd1 file, updated modules are installed after a restart.

Target specific versions

You may want to target a specific version of a module in your requirements.psd1 file. For example, if you wanted to use an older version of Az.Accounts than the one in the included Az module, you would need to target a specific version as shown in the following example:

PowerShell

```
@{  
    'Az.Accounts' = '1.9.5'  
}
```

In this case, you also need to add an import statement to the top of your profile.ps1 file, which looks like the following example:

PowerShell

```
Import-Module Az.Accounts -RequiredVersion '1.9.5'
```

In this way, the older version of the Az.Account module is loaded first when the function is started.

Dependency management considerations

The following considerations apply when using dependency management:

- Managed dependencies require access to <https://www.powershellgallery.com> to download modules. When running locally, make sure that the runtime can access this URL by adding any required firewall rules.
- Managed dependencies currently don't support modules that require the user to accept a license, either by accepting the license interactively, or by providing `-AcceptLicense` switch when invoking `Install-Module`.

Dependency management app settings

The following application settings can be used to change how the managed dependencies are downloaded and installed.

Function App setting	Default value	Description
MDMaxBackgroundUpgradePeriod	7.00:00:00 (seven days)	Controls the background update period for PowerShell function apps. To learn more, see MDMaxBackgroundUpgradePeriod .
MDSnapshotCheckPeriod	01:00:00 (one hour)	Specifies how often each PowerShell worker checks whether managed dependency upgrades have been installed. To learn more, see MDSnapshotCheckPeriod .
MDMinBackgroundUpgradePeriod	1.00:00:00 (one day)	The period of time after a previous upgrade check before another upgrade check is started. To learn more, see MDMinBackgroundUpgradePeriod .

Essentially, your app upgrade starts within `MDMaxBackgroundUpgradePeriod`, and the upgrade process completes within approximately the `MDSnapshotCheckPeriod`.

Custom modules

Leveraging your own custom modules in Azure Functions differs from how you would do it normally for PowerShell.

On your local computer, the module gets installed in one of the globally available folders in your `$env:PSModulePath`. When running in Azure, you don't have access to the modules installed on your machine. This means that the `$env:PSModulePath` for a PowerShell function app differs from `$env:PSModulePath` in a regular PowerShell script.

In Functions, `PSModulePath` contains two paths:

- A `Modules` folder that exists at the root of your function app.
- A path to a `Modules` folder that is controlled by the PowerShell language worker.

Function app-level modules folder

To use custom modules, you can place modules on which your functions depend in a `Modules` folder. From this folder, modules are automatically available to the functions runtime. Any function in the function app can use these modules.

ⓘ Note

Modules specified in the `requirements.psd1` file are automatically downloaded and included in the path so you don't need to include them in the modules folder. These are stored locally in the `$env:LOCALAPPDATA/AzureFunctions` folder and in the `/data/ManagedDependencies` folder when run in the cloud.

To take advantage of the custom module feature, create a `Modules` folder in the root of your function app. Copy the modules you want to use in your functions to this location.

PowerShell

```
mkdir ./Modules  
Copy-Item -Path /mymodules/mycustommodule -Destination ./Modules -Recurse
```

With a `Modules` folder, your function app should have the following folder structure:

```
PSFunctionApp  
| - MyFunction
```

```
| | - run.ps1
| | - function.json
| - Modules
| | - MyCustomModule
| | - MyOtherCustomModule
| | - MySpecialModule.psm1
| - local.settings.json
| - host.json
| - requirements.psd1
```

When you start your function app, the PowerShell language worker adds this `Modules` folder to the `$env:PSModulePath` so that you can rely on module autoloading just as you would in a regular PowerShell script.

Language worker level modules folder

Several modules are commonly used by the PowerShell language worker. These modules are defined in the last position of `PSModulePath`.

The current list of modules is as follows:

- [Microsoft.PowerShell.Archive](#) : module used for working with archives, like `.zip`, `.nupkg`, and others.
- `ThreadJob`: A thread-based implementation of the PowerShell job APIs.

By default, Functions uses the most recent version of these modules. To use a specific module version, put that specific version in the `Modules` folder of your function app.

Environment variables

In Functions, [app settings](#), such as service connection strings, are exposed as environment variables during execution. You can access these settings using `$env:NAME_OF_ENV_VAR`, as shown in the following example:

PowerShell

```
param($myTimer)

Write-Host "PowerShell timer trigger function ran! $(Get-Date)"
Write-Host $env:AzureWebJobsStorage
Write-Host $env:WEBSITE_SITE_NAME
```

There are several ways that you can add, update, and delete function app settings:

- In the Azure portal.
- By using the Azure CLI.
- By using Azure PowerShell.

Changes to function app settings require your function app to be restarted.

When running locally, app settings are read from the [local.settings.json](#) project file.

Concurrency

By default, the Functions PowerShell runtime can only process one invocation of a function at a time. However, this concurrency level might not be sufficient in the following situations:

- When you're trying to handle a large number of invocations at the same time.
- When you have functions that invoke other functions inside the same function app.

There are a few concurrency models that you could explore depending on the type of workload:

- Increase `FUNCTIONS_WORKER_PROCESS_COUNT`. This allows handling function invocations in multiple processes within the same instance, which introduces certain CPU and memory overhead. In general, I/O-bound functions will not suffer from this overhead. For CPU-bound functions, the impact may be significant.
- Increase the `PSWorkerInProcConcurrencyUpperBound` app setting value. This allows creating multiple runspaces within the same process, which significantly reduces CPU and memory overhead.

You set these environment variables in the [app settings](#) of your function app.

Depending on your use case, Durable Functions may significantly improve scalability. To learn more, see [Durable Functions application patterns](#).

ⓘ Note

You might get "requests are being queued due to no available runspaces" warnings, please note that this is not an error. The message is telling you that requests are being queued and they will be handled when the previous requests are completed.

Considerations for using concurrency

PowerShell is a *single-threaded* scripting language by default. However, concurrency can be added by using multiple PowerShell runspaces in the same process. The number of runspaces created, and therefore the number of concurrent threads per worker, is limited by the `PSWorkerInProcConcurrencyUpperBound` application setting. By default, the number of runspaces is set to 1,000 in version 4.x of the Functions runtime. In versions 3.x and below, the maximum number of runspaces is set to 1. The throughput will be impacted by the amount of CPU and memory available in the selected plan.

Azure PowerShell uses some *process-level* contexts and state to help save you from excess typing. However, if you turn on concurrency in your function app and invoke actions that change state, you could end up with race conditions. These race conditions are difficult to debug because one invocation relies on a certain state and the other invocation changed the state.

There's immense value in concurrency with Azure PowerShell, since some operations can take a considerable amount of time. However, you must proceed with caution. If you suspect that you're experiencing a race condition, set the `PSWorkerInProcConcurrencyUpperBound` app setting to `1` and instead use [language worker process level isolation](#) for concurrency.

Configure function `scriptFile`

By default, a PowerShell function is executed from `run.ps1`, a file that shares the same parent directory as its corresponding `function.json`.

The `scriptFile` property in the `function.json` can be used to get a folder structure that looks like the following example:

```
FunctionApp
| - host.json
| - myFunction
| | - function.json
| - lib
| | - PSFunction.ps1
```

In this case, the `function.json` for `myFunction` includes a `scriptFile` property referencing the file with the exported function to run.

JSON

```
{  
  "scriptFile": "../lib/PSFunction.ps1",  
  "bindings": [  
    // ...  
  ]  
}
```

Use PowerShell modules by configuring an entryPoint

This article has shown PowerShell functions in the default `run.ps1` script file generated by the templates. However, you can also include your functions in PowerShell modules. You can reference your specific function code in the module by using the `scriptFile` and `entryPoint` fields in the `function.json` configuration file.`

In this case, `entryPoint` is the name of a function or cmdlet in the PowerShell module referenced in `scriptFile`.

Consider the following folder structure:

```
FunctionApp  
| - host.json  
| - myFunction  
| | - function.json  
| - lib  
| | - PSFunction.psm1
```

Where `PSFunction.psm1` contains:

```
PowerShell  
  
function Invoke-PSTestFunc {  
    param($InputBinding, $TriggerMetadata)  
  
    Push-OutputBinding -Name OutputBinding -Value "output"  
}  
  
Export-ModuleMember -Function "Invoke-PSTestFunc"
```

In this example, the configuration for `myFunction` includes a `scriptFile` property that references `PSFunction.psm1`, which is a PowerShell module in another folder. The

`entryPoint` property references the `Invoke-PSTestFunc` function, which is the entry point in the module.

JSON

```
{  
  "scriptFile": "../lib/PSFunction.psm1",  
  "entryPoint": "Invoke-PSTestFunc",  
  "bindings": [  
    // ...  
  ]  
}
```

With this configuration, the `Invoke-PSTestFunc` gets executed exactly as a `run.ps1` would.

Considerations for PowerShell functions

When you work with PowerShell functions, be aware of the considerations in the following sections.

Cold Start

When developing Azure Functions in the [serverless hosting model](#), cold starts are a reality. *Cold start* refers to period of time it takes for your function app to start running to process a request. Cold start happens more frequently in the Consumption plan because your function app gets shut down during periods of inactivity.

Bundle modules instead of using Install-Module

Your script is run on every invocation. Avoid using `Install-Module` in your script. Instead use `Save-Module` before publishing so that your function doesn't have to waste time downloading the module. If cold starts are impacting your functions, consider deploying your function app to an [App Service plan](#) set to *always on* or to a [Premium plan](#).

Azure Functions Python developer guide

Article • 07/30/2024

This guide is an introduction to developing Azure Functions by using Python. The article assumes that you've already read the [Azure Functions developers guide](#).

Important

This article supports both the v1 and v2 programming model for Python in Azure Functions. The Python v1 model uses a `functions.json` file to define functions, and the new v2 model lets you instead use a decorator-based approach. This new approach results in a simpler file structure, and it's more code-centric. Choose the **v2** selector at the top of the article to learn about this new programming model.

As a Python developer, you might also be interested in these topics:

Get started

- [Visual Studio Code](#): Create your first Python app using Visual Studio Code.
- [Terminal or command prompt](#): Create your first Python app from the command prompt using Azure Functions Core Tools.
- [Samples](#): Review some existing Python apps in the Learn samples browser.

Development options

Both Python Functions programming models support local development in one of the following environments:

Python v2 programming model:

- [Visual Studio Code](#)
- [Terminal or command prompt](#)

Python v1 programming model:

- [Visual Studio Code](#)
- [Terminal or command prompt](#)

You can also create Python v1 functions in the Azure portal.

Tip

Although you can develop your Python-based Azure functions locally on Windows, Python is supported only on a Linux-based hosting plan when it's running in Azure. For more information, see the [list of supported operating system/runtime combinations](#).

Programming model

Azure Functions expects a function to be a stateless method in your Python script that processes input and produces output. By default, the runtime expects the method to be implemented as a global method in the *function_app.py* file.

Triggers and bindings can be declared and used in a function in a decorator based approach. They're defined in the same file, *function_app.py*, as the functions. As an example, the following *function_app.py* file represents a function trigger by an HTTP request.

Python

```
@app.function_name(name="HttpTrigger1")
@app.route(route="req")
def main(req):
    user = req.params.get("user")
    return f"Hello, {user}!"
```

You can also explicitly declare the attribute types and return type in the function by using Python type annotations. Doing so helps you use the IntelliSense and autocomplete features that are provided by many Python code editors.

Python

```
import azure.functions as func

app = func.FunctionApp()

@app.function_name(name="HttpTrigger1")
@app.route(route="req")
def main(req: func.HttpRequest) -> str:
    user = req.params.get("user")
    return f"Hello, {user}!"
```

To learn about known limitations with the v2 model and their workarounds, see [Troubleshoot Python errors in Azure Functions](#).

Alternative entry point

The entry point is only in the *function_app.py* file. However, you can reference functions within the project in *function_app.py* by using [blueprints](#) or by importing.

Folder structure

The recommended folder structure for a Python functions project looks like the following example:

```
Windows Command Prompt

<project_root>/
| - .venv/
| - .vscode/
| - function_app.py
| - additional_functions.py
| - tests/
| | - test_my_function.py
| - .funcignore
| - host.json
| - local.settings.json
| - requirements.txt
| - Dockerfile
```

The main project folder, *<project_root>*, can contain the following files:

- *.venv/*: (Optional) Contains a Python virtual environment that's used by local development.
- *.vscode/*: (Optional) Contains the stored Visual Studio Code configuration. To learn more, see [Visual Studio Code settings](#).
- *function_app.py*: The default location for all functions and their related triggers and bindings.
- *additional_functions.py*: (Optional) Any other Python files that contain functions (usually for logical grouping) that are referenced in *function_app.py* through blueprints.
- *tests/*: (Optional) Contains the test cases of your function app.
- *.funcignore*: (Optional) Declares files that shouldn't get published to Azure. Usually, this file contains *.vscode/* to ignore your editor setting, *.venv/* to ignore local

Python virtual environment, `tests/` to ignore test cases, and `local.settings.json` to prevent local app settings being published.

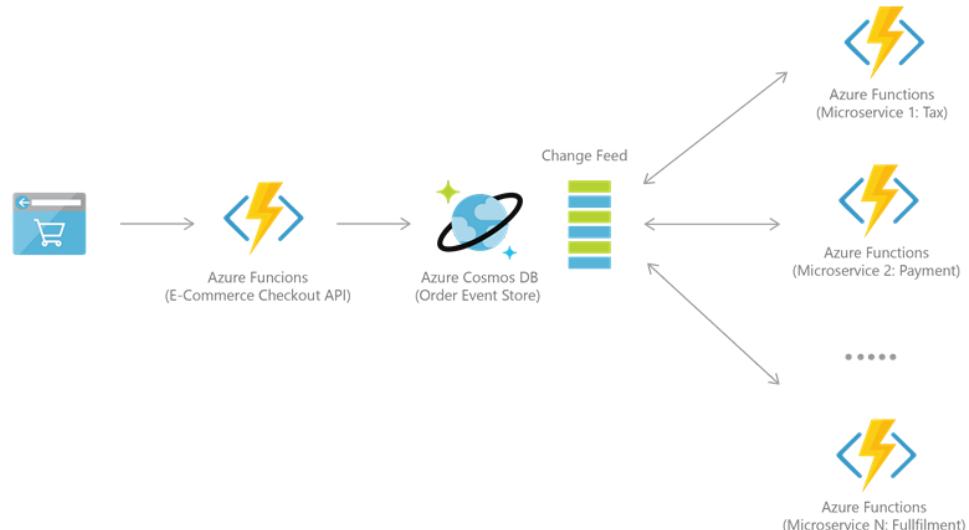

- `host.json`: Contains configuration options that affect all functions in a function app instance. This file does get published to Azure. Not all options are supported when running locally. To learn more, see [host.json](#).
- `local.settings.json`: Used to store app settings and connection strings when it's running locally. This file doesn't get published to Azure. To learn more, see [local.settings.json](#).
- `requirements.txt`: Contains the list of Python packages the system installs when it publishes to Azure.
- `Dockerfile`: (Optional) Used when publishing your project in a [custom container](#).

When you deploy your project to a function app in Azure, the entire contents of the main project folder, `<project_root>`, should be included in the package, but not the folder itself, which means that `host.json` should be in the package root. We recommend that you maintain your tests in a folder along with other functions (in this example, `tests/`). For more information, see [Unit testing](#).

Connect to a database

Azure Functions integrates well with [Azure Cosmos DB](#) for many [use cases](#), including IoT, ecommerce, gaming, etc.

For example, for [event sourcing](#), the two services are integrated to power event-driven architectures using Azure Cosmos DB's [change feed](#) functionality. The change feed provides downstream microservices the ability to reliably and incrementally read inserts and updates (for example, order events). This functionality can be used to provide a persistent event store as a message broker for state-changing events and drive order processing workflow between many microservices (which can be implemented as [serverless Azure Functions](#)).

To connect to Azure Cosmos DB, first [create an account, database, and container](#). Then you can connect your function code to Azure Cosmos DB using [trigger and bindings](#), like this [example](#).

To implement more complex app logic, you can also use the Python library for Cosmos DB. An asynchronous I/O implementation looks like this:

Python

```

pip install azure-cosmos
pip install aiohttp

from azure.cosmos.aio import CosmosClient
from azure.cosmos import exceptions
from azure.cosmos.partition_key import PartitionKey
import asyncio

# Replace these values with your Cosmos DB connection information
endpoint = "https://azure-cosmos-nosql.documents.azure.com:443/"
key = "master_key"
database_id = "cosmicwerx"
container_id = "cosmiccontainer"
partition_key = "/partition_key"

# Set the total throughput (RU/s) for the database and container
database_throughput = 1000

# Singleton CosmosClient instance
client = CosmosClient(endpoint, credential=key)

# Helper function to get or create database and container
async def get_or_create_container(client, database_id, container_id,
partition_key):

```

```

database = await client.create_database_if_not_exists(id=database_id)
print(f'Database "{database_id}" created or retrieved successfully.')

    container = await
database.create_container_if_not_exists(id=container_id,
partition_key=PartitionKey(path=partition_key))
    print(f'Container with id "{container_id}" created')

return container

async def create_products():
    container = await get_or_create_container(client, database_id,
container_id, partition_key)
    for i in range(10):
        await container.upsert_item({
            'id': f'item{i}',
            'productName': 'Widget',
            'productModel': f'Model {i}'
        })

async def get_products():
    items = []
    container = await get_or_create_container(client, database_id,
container_id, partition_key)
    async for item in container.read_all_items():
        items.append(item)
    return items

async def query_products(product_name):
    container = await get_or_create_container(client, database_id,
container_id, partition_key)
    query = f"SELECT * FROM c WHERE c.productName = '{product_name}'"
    items = []
    async for item in container.query_items(query=query,
enable_cross_partition_query=True):
        items.append(item)
    return items

async def main():
    await create_products()
    all_products = await get_products()
    print('All Products:', all_products)

    queried_products = await query_products('Widget')
    print('Queried Products:', queried_products)

if __name__ == "__main__":
    asyncio.run(main())

```

Blueprints

The Python v2 programming model introduces the concept of *blueprints*. A blueprint is a new class that's instantiated to register functions outside of the core function application. The functions registered in blueprint instances aren't indexed directly by the function runtime. To get these blueprint functions indexed, the function app needs to register the functions from blueprint instances.

Using blueprints provides the following benefits:

- Lets you break up the function app into modular components, which enables you to define functions in multiple Python files and divide them into different components per file.
- Provides extensible public function app interfaces to build and reuse your own APIs.

The following example shows how to use blueprints:

First, in an *http_blueprint.py* file, an HTTP-triggered function is first defined and added to a blueprint object.

Python

```
import logging

import azure.functions as func

bp = func.Blueprint()

@bp.route(route="default_template")
def default_template(req: func.HttpRequest) -> func.HttpResponse:
    logging.info('Python HTTP trigger function processed a request.')

    name = req.params.get('name')
    if not name:
        try:
            req_body = req.get_json()
        except ValueError:
            pass
        else:
            name = req_body.get('name')

    if name:
        return func.HttpResponse(
            f"Hello, {name}. This HTTP-triggered function "
            f"executed successfully.")
    else:
        return func.HttpResponse(
            "This HTTP-triggered function executed successfully. "
            "Pass a name in the query string or in the request body for a"
            " personalized response.",
```

```
    status_code=200
)
```

Next, in the `function_app.py` file, the `blueprint` object is imported and its functions are registered to the function app.

Python

```
import azure.functions as func
from http_blueprint import bp

app = func.FunctionApp()

app.register_functions(bp)
```

ⓘ Note

Durable Functions also supports blueprints. To create blueprints for Durable Functions apps, register your orchestration, activity, and entity triggers and client bindings using the [azure-functions-durable](#) Blueprint class, as shown [here](#). The resulting blueprint can then be registered as normal. See our [sample](#) for an example.

Triggers and inputs

Inputs are divided into two categories in Azure Functions: trigger input and other input. Although they're defined using different decorators, their usage is similar in Python code. Connection strings or secrets for trigger and input sources map to values in the `local.settings.json` file when they're running locally, and they map to the application settings when they're running in Azure.

As an example, the following code demonstrates how to define a Blob Storage input binding:

JSON

```
// local.settings.json
{
  "IsEncrypted": false,
  "Values": {
    "FUNCTIONS_WORKER_RUNTIME": "python",
    "STORAGE_CONNECTION_STRING": "<AZURE_STORAGE_CONNECTION_STRING>",
    "AzureWebJobsStorage": "<azure-storage-connection-string>",
    "AzureWebJobsFeatureFlags": "EnableWorkerIndexing"
```

```
}
```

Python

```
# function_app.py
import azure.functions as func
import logging

app = func.FunctionApp()

@app.route(route="req")
@app.read_blob(arg_name="obj", path="samples/{id}",
               connection="STORAGE_CONNECTION_STRING")
def main(req: func.HttpRequest, obj: func.InputStream):
    logging.info(f'Python HTTP-triggered function processed: {obj.read()}')
```

When the function is invoked, the HTTP request is passed to the function as `req`. An entry is retrieved from the Azure Blob Storage account based on the *ID* in the route URL and made available as `obj` in the function body. Here, the specified storage account is the connection string that's found in the `STORAGE_CONNECTION_STRING` app setting.

For data intensive binding operations, you may want to use a separate storage account. For more information, see [Storage account guidance](#).

SDK type bindings (preview)

For select triggers and bindings, you can work with data types implemented by the underlying Azure SDKs and frameworks. These *SDK type bindings* let you interact with binding data as if you were using the underlying service SDK.

Functions supports Python SDK type bindings for Azure Blob storage, which lets you work with blob data using the underlying `BlobClient` type.

ⓘ Important

SDK type bindings support for Python is currently in preview:

- You must use the Python v2 programming model.
- Currently, only synchronous SDK types are supported.

Prerequisites

- Azure Functions runtime version version 4.34, or a later version.
- Python ↗ version 3.9, or a later supported version.

Enable SDK type bindings for the Blob storage extension

1. Add the `azurefunctions-extensions-bindings-blob` extension package to the `requirements.txt` file in the project, which should include at least these packages:

```
text  
  
azure-functions  
azurefunctions-extensions-bindings-blob
```

2. Add this code to the `function_app.py` file in the project, which imports the SDK type bindings:

```
Python  
  
import azurefunctions.extensions.bindings.blob as blob
```

SDK type bindings examples

This example shows how to get the `BlobClient` from both a Blob storage trigger (`blob_trigger`) and from the input binding on an HTTP trigger (`blob_input`):

```
Python  
  
import logging  
  
import azure.functions as func  
import azurefunctions.extensions.bindings.blob as blob  
  
app = func.FunctionApp(http_auth_level=func.AuthLevel.ANONYMOUS)  
  
@app.blob_trigger(  
    arg_name="client", path="PATH/TO/BLOB", connection="AzureWebJobsStorage"  
)  
def blob_trigger(client: blob.BlobClient):  
    logging.info(  
        f"Python blob trigger function processed blob \n"  
        f"Properties: {client.get_blob_properties()}\n"  
        f"Blob content head: {client.download_blob().read(size=1)}"  
    )  
  
@app.route(route="file")
```

```
@app.blob_input(  
    arg_name="client", path="PATH/TO/BLOB", connection="AzureWebJobsStorage"  
)  
def blob_input(req: func.HttpRequest, client: blob.BlobClient):  
    logging.info(  
        f"Python blob input function processed blob \n"  
        f"Properties: {client.get_blob_properties()}\n"  
        f"Blob content head: {client.download_blob().read(size=1)}"  
    )  
    return "ok"
```

You can view other SDK type bindings samples for Blob storage in the Python extensions repository:

- [ContainerClient type ↗](#)
- [StorageStreamDownloader type ↗](#)

HTTP streams (preview)

HTTP streams lets you accept and return data from your HTTP endpoints using FastAPI request and response APIs enabled in your functions. These APIs lets the host process large data in HTTP messages as chunks instead of reading an entire message into memory.

This feature makes it possible to handle large data stream, OpenAI integrations, deliver dynamic content, and support other core HTTP scenarios requiring real-time interactions over HTTP. You can also use FastAPI response types with HTTP streams. Without HTTP streams, the size of your HTTP requests and responses are limited by memory restrictions that can be encountered when processing entire message payloads all in memory.

ⓘ Important

HTTP streams support for Python is currently in preview and requires you to use the Python v2 programming model.

Prerequisites

- [Azure Functions runtime](#) version 4.34.1, or a later version.
- [Python ↗](#) version 3.8, or a later [supported version](#).

Enable HTTP streams

HTTP streams are disabled by default. You need to enable this feature in your application settings and also update your code to use the FastAPI package. Note that when enabling HTTP streams, the function app will default to using HTTP streaming, and the original HTTP functionality will not work.

1. Add the `azurefunctions-extensions-http-fastapi` extension package to the `requirements.txt` file in the project, which should include at least these packages:

```
text  
  
azure-functions  
azurefunctions-extensions-http-fastapi
```

2. Add this code to the `function_app.py` file in the project, which imports the FastAPI extension:

```
Python  
  
from azurefunctions.extensions.http.fastapi import Request,  
StreamingResponse
```

3. When you deploy to Azure, add the following [application setting](#) in your function app:

```
"PYTHON_ENABLE_INIT_INDEXING": "1"
```

If you are deploying to Linux Consumption, also add

```
"PYTHON_ISOLATE_WORKER_DEPENDENCIES": "1"
```

When running locally, you also need to add these same settings to the `local.settings.json` project file.

HTTP streams examples

After you enable the HTTP streaming feature, you can create functions that stream data over HTTP.

This example is an HTTP triggered function that streams HTTP response data. You might use these capabilities to support scenarios like sending event data through a pipeline for real time visualization or detecting anomalies in large sets of data and providing instant notifications.

```
Python
```

```

import time

import azure.functions as func
from azurefunctions.extensions.http.fastapi import Request,
StreamingResponse

app = func.FunctionApp(http_auth_level=func.AuthLevel.ANONYMOUS)

def generate_sensor_data():
    """Generate real-time sensor data."""
    for i in range(10):
        # Simulate temperature and humidity readings
        temperature = 20 + i
        humidity = 50 + i
        yield f"data: {{'temperature': {temperature}, 'humidity': {humidity}}}\n\n"
    time.sleep(1)

@app.route(route="stream", methods=[func.HttpMethod.GET])
async def stream_sensor_data(req: Request) -> StreamingResponse:
    """Endpoint to stream real-time sensor data."""
    return StreamingResponse(generate_sensor_data(), media_type="text/event-stream")

```

This example is an HTTP triggered function that receives and processes streaming data from a client in real time. It demonstrates streaming upload capabilities that can be helpful for scenarios like processing continuous data streams and handling event data from IoT devices.

Python

```

import azure.functions as func
from azurefunctions.extensions.http.fastapi import JSONResponse, Request

app = func.FunctionApp(http_auth_level=func.AuthLevel.ANONYMOUS)

@app.route(route="streaming_upload", methods=[func.HttpMethod.POST])
async def streaming_upload(req: Request) -> JSONResponse:
    """Handle streaming upload requests."""
    # Process each chunk of data as it arrives
    async for chunk in req.stream():
        process_data_chunk(chunk)

    # Once all data is received, return a JSON response indicating
    # successful processing
    return JSONResponse({"status": "Data uploaded and processed
successfully"})

```

```
def process_data_chunk(chunk: bytes):
    """Process each data chunk."""
    # Add custom processing logic here
    pass
```

Calling HTTP streams

You must use an HTTP client library to make streaming calls to a function's FastAPI endpoints. The client tool or browser you're using might not natively support streaming or could only return the first chunk of data.

You can use a client script like this to send streaming data to an HTTP endpoint:

Python

```
import httpx # Be sure to add 'httpx' to 'requirements.txt'
import asyncio

async def stream_generator(file_path):
    chunk_size = 2 * 1024 # Define your own chunk size
    with open(file_path, 'rb') as file:
        while chunk := file.read(chunk_size):
            yield chunk
            print(f"Sent chunk: {len(chunk)} bytes")

async def stream_to_server(url, file_path):
    timeout = httpx.Timeout(60.0, connect=60.0)
    async with httpx.AsyncClient(timeout=timeout) as client:
        response = await client.post(url,
content=stream_generator(file_path))
    return response

async def stream_response(response):
    if response.status_code == 200:
        async for chunk in response.aiter_raw():
            print(f"Received chunk: {len(chunk)} bytes")
    else:
        print(f"Error: {response}")

async def main():
    print('helloworld')
    # Customize your streaming endpoint served from core tool in variable
    'url' if different.
    url = 'http://localhost:7071/api/streaming_upload'
    file_path = r'<file path>'

    response = await stream_to_server(url, file_path)
    print(response)
```

```
if __name__ == "__main__":
    asyncio.run(main())
```

Outputs

Output can be expressed both in return value and output parameters. If there's only one output, we recommend using the return value. For multiple outputs, you'll have to use output parameters.

To produce multiple outputs, use the `set()` method provided by the `azure.functions.Out` interface to assign a value to the binding. For example, the following function can push a message to a queue and also return an HTTP response.

Python

```
# function_app.py
import azure.functions as func

app = func.FunctionApp()

@app.write_blob(arg_name="msg", path="output-container/{name}",
                connection="CONNECTION_STRING")
def test_function(req: func.HttpRequest,
                  msg: func.Out[str]) -> str:

    message = req.params.get('body')
    msg.set(message)
    return message
```

Logging

Access to the Azure Functions runtime logger is available via a root [logging](#) handler in your function app. This logger is tied to Application Insights and allows you to flag warnings and errors that occur during the function execution.

The following example logs an info message when the function is invoked via an HTTP trigger.

Python

```
import logging

def main(req):
    logging.info('Python HTTP trigger function processed a request.')
```

More logging methods are available that let you write to the console at different trace levels:

[+] Expand table

Method	Description
<code>critical(_message_)</code>	Writes a message with level CRITICAL on the root logger.
<code>error(_message_)</code>	Writes a message with level ERROR on the root logger.
<code>warning(_message_)</code>	Writes a message with level WARNING on the root logger.
<code>info(_message_)</code>	Writes a message with level INFO on the root logger.
<code>debug(_message_)</code>	Writes a message with level DEBUG on the root logger.

To learn more about logging, see [Monitor Azure Functions](#).

Logging from created threads

To see logs coming from your created threads, include the `context` argument in the function's signature. This argument contains an attribute `thread_local_storage` that stores a local `invocation_id`. This can be set to the function's current `invocation_id` to ensure the context is changed.

Python

```
import azure.functions as func
import logging
import threading

def main(req, context):
    logging.info('Python HTTP trigger function processed a request.')
    t = threading.Thread(target=log_function, args=(context,))
    t.start()

def log_function(context):
    context.thread_local_storage.invocation_id = context.invocation_id
    logging.info('Logging from thread.')
```

Log custom telemetry

By default, the Functions runtime collects logs and other telemetry data that are generated by your functions. This telemetry ends up as traces in Application Insights. Request and dependency telemetry for certain Azure services are also collected by default by [triggers and bindings](#).

To collect custom request and custom dependency telemetry outside of bindings, you can use the [OpenCensus Python Extensions](#). This extension sends custom telemetry data to your Application Insights instance. You can find a list of supported extensions at the [OpenCensus repository](#).

ⓘ Note

To use the OpenCensus Python extensions, you need to enable [Python worker extensions](#) in your function app by setting `PYTHON_ENABLE_WORKER_EXTENSIONS` to `1`. You also need to switch to using the Application Insights connection string by adding the [APPLICATIONINSIGHTS CONNECTION STRING](#) setting to your [application settings](#), if it's not already there.

text

```
// requirements.txt
...
opencensus-extension-azure-functions
opencensus-ext-requests
```

Python

```
import json
import logging

import requests
from opencensus.extension.azure.functions import OpenCensusExtension
from opencensus.trace import config_integration

config_integration.trace_integrations(['requests'])

OpenCensusExtension.configure()

def main(req, context):
    logging.info('Executing HttpTrigger with OpenCensus extension')

    # You must use contexttracer to create spans
    with context.tracer.span("parent"):
        response = requests.get(url='http://example.com')

    return json.dumps({
        'method': req.method,
```

```
'response': response.status_code,
'ctx_func_name': context.function_name,
'ctx_func_dir': context.function_directory,
'ctx_invocation_id': context.invocation_id,
'ctx_trace_context_Traceparent': context.trace_context.Traceparent,
'ctx_trace_context_Tracestate': context.trace_context.Tracestate,
'ctx_retry_context_RetryCount': context.retry_context.retry_count,
'ctx_retry_context_MaxRetryCount':
context.retry_context.max_retry_count,
})
```

HTTP trigger

The HTTP trigger is defined as a method that takes a named binding parameter, which is an `HttpRequest` object, and returns an `HttpResponse` object. You apply the `function_name` decorator to the method to define the function name, while the HTTP endpoint is set by applying the `route` decorator.

This example is from the HTTP trigger template for the Python v2 programming model, where the binding parameter name is `req`. It's the sample code that's provided when you create a function by using Azure Functions Core Tools or Visual Studio Code.

Python

```
@app.function_name(name="HttpTrigger1")
@app.route(route="hello")
def test_function(req: func.HttpRequest) -> func.HttpResponse:
    logging.info('Python HTTP trigger function processed a request.')

    name = req.params.get('name')
    if not name:
        try:
            req_body = req.get_json()
        except ValueError:
            pass
    else:
        name = req_body.get('name')

    if name:
        return func.HttpResponse(f"Hello, {name}. This HTTP-triggered
function executed successfully.")
    else:
        return func.HttpResponse(
            "This HTTP-triggered function executed successfully. Pass a
name in the query string or in the request body for a personalized
response.",
            status_code=200
        )
```

From the `HttpRequest` object, you can get request headers, query parameters, route parameters, and the message body. In this function, you obtain the value of the `name` query parameter from the `params` parameter of the `HttpRequest` object. You read the JSON-encoded message body by using the `get_json` method.

Likewise, you can set the `status_code` and `headers` for the response message in the returned `HttpResponse` object.

To pass in a name in this example, paste the URL that's provided when you're running the function, and then append it with `?name={name}`.

Web frameworks

You can use Asynchronous Server Gateway Interface (ASGI)-compatible and Web Server Gateway Interface (WSGI)-compatible frameworks, such as Flask and FastAPI, with your HTTP-triggered Python functions. You must first update the `host.json` file to include an HTTP `routePrefix`, as shown in the following example:

```
JSON

{
  "version": "2.0",
  "logging": {
    {
      "applicationInsights": {
        {
          "samplingSettings": {
            {
              "isEnabled": true,
              "excludedTypes": "Request"
            }
          }
        },
        "extensionBundle": {
          {
            "id": "Microsoft.Azure.Functions.ExtensionBundle",
            "version": "[2.*, 3.0.0)"
          },
          "extensions": {
            {
              "http": {
                {
                  "routePrefix": ""
                }
              }
            }
          }
        }
      }
    }
  }
}
```

The framework code looks like the following example:

ASGI

`AsgiFunctionApp` is the top-level function app class for constructing ASGI HTTP functions.

Python

```
# function_app.py

import azure.functions as func
from fastapi import FastAPI, Request, Response

fast_app = FastAPI()

@fast_app.get("/return_http_no_body")
async def return_http_no_body():
    return Response(content="", media_type="text/plain")

app = func.AsgiFunctionApp(app=fast_app,
                           http_auth_level=func.AuthLevel.ANONYMOUS)
```

Scaling and performance

For scaling and performance best practices for Python function apps, see the [Python scaling and performance](#) article.

Context

To get the invocation context of a function when it's running, include the `context` argument in its signature.

For example:

Python

```
import azure.functions

def main(req: azure.functions.HttpRequest,
        context: azure.functions.Context) -> str:
    return f'{context.invocation_id}'
```

The [Context](#) class has the following string attributes:

[+] [Expand table](#)

Attribute	Description
<code>function_directory</code>	The directory in which the function is running.
<code>function_name</code>	The name of the function.
<code>invocation_id</code>	The ID of the current function invocation.
<code>thread_local_storage</code>	The thread local storage of the function. Contains a local <code>invocation_id</code> for logging from created threads .
<code>trace_context</code>	The context for distributed tracing. For more information, see Trace Context .
<code>retry_context</code>	The context for retries to the function. For more information, see retry-policies .

Global variables

It isn't guaranteed that the state of your app will be preserved for future executions. However, the Azure Functions runtime often reuses the same process for multiple executions of the same app. To cache the results of an expensive computation, declare it as a global variable.

Python

```
CACHED_DATA = None

def main(req):
    global CACHED_DATA
    if CACHED_DATA is None:
        CACHED_DATA = load_json()

    # ... use CACHED_DATA in code
```

Environment variables

In Azure Functions, [application settings](#), such as service connection strings, are exposed as environment variables when they're running. There are two main ways to access these settings in your code.

Method	Description
<code>os.environ["myAppSetting"]</code>	Tries to get the application setting by key name, and raises an error when it's unsuccessful.
<code>os.getenv("myAppSetting")</code>	Tries to get the application setting by key name, and returns <code>null</code> when it's unsuccessful.

Both of these ways require you to declare `import os`.

The following example uses `os.environ["myAppSetting"]` to get the [application setting](#), with the key named `myAppSetting`:

Python

```
import logging
import os

import azure.functions as func

app = func.FunctionApp()

@app.function_name(name="HttpTrigger1")
@app.route(route="req")
def main(req: func.HttpRequest) -> func.HttpResponse:
    # Get the setting named 'myAppSetting'
    my_app_setting_value = os.environ["myAppSetting"]
    logging.info(f'My app setting value:{my_app_setting_value}')
```

For local development, application settings are [maintained in the `local.settings.json` file](#).

When you're using the new programming model, enable the following app setting in the `local.settings.json` file, as shown here:

JSON

```
"AzureWebJobsFeatureFlags": "EnableWorkerIndexing"
```

When you're deploying the function, this setting isn't created automatically. You must explicitly create this setting in your function app in Azure for it to run by using the v2 model.

Python version

Azure Functions supports the following Python versions:

[+] Expand table

Functions version	Python* versions
4.x	3.11 3.10 3.9 3.8 3.7
3.x	3.9 3.8 3.7

* Official Python distributions

To request a specific Python version when you create your function app in Azure, use the `--runtime-version` option of the [az functionapp create](#) command. The Functions runtime version is set by the `--functions-version` option. The Python version is set when the function app is created, and it can't be changed for apps running in a Consumption plan.

The runtime uses the available Python version when you run it locally.

Changing Python version

To set a Python function app to a specific language version, you need to specify the language and the version of the language in the `LinuxFxVersion` field in the site configuration. For example, to change the Python app to use Python 3.8, set `linuxFxVersion` to `python|3.8`.

To learn how to view and change the `linuxFxVersion` site setting, see [How to target Azure Functions runtime versions](#).

For more general information, see the [Azure Functions runtime support policy](#) and [Supported languages in Azure Functions](#).

Package management

When you're developing locally by using Core Tools or Visual Studio Code, add the names and versions of the required packages to the `requirements.txt` file, and then install them by using `pip`.

For example, you can use the following `requirements.txt` file and `pip` command to install the `requests` package from PyPI.

```
txt
```

```
requests==2.19.1
```

```
Bash
```

```
pip install -r requirements.txt
```

When running your functions in an [App Service plan](#), dependencies that you define in `requirements.txt` are given precedence over built-in Python modules, such as `logging`. This precedence can cause conflicts when built-in modules have the same names as directories in your code. When running in a [Consumption plan](#) or an [Elastic Premium plan](#), conflicts are less likely because your dependencies aren't prioritized by default.

To prevent issues running in an App Service plan, don't name your directories the same as any Python native modules and don't include Python native libraries in your project's `requirements.txt` file.

Publishing to Azure

When you're ready to publish, make sure that all your publicly available dependencies are listed in the `requirements.txt` file. You can locate this file at the root of your project directory.

You can find the project files and folders that are excluded from publishing, including the virtual environment folder, in the root directory of your project.

There are three build actions supported for publishing your Python project to Azure: remote build, local build, and builds using custom dependencies.

You can also use Azure Pipelines to build your dependencies and publish by using continuous delivery (CD). To learn more, see [Continuous delivery with Azure Pipelines](#).

Remote build

When you use remote build, dependencies that are restored on the server and native dependencies match the production environment. This results in a smaller deployment package to upload. Use remote build when you're developing Python apps on Windows.

If your project has custom dependencies, you can [use remote build with extra index URL](#).

Dependencies are obtained remotely based on the contents of the *requirements.txt* file. [Remote build](#) is the recommended build method. By default, Core Tools requests a remote build when you use the following [func azure functionapp publish](#) command to publish your Python project to Azure.

```
Bash
```

```
func azure functionapp publish <APP_NAME>
```

Remember to replace `<APP_NAME>` with the name of your function app in Azure.

The [Azure Functions Extension for Visual Studio Code](#) also requests a remote build by default.

Local build

Dependencies are obtained locally based on the contents of the *requirements.txt* file. You can prevent doing a remote build by using the following [func azure functionapp publish](#) command to publish with a local build:

```
command
```

```
func azure functionapp publish <APP_NAME> --build local
```

Remember to replace `<APP_NAME>` with the name of your function app in Azure.

When you use the `--build local` option, project dependencies are read from the *requirements.txt* file, and those dependent packages are downloaded and installed locally. Project files and dependencies are deployed from your local computer to Azure. This results in a larger deployment package being uploaded to Azure. If for some reason you can't get the *requirements.txt* file by using Core Tools, you must use the custom dependencies option for publishing.

We don't recommend using local builds when you're developing locally on Windows.

Custom dependencies

When your project has dependencies that aren't found in the [Python Package Index](#), there are two ways to build the project. The first way, the *build* method, depends on

how you build the project.

Remote build with extra index URL

When your packages are available from an accessible custom package index, use a remote build. Before you publish, be sure to [create an app setting](#) named `PIP_EXTRA_INDEX_URL`. The value for this setting is the URL of your custom package index. Using this setting tells the remote build to run `pip install` by using the `--extra-index-url` option. To learn more, see the [Python pip install documentation](#).

You can also use basic authentication credentials with your extra package index URLs. To learn more, see [Basic authentication credentials](#) in the Python documentation.

Install local packages

If your project uses packages that aren't publicly available to our tools, you can make them available to your app by putting them in the `__app__/python_packages` directory. Before you publish, run the following command to install the dependencies locally:

command

```
pip install --target="<PROJECT_DIR>/python_packages/lib/site-packages" -r requirements.txt
```

When you're using custom dependencies, you should use the `--no-build` publishing option, because you've already installed the dependencies into the project folder.

command

```
func azure functionapp publish <APP_NAME> --no-build
```

Remember to replace `<APP_NAME>` with the name of your function app in Azure.

Unit testing

Functions that are written in Python can be tested like other Python code by using standard testing frameworks. For most bindings, it's possible to create a mock input object by creating an instance of an appropriate class from the `azure.functions` package. Since the [azure.functions](#) package isn't immediately available, be sure to install it via your `requirements.txt` file as described in the [package management](#) section above.

With `my_second_function` as an example, the following is a mock test of an HTTP-triggered function:

First, create the `<project_root>/function_app.py` file and implement the `my_second_function` function as the HTTP trigger and `shared_code.my_second_helper_function`.

Python

```
# <project_root>/function_app.py
import azure.functions as func
import logging

# Use absolute import to resolve shared_code modules
from shared_code import my_second_helper_function

app = func.FunctionApp()

# Define the HTTP trigger that accepts the ?value=<int> query parameter
# Double the value and return the result in HttpResponseMessage
@app.function_name(name="my_second_function")
@app.route(route="hello")
def main(req: func.HttpRequest) -> func.HttpResponse:
    logging.info('Executing my_second_function.')

    initial_value: int = int(req.params.get('value'))
    doubled_value: int = my_second_helper_function.double(initial_value)

    return func.HttpResponse(
        body=f'{initial_value} * 2 = {doubled_value}',
        status_code=200
    )
```

Python

```
# <project_root>/shared_code/__init__.py
# Empty __init__.py file marks shared_code folder as a Python package
```

Python

```
# <project_root>/shared_code/my_second_helper_function.py

def double(value: int) -> int:
    return value * 2
```

You can start writing test cases for your HTTP trigger.

Python

```
# <project_root>/tests/test_my_second_function.py
import unittest
import azure.functions as func

from function_app import main

class TestFunction(unittest.TestCase):
    def test_my_second_function(self):
        # Construct a mock HTTP request.
        req = func.HttpRequest(method='GET',
                               body=None,
                               url='/api/my_second_function',
                               params={'value': '21'})

        # Call the function.
        func_call = main.build().get_user_function()
        resp = func_call(req)
        # Check the output.
        self.assertEqual(
            resp.get_body(),
            b'21 * 2 = 42',
        )
    
```

Inside your `.venv` Python virtual environment folder, install your favorite Python test framework, such as `pip install pytest`. Then run `pytest tests` to check the test result.

Temporary files

The `tempfile.gettempdir()` method returns a temporary folder, which on Linux is `/tmp`. Your application can use this directory to store temporary files that are generated and used by your functions when they're running.

ⓘ Important

Files written to the temporary directory aren't guaranteed to persist across invocations. During scale out, temporary files aren't shared between instances.

The following example creates a named temporary file in the temporary directory (`/tmp`):

Python

```
import logging
import azure.functions as func
import tempfile

from os import listdir
```

```
---  
tempFilePath = tempfile.gettempdir()  
fp = tempfile.NamedTemporaryFile()  
fp.write(b'Hello world!')  
filesDirListInTemp = listdir(tempFilePath)
```

We recommend that you maintain your tests in a folder that's separate from the project folder. This action keeps you from deploying test code with your app.

Preinstalled libraries

A few libraries come with the Python functions runtime.

The Python standard library

The Python standard library contains a list of built-in Python modules that are shipped with each Python distribution. Most of these libraries help you access system functionality, such as file input/output (I/O). On Windows systems, these libraries are installed with Python. On Unix-based systems, they're provided by package collections.

To view the library for your Python version, go to:

- [Python 3.8 standard library ↗](#)
- [Python 3.9 standard library ↗](#)
- [Python 3.10 standard library ↗](#)
- [Python 3.11 standard library ↗](#)

Azure Functions Python worker dependencies

The Azure Functions Python worker requires a specific set of libraries. You can also use these libraries in your functions, but they aren't a part of the Python standard. If your functions rely on any of these libraries, they might be unavailable to your code when it's running outside of Azure Functions.

Note

If your function app's *requirements.txt* file contains an `azure-functions-worker` entry, remove it. The functions worker is automatically managed by the Azure Functions platform, and we regularly update it with new features and bug fixes. Manually installing an old version of worker in the *requirements.txt* file might cause unexpected issues.

(!) Note

If your package contains certain libraries that might collide with worker's dependencies (for example, protobuf, tensorflow, or grpcio), configure **PYTHON_ISOLATE_WORKER_DEPENDENCIES** to 1 in app settings to prevent your application from referring to worker's dependencies.

The Azure Functions Python library

Every Python worker update includes a new version of the [Azure Functions Python library \(azure.functions\)](#). This approach makes it easier to continuously update your Python function apps, because each update is backwards-compatible. For a list of releases of this library, go to [azure-functions PyPi](#).

The runtime library version is fixed by Azure, and it can't be overridden by *requirements.txt*. The `azure-functions` entry in *requirements.txt* is only for linting and customer awareness.

Use the following code to track the actual version of the Python functions library in your runtime:

Python

```
getattr(azure.functions, '__version__', '< 1.2.1')
```

Runtime system libraries

For a list of preinstalled system libraries in Python worker Docker images, see the following:

[+] Expand table

Functions runtime	Debian version	Python versions
Version 3.x	Buster	Python 3.7 Python 3.8 Python 3.9

Python worker extensions

The Python worker process that runs in Azure Functions lets you integrate third-party libraries into your function app. These extension libraries act as middleware that can inject specific operations during the lifecycle of your function's execution.

Extensions are imported in your function code much like a standard Python library module. Extensions are run based on the following scopes:

[+] [Expand table](#)

Scope	Description
Application-level	When imported into any function trigger, the extension applies to every function execution in the app.
Function-level	Execution is limited to only the specific function trigger into which it's imported.

Review the information for each extension to learn more about the scope in which the extension runs.

Extensions implement a Python worker extension interface. This action lets the Python worker process call into the extension code during the function's execution lifecycle. To learn more, see [Create extensions](#).

Using extensions

You can use a Python worker extension library in your Python functions by doing the following:

1. Add the extension package in the *requirements.txt* file for your project.
2. Install the library into your app.
3. Add the following application settings:
 - Locally: Enter `"PYTHON_ENABLE_WORKER_EXTENSIONS": "1"` in the `Values` section of your [*local.settings.json* file](#).
 - Azure: Enter `PYTHON_ENABLE_WORKER_EXTENSIONS=1` in your [app settings](#).
4. Import the extension module into your function trigger.
5. Configure the extension instance, if needed. Configuration requirements should be called out in the extension's documentation.

Important

Third-party Python worker extension libraries aren't supported or warrantied by Microsoft. You must make sure that any extensions that you use in your function

app is trustworthy, and you bear the full risk of using a malicious or poorly written extension.

Third-parties should provide specific documentation on how to install and consume their extensions in your function app. For a basic example of how to consume an extension, see [Consuming your extension](#).

Here are examples of using extensions in a function app, by scope:

Application-level

Python

```
# <project_root>/requirements.txt
application-level-extension==1.0.0
```

Python

```
# <project_root>/Trigger/__init__.py

from application_level_extension import AppExtension
AppExtension.configure(key=value)

def main(req, context):
    # Use context.app_ext_attributes here
```

Creating extensions

Extensions are created by third-party library developers who have created functionality that can be integrated into Azure Functions. An extension developer designs, implements, and releases Python packages that contain custom logic designed specifically to be run in the context of function execution. These extensions can be published either to the PyPI registry or to GitHub repositories.

To learn how to create, package, publish, and consume a Python worker extension package, see [Develop Python worker extensions for Azure Functions](#).

Application-level extensions

An extension that's inherited from [AppExtensionBase](#) runs in an *application* scope.

`AppExtensionBase` exposes the following abstract class methods for you to implement:

[\[\] Expand table](#)

Method	Description
<code>init</code>	Called after the extension is imported.
<code>configure</code>	Called from function code when it's needed to configure the extension.
<code>post_function_load_app_level</code>	Called right after the function is loaded. The function name and function directory are passed to the extension. Keep in mind that the function directory is read-only, and any attempt to write to a local file in this directory fails.
<code>pre_invocation_app_level</code>	Called right before the function is triggered. The function context and function invocation arguments are passed to the extension. You can usually pass other attributes in the context object for the function code to consume.
<code>post_invocation_app_level</code>	Called right after the function execution finishes. The function context, function invocation arguments, and invocation return object are passed to the extension. This implementation is a good place to validate whether execution of the lifecycle hooks succeeded.

Function-level extensions

An extension that inherits from [FuncExtensionBase](#) runs in a specific function trigger.

`FuncExtensionBase` exposes the following abstract class methods for implementations:

[\[\] Expand table](#)

Method	Description
<code>__init__</code>	The constructor of the extension. It's called when an extension instance is initialized in a specific function. When you're implementing this abstract method, you might want to accept a <code>filename</code> parameter and pass it to the parent's method <code>super().__init__(filename)</code> for proper extension registration.
<code>post_function_load</code>	Called right after the function is loaded. The function name and function directory are passed to the extension. Keep in mind that the function directory is read-only, and any attempt to write to a local file in this directory fails.
<code>pre_invocation</code>	Called right before the function is triggered. The function context and function invocation arguments are passed to the extension. You can usually

Method	Description
	pass other attributes in the context object for the function code to consume.
<code>post_invocation</code>	Called right after the function execution finishes. The function context, function invocation arguments, and invocation return object are passed to the extension. This implementation is a good place to validate whether execution of the lifecycle hooks succeeded.

Cross-origin resource sharing

Azure Functions supports cross-origin resource sharing (CORS). CORS is configured [in the portal](#) and through the [Azure CLI](#). The CORS allowed origins list applies at the function app level. With CORS enabled, responses include the `Access-Control-Allow-Origin` header. For more information, see [Cross-origin resource sharing](#).

Cross-origin resource sharing (CORS) is fully supported for Python function apps.

Async

By default, a host instance for Python can process only one function invocation at a time. This is because Python is a single-threaded runtime. For a function app that processes a large number of I/O events or is being I/O bound, you can significantly improve performance by running functions asynchronously. For more information, see [Improve throughout performance of Python apps in Azure Functions](#).

Shared memory (preview)

To improve throughput, Azure Functions lets your out-of-process Python language worker share memory with the Functions host process. When your function app is hitting bottlenecks, you can enable shared memory by adding an application setting named `FUNCTIONS_WORKER_SHARED_MEMORY_DATA_TRANSFER_ENABLED` with a value of `1`. With shared memory enabled, you can then use the `DOCKER_SHM_SIZE` setting to set the shared memory to something like `268435456`, which is equivalent to 256 MB.

For example, you might enable shared memory to reduce bottlenecks when you're using Blob Storage bindings to transfer payloads larger than 1 MB.

This functionality is available only for function apps that are running in Premium and Dedicated (Azure App Service) plans. To learn more, see [Shared memory](#).

Known issues and FAQ

Here are two troubleshooting guides for common issues:

- [ModuleNotFoundError and ImportError](#)
- [Can't import 'cygrpc'](#)

Here are two troubleshooting guides for known issues with the v2 programming model:

- [Couldn't load file or assembly](#)
- [Unable to resolve the Azure Storage connection named Storage](#)

All known issues and feature requests are tracked in a [GitHub issues list ↗](#). If you run into a problem and can't find the issue in GitHub, open a new issue, and include a detailed description of the problem.

Azure Functions Python developer guide

Article • 07/30/2024

This guide is an introduction to developing Azure Functions by using Python. The article assumes that you've already read the [Azure Functions developers guide](#).

Important

This article supports both the v1 and v2 programming model for Python in Azure Functions. The Python v1 model uses a `functions.json` file to define functions, and the new v2 model lets you instead use a decorator-based approach. This new approach results in a simpler file structure, and it's more code-centric. Choose the **v2** selector at the top of the article to learn about this new programming model.

As a Python developer, you might also be interested in these topics:

Get started

- [Visual Studio Code](#): Create your first Python app using Visual Studio Code.
- [Terminal or command prompt](#): Create your first Python app from the command prompt using Azure Functions Core Tools.
- [Samples](#): Review some existing Python apps in the Learn samples browser.

Development options

Both Python Functions programming models support local development in one of the following environments:

Python v2 programming model:

- [Visual Studio Code](#)
- [Terminal or command prompt](#)

Python v1 programming model:

- [Visual Studio Code](#)
- [Terminal or command prompt](#)

You can also create Python v1 functions in the Azure portal.

Tip

Although you can develop your Python-based Azure functions locally on Windows, Python is supported only on a Linux-based hosting plan when it's running in Azure. For more information, see the [list of supported operating system/runtime combinations](#).

Programming model

Azure Functions expects a function to be a stateless method in your Python script that processes input and produces output. By default, the runtime expects the method to be implemented as a global method in the *function_app.py* file.

Triggers and bindings can be declared and used in a function in a decorator based approach. They're defined in the same file, *function_app.py*, as the functions. As an example, the following *function_app.py* file represents a function trigger by an HTTP request.

Python

```
@app.function_name(name="HttpTrigger1")
@app.route(route="req")
def main(req):
    user = req.params.get("user")
    return f"Hello, {user}!"
```

You can also explicitly declare the attribute types and return type in the function by using Python type annotations. Doing so helps you use the IntelliSense and autocomplete features that are provided by many Python code editors.

Python

```
import azure.functions as func

app = func.FunctionApp()

@app.function_name(name="HttpTrigger1")
@app.route(route="req")
def main(req: func.HttpRequest) -> str:
    user = req.params.get("user")
    return f"Hello, {user}!"
```

To learn about known limitations with the v2 model and their workarounds, see [Troubleshoot Python errors in Azure Functions](#).

Alternative entry point

The entry point is only in the *function_app.py* file. However, you can reference functions within the project in *function_app.py* by using [blueprints](#) or by importing.

Folder structure

The recommended folder structure for a Python functions project looks like the following example:

```
Windows Command Prompt

<project_root>/
| - .venv/
| - .vscode/
| - function_app.py
| - additional_functions.py
| - tests/
| | - test_my_function.py
| - .funcignore
| - host.json
| - local.settings.json
| - requirements.txt
| - Dockerfile
```

The main project folder, *<project_root>*, can contain the following files:

- *.venv/*: (Optional) Contains a Python virtual environment that's used by local development.
- *.vscode/*: (Optional) Contains the stored Visual Studio Code configuration. To learn more, see [Visual Studio Code settings](#).
- *function_app.py*: The default location for all functions and their related triggers and bindings.
- *additional_functions.py*: (Optional) Any other Python files that contain functions (usually for logical grouping) that are referenced in *function_app.py* through blueprints.
- *tests/*: (Optional) Contains the test cases of your function app.
- *.funcignore*: (Optional) Declares files that shouldn't get published to Azure. Usually, this file contains *.vscode/* to ignore your editor setting, *.venv/* to ignore local

Python virtual environment, `tests/` to ignore test cases, and `local.settings.json` to prevent local app settings being published.

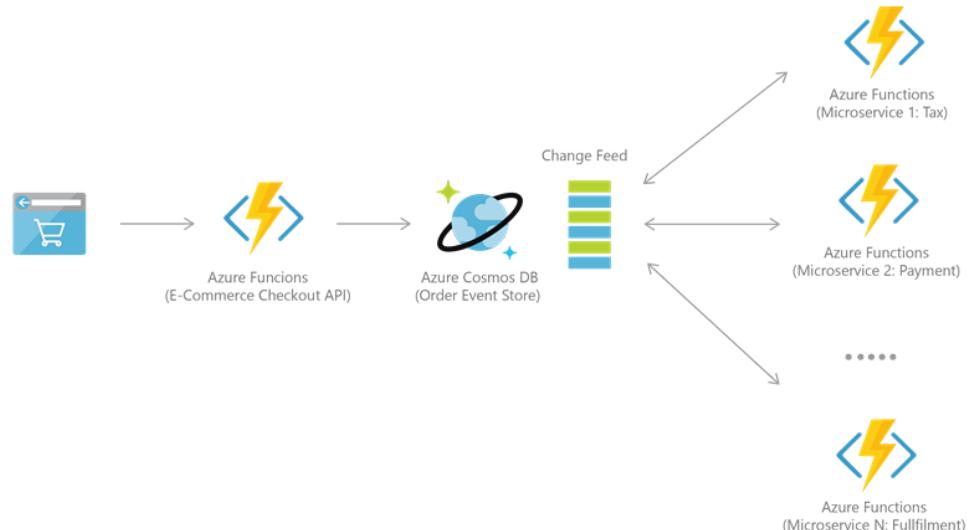

- `host.json`: Contains configuration options that affect all functions in a function app instance. This file does get published to Azure. Not all options are supported when running locally. To learn more, see [host.json](#).
- `local.settings.json`: Used to store app settings and connection strings when it's running locally. This file doesn't get published to Azure. To learn more, see [local.settings.json](#).
- `requirements.txt`: Contains the list of Python packages the system installs when it publishes to Azure.
- `Dockerfile`: (Optional) Used when publishing your project in a [custom container](#).

When you deploy your project to a function app in Azure, the entire contents of the main project folder, `<project_root>`, should be included in the package, but not the folder itself, which means that `host.json` should be in the package root. We recommend that you maintain your tests in a folder along with other functions (in this example, `tests/`). For more information, see [Unit testing](#).

Connect to a database

Azure Functions integrates well with [Azure Cosmos DB](#) for many [use cases](#), including IoT, ecommerce, gaming, etc.

For example, for [event sourcing](#), the two services are integrated to power event-driven architectures using Azure Cosmos DB's [change feed](#) functionality. The change feed provides downstream microservices the ability to reliably and incrementally read inserts and updates (for example, order events). This functionality can be used to provide a persistent event store as a message broker for state-changing events and drive order processing workflow between many microservices (which can be implemented as [serverless Azure Functions](#)).

To connect to Azure Cosmos DB, first [create an account, database, and container](#). Then you can connect your function code to Azure Cosmos DB using [trigger and bindings](#), like this [example](#).

To implement more complex app logic, you can also use the Python library for Cosmos DB. An asynchronous I/O implementation looks like this:

Python

```

pip install azure-cosmos
pip install aiohttp

from azure.cosmos.aio import CosmosClient
from azure.cosmos import exceptions
from azure.cosmos.partition_key import PartitionKey
import asyncio

# Replace these values with your Cosmos DB connection information
endpoint = "https://azure-cosmos-nosql.documents.azure.com:443/"
key = "master_key"
database_id = "cosmicwerx"
container_id = "cosmiccontainer"
partition_key = "/partition_key"

# Set the total throughput (RU/s) for the database and container
database_throughput = 1000

# Singleton CosmosClient instance
client = CosmosClient(endpoint, credential=key)

# Helper function to get or create database and container
async def get_or_create_container(client, database_id, container_id,
partition_key):

```

```

database = await client.create_database_if_not_exists(id=database_id)
print(f'Database "{database_id}" created or retrieved successfully.')

        container = await
database.create_container_if_not_exists(id=container_id,
partition_key=PartitionKey(path=partition_key))
        print(f'Container with id "{container_id}" created')

    return container

async def create_products():
    container = await get_or_create_container(client, database_id,
container_id, partition_key)
    for i in range(10):
        await container.upsert_item({
            'id': f'item{i}',
            'productName': 'Widget',
            'productModel': f'Model {i}'
        })

async def get_products():
    items = []
    container = await get_or_create_container(client, database_id,
container_id, partition_key)
    async for item in container.read_all_items():
        items.append(item)
    return items

async def query_products(product_name):
    container = await get_or_create_container(client, database_id,
container_id, partition_key)
    query = f"SELECT * FROM c WHERE c.productName = '{product_name}'"
    items = []
    async for item in container.query_items(query=query,
enable_cross_partition_query=True):
        items.append(item)
    return items

async def main():
    await create_products()
    all_products = await get_products()
    print('All Products:', all_products)

    queried_products = await query_products('Widget')
    print('Queried Products:', queried_products)

if __name__ == "__main__":
    asyncio.run(main())

```

Blueprints

The Python v2 programming model introduces the concept of *blueprints*. A blueprint is a new class that's instantiated to register functions outside of the core function application. The functions registered in blueprint instances aren't indexed directly by the function runtime. To get these blueprint functions indexed, the function app needs to register the functions from blueprint instances.

Using blueprints provides the following benefits:

- Lets you break up the function app into modular components, which enables you to define functions in multiple Python files and divide them into different components per file.
- Provides extensible public function app interfaces to build and reuse your own APIs.

The following example shows how to use blueprints:

First, in an *http_blueprint.py* file, an HTTP-triggered function is first defined and added to a blueprint object.

Python

```
import logging

import azure.functions as func

bp = func.Blueprint()

@bp.route(route="default_template")
def default_template(req: func.HttpRequest) -> func.HttpResponse:
    logging.info('Python HTTP trigger function processed a request.')

    name = req.params.get('name')
    if not name:
        try:
            req_body = req.get_json()
        except ValueError:
            pass
        else:
            name = req_body.get('name')

    if name:
        return func.HttpResponse(
            f"Hello, {name}. This HTTP-triggered function "
            f"executed successfully.")
    else:
        return func.HttpResponse(
            "This HTTP-triggered function executed successfully. "
            "Pass a name in the query string or in the request body for a"
            " personalized response.",
```

```
    status_code=200
)
```

Next, in the `function_app.py` file, the `blueprint` object is imported and its functions are registered to the function app.

Python

```
import azure.functions as func
from http_blueprint import bp

app = func.FunctionApp()

app.register_functions(bp)
```

ⓘ Note

Durable Functions also supports blueprints. To create blueprints for Durable Functions apps, register your orchestration, activity, and entity triggers and client bindings using the [azure-functions-durable](#) Blueprint class, as shown [here](#). The resulting blueprint can then be registered as normal. See our [sample](#) for an example.

Triggers and inputs

Inputs are divided into two categories in Azure Functions: trigger input and other input. Although they're defined using different decorators, their usage is similar in Python code. Connection strings or secrets for trigger and input sources map to values in the `local.settings.json` file when they're running locally, and they map to the application settings when they're running in Azure.

As an example, the following code demonstrates how to define a Blob Storage input binding:

JSON

```
// local.settings.json
{
  "IsEncrypted": false,
  "Values": {
    "FUNCTIONS_WORKER_RUNTIME": "python",
    "STORAGE_CONNECTION_STRING": "<AZURE_STORAGE_CONNECTION_STRING>",
    "AzureWebJobsStorage": "<azure-storage-connection-string>",
    "AzureWebJobsFeatureFlags": "EnableWorkerIndexing"
```

```
}
```

Python

```
# function_app.py
import azure.functions as func
import logging

app = func.FunctionApp()

@app.route(route="req")
@app.read_blob(arg_name="obj", path="samples/{id}",
               connection="STORAGE_CONNECTION_STRING")
def main(req: func.HttpRequest, obj: func.InputStream):
    logging.info(f'Python HTTP-triggered function processed: {obj.read()}')
```

When the function is invoked, the HTTP request is passed to the function as `req`. An entry is retrieved from the Azure Blob Storage account based on the *ID* in the route URL and made available as `obj` in the function body. Here, the specified storage account is the connection string that's found in the `STORAGE_CONNECTION_STRING` app setting.

For data intensive binding operations, you may want to use a separate storage account. For more information, see [Storage account guidance](#).

SDK type bindings (preview)

For select triggers and bindings, you can work with data types implemented by the underlying Azure SDKs and frameworks. These *SDK type bindings* let you interact with binding data as if you were using the underlying service SDK.

Functions supports Python SDK type bindings for Azure Blob storage, which lets you work with blob data using the underlying `BlobClient` type.

ⓘ Important

SDK type bindings support for Python is currently in preview:

- You must use the Python v2 programming model.
- Currently, only synchronous SDK types are supported.

Prerequisites

- Azure Functions runtime version version 4.34, or a later version.
- Python ↗ version 3.9, or a later supported version.

Enable SDK type bindings for the Blob storage extension

1. Add the `azurefunctions-extensions-bindings-blob` extension package to the `requirements.txt` file in the project, which should include at least these packages:

```
text  
  
azure-functions  
azurefunctions-extensions-bindings-blob
```

2. Add this code to the `function_app.py` file in the project, which imports the SDK type bindings:

```
Python  
  
import azurefunctions.extensions.bindings.blob as blob
```

SDK type bindings examples

This example shows how to get the `BlobClient` from both a Blob storage trigger (`blob_trigger`) and from the input binding on an HTTP trigger (`blob_input`):

```
Python  
  
import logging  
  
import azure.functions as func  
import azurefunctions.extensions.bindings.blob as blob  
  
app = func.FunctionApp(http_auth_level=func.AuthLevel.ANONYMOUS)  
  
@app.blob_trigger(  
    arg_name="client", path="PATH/TO/BLOB", connection="AzureWebJobsStorage"  
)  
def blob_trigger(client: blob.BlobClient):  
    logging.info(  
        f"Python blob trigger function processed blob \n"  
        f"Properties: {client.get_blob_properties()}\n"  
        f"Blob content head: {client.download_blob().read(size=1)}"  
    )  
  
@app.route(route="file")
```

```
@app.blob_input(  
    arg_name="client", path="PATH/TO/BLOB", connection="AzureWebJobsStorage"  
)  
def blob_input(req: func.HttpRequest, client: blob.BlobClient):  
    logging.info(  
        f"Python blob input function processed blob \n"  
        f"Properties: {client.get_blob_properties()}\n"  
        f"Blob content head: {client.download_blob().read(size=1)}"  
    )  
    return "ok"
```

You can view other SDK type bindings samples for Blob storage in the Python extensions repository:

- [ContainerClient type ↗](#)
- [StorageStreamDownloader type ↗](#)

HTTP streams (preview)

HTTP streams lets you accept and return data from your HTTP endpoints using FastAPI request and response APIs enabled in your functions. These APIs lets the host process large data in HTTP messages as chunks instead of reading an entire message into memory.

This feature makes it possible to handle large data stream, OpenAI integrations, deliver dynamic content, and support other core HTTP scenarios requiring real-time interactions over HTTP. You can also use FastAPI response types with HTTP streams. Without HTTP streams, the size of your HTTP requests and responses are limited by memory restrictions that can be encountered when processing entire message payloads all in memory.

ⓘ Important

HTTP streams support for Python is currently in preview and requires you to use the Python v2 programming model.

Prerequisites

- [Azure Functions runtime](#) version 4.34.1, or a later version.
- [Python ↗](#) version 3.8, or a later [supported version](#).

Enable HTTP streams

HTTP streams are disabled by default. You need to enable this feature in your application settings and also update your code to use the FastAPI package. Note that when enabling HTTP streams, the function app will default to using HTTP streaming, and the original HTTP functionality will not work.

1. Add the `azurefunctions-extensions-http-fastapi` extension package to the `requirements.txt` file in the project, which should include at least these packages:

```
text  
  
azure-functions  
azurefunctions-extensions-http-fastapi
```

2. Add this code to the `function_app.py` file in the project, which imports the FastAPI extension:

```
Python  
  
from azurefunctions.extensions.http.fastapi import Request,  
StreamingResponse
```

3. When you deploy to Azure, add the following [application setting](#) in your function app:

```
"PYTHON_ENABLE_INIT_INDEXING": "1"
```

If you are deploying to Linux Consumption, also add

```
"PYTHON_ISOLATE_WORKER_DEPENDENCIES": "1"
```

When running locally, you also need to add these same settings to the `local.settings.json` project file.

HTTP streams examples

After you enable the HTTP streaming feature, you can create functions that stream data over HTTP.

This example is an HTTP triggered function that streams HTTP response data. You might use these capabilities to support scenarios like sending event data through a pipeline for real time visualization or detecting anomalies in large sets of data and providing instant notifications.

```
Python
```

```

import time

import azure.functions as func
from azurefunctions.extensions.http.fastapi import Request,
StreamingResponse

app = func.FunctionApp(http_auth_level=func.AuthLevel.ANONYMOUS)

def generate_sensor_data():
    """Generate real-time sensor data."""
    for i in range(10):
        # Simulate temperature and humidity readings
        temperature = 20 + i
        humidity = 50 + i
        yield f"data: {{'temperature': {temperature}, 'humidity': {humidity}}}\n\n"
    time.sleep(1)

@app.route(route="stream", methods=[func.HttpMethod.GET])
async def stream_sensor_data(req: Request) -> StreamingResponse:
    """Endpoint to stream real-time sensor data."""
    return StreamingResponse(generate_sensor_data(), media_type="text/event-stream")

```

This example is an HTTP triggered function that receives and processes streaming data from a client in real time. It demonstrates streaming upload capabilities that can be helpful for scenarios like processing continuous data streams and handling event data from IoT devices.

Python

```

import azure.functions as func
from azurefunctions.extensions.http.fastapi import JSONResponse, Request

app = func.FunctionApp(http_auth_level=func.AuthLevel.ANONYMOUS)

@app.route(route="streaming_upload", methods=[func.HttpMethod.POST])
async def streaming_upload(req: Request) -> JSONResponse:
    """Handle streaming upload requests."""
    # Process each chunk of data as it arrives
    async for chunk in req.stream():
        process_data_chunk(chunk)

    # Once all data is received, return a JSON response indicating
    # successful processing
    return JSONResponse({"status": "Data uploaded and processed
successfully"})

```

```
def process_data_chunk(chunk: bytes):
    """Process each data chunk."""
    # Add custom processing logic here
    pass
```

Calling HTTP streams

You must use an HTTP client library to make streaming calls to a function's FastAPI endpoints. The client tool or browser you're using might not natively support streaming or could only return the first chunk of data.

You can use a client script like this to send streaming data to an HTTP endpoint:

Python

```
import httpx # Be sure to add 'httpx' to 'requirements.txt'
import asyncio

async def stream_generator(file_path):
    chunk_size = 2 * 1024 # Define your own chunk size
    with open(file_path, 'rb') as file:
        while chunk := file.read(chunk_size):
            yield chunk
            print(f"Sent chunk: {len(chunk)} bytes")

async def stream_to_server(url, file_path):
    timeout = httpx.Timeout(60.0, connect=60.0)
    async with httpx.AsyncClient(timeout=timeout) as client:
        response = await client.post(url,
content=stream_generator(file_path))
    return response

async def stream_response(response):
    if response.status_code == 200:
        async for chunk in response.aiter_raw():
            print(f"Received chunk: {len(chunk)} bytes")
    else:
        print(f"Error: {response}")

async def main():
    print('helloworld')
    # Customize your streaming endpoint served from core tool in variable
    'url' if different.
    url = 'http://localhost:7071/api/streaming_upload'
    file_path = r'<file path>'

    response = await stream_to_server(url, file_path)
    print(response)
```

```
if __name__ == "__main__":
    asyncio.run(main())
```

Outputs

Output can be expressed both in return value and output parameters. If there's only one output, we recommend using the return value. For multiple outputs, you'll have to use output parameters.

To produce multiple outputs, use the `set()` method provided by the `azure.functions.Out` interface to assign a value to the binding. For example, the following function can push a message to a queue and also return an HTTP response.

Python

```
# function_app.py
import azure.functions as func

app = func.FunctionApp()

@app.write_blob(arg_name="msg", path="output-container/{name}",
                connection="CONNECTION_STRING")
def test_function(req: func.HttpRequest,
                  msg: func.Out[str]) -> str:

    message = req.params.get('body')
    msg.set(message)
    return message
```

Logging

Access to the Azure Functions runtime logger is available via a root [logging](#) handler in your function app. This logger is tied to Application Insights and allows you to flag warnings and errors that occur during the function execution.

The following example logs an info message when the function is invoked via an HTTP trigger.

Python

```
import logging

def main(req):
    logging.info('Python HTTP trigger function processed a request.')
```

More logging methods are available that let you write to the console at different trace levels:

[+] Expand table

Method	Description
<code>critical(_message_)</code>	Writes a message with level CRITICAL on the root logger.
<code>error(_message_)</code>	Writes a message with level ERROR on the root logger.
<code>warning(_message_)</code>	Writes a message with level WARNING on the root logger.
<code>info(_message_)</code>	Writes a message with level INFO on the root logger.
<code>debug(_message_)</code>	Writes a message with level DEBUG on the root logger.

To learn more about logging, see [Monitor Azure Functions](#).

Logging from created threads

To see logs coming from your created threads, include the `context` argument in the function's signature. This argument contains an attribute `thread_local_storage` that stores a local `invocation_id`. This can be set to the function's current `invocation_id` to ensure the context is changed.

Python

```
import azure.functions as func
import logging
import threading

def main(req, context):
    logging.info('Python HTTP trigger function processed a request.')
    t = threading.Thread(target=log_function, args=(context,))
    t.start()

def log_function(context):
    context.thread_local_storage.invocation_id = context.invocation_id
    logging.info('Logging from thread.')
```

Log custom telemetry

By default, the Functions runtime collects logs and other telemetry data that are generated by your functions. This telemetry ends up as traces in Application Insights. Request and dependency telemetry for certain Azure services are also collected by default by [triggers and bindings](#).

To collect custom request and custom dependency telemetry outside of bindings, you can use the [OpenCensus Python Extensions](#). This extension sends custom telemetry data to your Application Insights instance. You can find a list of supported extensions at the [OpenCensus repository](#).

ⓘ Note

To use the OpenCensus Python extensions, you need to enable [Python worker extensions](#) in your function app by setting `PYTHON_ENABLE_WORKER_EXTENSIONS` to `1`. You also need to switch to using the Application Insights connection string by adding the [APPLICATIONINSIGHTS CONNECTION STRING](#) setting to your [application settings](#), if it's not already there.

text

```
// requirements.txt
...
opencensus-extension-azure-functions
opencensus-ext-requests
```

Python

```
import json
import logging

import requests
from opencensus.extension.azure.functions import OpenCensusExtension
from opencensus.trace import config_integration

config_integration.trace_integrations(['requests'])

OpenCensusExtension.configure()

def main(req, context):
    logging.info('Executing HttpTrigger with OpenCensus extension')

    # You must use contexttracer to create spans
    with context.tracer.span("parent"):
        response = requests.get(url='http://example.com')

    return json.dumps({
        'method': req.method,
```

```
'response': response.status_code,
'ctx_func_name': context.function_name,
'ctx_func_dir': context.function_directory,
'ctx_invocation_id': context.invocation_id,
'ctx_trace_context_Traceparent': context.trace_context.Traceparent,
'ctx_trace_context_Tracestate': context.trace_context.Tracestate,
'ctx_retry_context_RetryCount': context.retry_context.retry_count,
'ctx_retry_context_MaxRetryCount':
context.retry_context.max_retry_count,
})
```

HTTP trigger

The HTTP trigger is defined as a method that takes a named binding parameter, which is an `HttpRequest` object, and returns an `HttpResponse` object. You apply the `function_name` decorator to the method to define the function name, while the HTTP endpoint is set by applying the `route` decorator.

This example is from the HTTP trigger template for the Python v2 programming model, where the binding parameter name is `req`. It's the sample code that's provided when you create a function by using Azure Functions Core Tools or Visual Studio Code.

Python

```
@app.function_name(name="HttpTrigger1")
@app.route(route="hello")
def test_function(req: func.HttpRequest) -> func.HttpResponse:
    logging.info('Python HTTP trigger function processed a request.')

    name = req.params.get('name')
    if not name:
        try:
            req_body = req.get_json()
        except ValueError:
            pass
    else:
        name = req_body.get('name')

    if name:
        return func.HttpResponse(f"Hello, {name}. This HTTP-triggered
function executed successfully.")
    else:
        return func.HttpResponse(
            "This HTTP-triggered function executed successfully. Pass a
name in the query string or in the request body for a personalized
response.",
            status_code=200
        )
```

From the `HttpRequest` object, you can get request headers, query parameters, route parameters, and the message body. In this function, you obtain the value of the `name` query parameter from the `params` parameter of the `HttpRequest` object. You read the JSON-encoded message body by using the `get_json` method.

Likewise, you can set the `status_code` and `headers` for the response message in the returned `HttpResponse` object.

To pass in a name in this example, paste the URL that's provided when you're running the function, and then append it with `?name={name}`.

Web frameworks

You can use Asynchronous Server Gateway Interface (ASGI)-compatible and Web Server Gateway Interface (WSGI)-compatible frameworks, such as Flask and FastAPI, with your HTTP-triggered Python functions. You must first update the `host.json` file to include an HTTP `routePrefix`, as shown in the following example:

```
JSON

{
  "version": "2.0",
  "logging": {
    {
      "applicationInsights": {
        {
          "samplingSettings": {
            {
              "isEnabled": true,
              "excludedTypes": "Request"
            }
          }
        },
        "extensionBundle": {
          {
            "id": "Microsoft.Azure.Functions.ExtensionBundle",
            "version": "[2.*, 3.0.0)"
          },
          "extensions": {
            {
              "http": {
                {
                  "routePrefix": ""
                }
              }
            }
          }
        }
      }
    }
  }
}
```

The framework code looks like the following example:

ASGI

`AsgiFunctionApp` is the top-level function app class for constructing ASGI HTTP functions.

Python

```
# function_app.py

import azure.functions as func
from fastapi import FastAPI, Request, Response

fast_app = FastAPI()

@fast_app.get("/return_http_no_body")
async def return_http_no_body():
    return Response(content="", media_type="text/plain")

app = func.AsgiFunctionApp(app=fast_app,
                           http_auth_level=func.AuthLevel.ANONYMOUS)
```

Scaling and performance

For scaling and performance best practices for Python function apps, see the [Python scaling and performance](#) article.

Context

To get the invocation context of a function when it's running, include the `context` argument in its signature.

For example:

Python

```
import azure.functions

def main(req: azure.functions.HttpRequest,
        context: azure.functions.Context) -> str:
    return f'{context.invocation_id}'
```

The [Context](#) class has the following string attributes:

[\[\] Expand table](#)

Attribute	Description
<code>function_directory</code>	The directory in which the function is running.
<code>function_name</code>	The name of the function.
<code>invocation_id</code>	The ID of the current function invocation.
<code>thread_local_storage</code>	The thread local storage of the function. Contains a local <code>invocation_id</code> for logging from created threads .
<code>trace_context</code>	The context for distributed tracing. For more information, see Trace Context .
<code>retry_context</code>	The context for retries to the function. For more information, see retry-policies .

Global variables

It isn't guaranteed that the state of your app will be preserved for future executions. However, the Azure Functions runtime often reuses the same process for multiple executions of the same app. To cache the results of an expensive computation, declare it as a global variable.

Python

```
CACHED_DATA = None

def main(req):
    global CACHED_DATA
    if CACHED_DATA is None:
        CACHED_DATA = load_json()

    # ... use CACHED_DATA in code
```

Environment variables

In Azure Functions, [application settings](#), such as service connection strings, are exposed as environment variables when they're running. There are two main ways to access these settings in your code.

Method	Description
<code>os.environ["myAppSetting"]</code>	Tries to get the application setting by key name, and raises an error when it's unsuccessful.
<code>os.getenv("myAppSetting")</code>	Tries to get the application setting by key name, and returns <code>null</code> when it's unsuccessful.

Both of these ways require you to declare `import os`.

The following example uses `os.environ["myAppSetting"]` to get the [application setting](#), with the key named `myAppSetting`:

Python

```
import logging
import os

import azure.functions as func

app = func.FunctionApp()

@app.function_name(name="HttpTrigger1")
@app.route(route="req")
def main(req: func.HttpRequest) -> func.HttpResponse:
    # Get the setting named 'myAppSetting'
    my_app_setting_value = os.environ["myAppSetting"]
    logging.info(f'My app setting value:{my_app_setting_value}')
```

For local development, application settings are [maintained in the `local.settings.json` file](#).

When you're using the new programming model, enable the following app setting in the `local.settings.json` file, as shown here:

JSON

```
"AzureWebJobsFeatureFlags": "EnableWorkerIndexing"
```

When you're deploying the function, this setting isn't created automatically. You must explicitly create this setting in your function app in Azure for it to run by using the v2 model.

Python version

Azure Functions supports the following Python versions:

[+] Expand table

Functions version	Python* versions
4.x	3.11 3.10 3.9 3.8 3.7
3.x	3.9 3.8 3.7

* Official Python distributions

To request a specific Python version when you create your function app in Azure, use the `--runtime-version` option of the [az functionapp create](#) command. The Functions runtime version is set by the `--functions-version` option. The Python version is set when the function app is created, and it can't be changed for apps running in a Consumption plan.

The runtime uses the available Python version when you run it locally.

Changing Python version

To set a Python function app to a specific language version, you need to specify the language and the version of the language in the `LinuxFxVersion` field in the site configuration. For example, to change the Python app to use Python 3.8, set `linuxFxVersion` to `python|3.8`.

To learn how to view and change the `linuxFxVersion` site setting, see [How to target Azure Functions runtime versions](#).

For more general information, see the [Azure Functions runtime support policy](#) and [Supported languages in Azure Functions](#).

Package management

When you're developing locally by using Core Tools or Visual Studio Code, add the names and versions of the required packages to the `requirements.txt` file, and then install them by using `pip`.

For example, you can use the following `requirements.txt` file and `pip` command to install the `requests` package from PyPI.

```
txt
```

```
requests==2.19.1
```

```
Bash
```

```
pip install -r requirements.txt
```

When running your functions in an [App Service plan](#), dependencies that you define in `requirements.txt` are given precedence over built-in Python modules, such as `logging`. This precedence can cause conflicts when built-in modules have the same names as directories in your code. When running in a [Consumption plan](#) or an [Elastic Premium plan](#), conflicts are less likely because your dependencies aren't prioritized by default.

To prevent issues running in an App Service plan, don't name your directories the same as any Python native modules and don't include Python native libraries in your project's `requirements.txt` file.

Publishing to Azure

When you're ready to publish, make sure that all your publicly available dependencies are listed in the `requirements.txt` file. You can locate this file at the root of your project directory.

You can find the project files and folders that are excluded from publishing, including the virtual environment folder, in the root directory of your project.

There are three build actions supported for publishing your Python project to Azure: remote build, local build, and builds using custom dependencies.

You can also use Azure Pipelines to build your dependencies and publish by using continuous delivery (CD). To learn more, see [Continuous delivery with Azure Pipelines](#).

Remote build

When you use remote build, dependencies that are restored on the server and native dependencies match the production environment. This results in a smaller deployment package to upload. Use remote build when you're developing Python apps on Windows.

If your project has custom dependencies, you can [use remote build with extra index URL](#).

Dependencies are obtained remotely based on the contents of the *requirements.txt* file. [Remote build](#) is the recommended build method. By default, Core Tools requests a remote build when you use the following [func azure functionapp publish](#) command to publish your Python project to Azure.

```
Bash
```

```
func azure functionapp publish <APP_NAME>
```

Remember to replace `<APP_NAME>` with the name of your function app in Azure.

The [Azure Functions Extension for Visual Studio Code](#) also requests a remote build by default.

Local build

Dependencies are obtained locally based on the contents of the *requirements.txt* file. You can prevent doing a remote build by using the following [func azure functionapp publish](#) command to publish with a local build:

```
command
```

```
func azure functionapp publish <APP_NAME> --build local
```

Remember to replace `<APP_NAME>` with the name of your function app in Azure.

When you use the `--build local` option, project dependencies are read from the *requirements.txt* file, and those dependent packages are downloaded and installed locally. Project files and dependencies are deployed from your local computer to Azure. This results in a larger deployment package being uploaded to Azure. If for some reason you can't get the *requirements.txt* file by using Core Tools, you must use the custom dependencies option for publishing.

We don't recommend using local builds when you're developing locally on Windows.

Custom dependencies

When your project has dependencies that aren't found in the [Python Package Index](#), there are two ways to build the project. The first way, the *build* method, depends on

how you build the project.

Remote build with extra index URL

When your packages are available from an accessible custom package index, use a remote build. Before you publish, be sure to [create an app setting](#) named `PIP_EXTRA_INDEX_URL`. The value for this setting is the URL of your custom package index. Using this setting tells the remote build to run `pip install` by using the `--extra-index-url` option. To learn more, see the [Python pip install documentation](#).

You can also use basic authentication credentials with your extra package index URLs. To learn more, see [Basic authentication credentials](#) in the Python documentation.

Install local packages

If your project uses packages that aren't publicly available to our tools, you can make them available to your app by putting them in the `__app__/python_packages` directory. Before you publish, run the following command to install the dependencies locally:

command

```
pip install --target="<PROJECT_DIR>/python_packages/lib/site-packages" -r requirements.txt
```

When you're using custom dependencies, you should use the `--no-build` publishing option, because you've already installed the dependencies into the project folder.

command

```
func azure functionapp publish <APP_NAME> --no-build
```

Remember to replace `<APP_NAME>` with the name of your function app in Azure.

Unit testing

Functions that are written in Python can be tested like other Python code by using standard testing frameworks. For most bindings, it's possible to create a mock input object by creating an instance of an appropriate class from the `azure.functions` package. Since the [azure.functions](#) package isn't immediately available, be sure to install it via your `requirements.txt` file as described in the [package management](#) section above.

With `my_second_function` as an example, the following is a mock test of an HTTP-triggered function:

First, create the `<project_root>/function_app.py` file and implement the `my_second_function` function as the HTTP trigger and `shared_code.my_second_helper_function`.

Python

```
# <project_root>/function_app.py
import azure.functions as func
import logging

# Use absolute import to resolve shared_code modules
from shared_code import my_second_helper_function

app = func.FunctionApp()

# Define the HTTP trigger that accepts the ?value=<int> query parameter
# Double the value and return the result in HttpResponseMessage
@app.function_name(name="my_second_function")
@app.route(route="hello")
def main(req: func.HttpRequest) -> func.HttpResponse:
    logging.info('Executing my_second_function.')

    initial_value: int = int(req.params.get('value'))
    doubled_value: int = my_second_helper_function.double(initial_value)

    return func.HttpResponse(
        body=f'{initial_value} * 2 = {doubled_value}',
        status_code=200
    )
```

Python

```
# <project_root>/shared_code/__init__.py
# Empty __init__.py file marks shared_code folder as a Python package
```

Python

```
# <project_root>/shared_code/my_second_helper_function.py

def double(value: int) -> int:
    return value * 2
```

You can start writing test cases for your HTTP trigger.

Python

```
# <project_root>/tests/test_my_second_function.py
import unittest
import azure.functions as func

from function_app import main

class TestFunction(unittest.TestCase):
    def test_my_second_function(self):
        # Construct a mock HTTP request.
        req = func.HttpRequest(method='GET',
                               body=None,
                               url='/api/my_second_function',
                               params={'value': '21'})

        # Call the function.
        func_call = main.build().get_user_function()
        resp = func_call(req)
        # Check the output.
        self.assertEqual(
            resp.get_body(),
            b'21 * 2 = 42',
        )
    
```

Inside your `.venv` Python virtual environment folder, install your favorite Python test framework, such as `pip install pytest`. Then run `pytest tests` to check the test result.

Temporary files

The `tempfile.gettempdir()` method returns a temporary folder, which on Linux is `/tmp`. Your application can use this directory to store temporary files that are generated and used by your functions when they're running.

ⓘ Important

Files written to the temporary directory aren't guaranteed to persist across invocations. During scale out, temporary files aren't shared between instances.

The following example creates a named temporary file in the temporary directory (`/tmp`):

Python

```
import logging
import azure.functions as func
import tempfile

from os import listdir
```

```
----  
tempFilePath = tempfile.gettempdir()  
fp = tempfile.NamedTemporaryFile()  
fp.write(b'Hello world!')  
filesDirListInTemp = listdir(tempFilePath)
```

We recommend that you maintain your tests in a folder that's separate from the project folder. This action keeps you from deploying test code with your app.

Preinstalled libraries

A few libraries come with the Python functions runtime.

The Python standard library

The Python standard library contains a list of built-in Python modules that are shipped with each Python distribution. Most of these libraries help you access system functionality, such as file input/output (I/O). On Windows systems, these libraries are installed with Python. On Unix-based systems, they're provided by package collections.

To view the library for your Python version, go to:

- [Python 3.8 standard library ↗](#)
- [Python 3.9 standard library ↗](#)
- [Python 3.10 standard library ↗](#)
- [Python 3.11 standard library ↗](#)

Azure Functions Python worker dependencies

The Azure Functions Python worker requires a specific set of libraries. You can also use these libraries in your functions, but they aren't a part of the Python standard. If your functions rely on any of these libraries, they might be unavailable to your code when it's running outside of Azure Functions.

Note

If your function app's *requirements.txt* file contains an `azure-functions-worker` entry, remove it. The functions worker is automatically managed by the Azure Functions platform, and we regularly update it with new features and bug fixes. Manually installing an old version of worker in the *requirements.txt* file might cause unexpected issues.

(!) Note

If your package contains certain libraries that might collide with worker's dependencies (for example, protobuf, tensorflow, or grpcio), configure **PYTHON_ISOLATE_WORKER_DEPENDENCIES** to 1 in app settings to prevent your application from referring to worker's dependencies.

The Azure Functions Python library

Every Python worker update includes a new version of the [Azure Functions Python library \(azure.functions\)](#). This approach makes it easier to continuously update your Python function apps, because each update is backwards-compatible. For a list of releases of this library, go to [azure-functions PyPi](#).

The runtime library version is fixed by Azure, and it can't be overridden by *requirements.txt*. The `azure-functions` entry in *requirements.txt* is only for linting and customer awareness.

Use the following code to track the actual version of the Python functions library in your runtime:

Python

```
getattr(azure.functions, '__version__', '< 1.2.1')
```

Runtime system libraries

For a list of preinstalled system libraries in Python worker Docker images, see the following:

[+] Expand table

Functions runtime	Debian version	Python versions
Version 3.x	Buster	Python 3.7 Python 3.8 Python 3.9

Python worker extensions

The Python worker process that runs in Azure Functions lets you integrate third-party libraries into your function app. These extension libraries act as middleware that can inject specific operations during the lifecycle of your function's execution.

Extensions are imported in your function code much like a standard Python library module. Extensions are run based on the following scopes:

[+] [Expand table](#)

Scope	Description
Application-level	When imported into any function trigger, the extension applies to every function execution in the app.
Function-level	Execution is limited to only the specific function trigger into which it's imported.

Review the information for each extension to learn more about the scope in which the extension runs.

Extensions implement a Python worker extension interface. This action lets the Python worker process call into the extension code during the function's execution lifecycle. To learn more, see [Create extensions](#).

Using extensions

You can use a Python worker extension library in your Python functions by doing the following:

1. Add the extension package in the *requirements.txt* file for your project.
2. Install the library into your app.
3. Add the following application settings:
 - Locally: Enter `"PYTHON_ENABLE_WORKER_EXTENSIONS": "1"` in the `Values` section of your [*local.settings.json* file](#).
 - Azure: Enter `PYTHON_ENABLE_WORKER_EXTENSIONS=1` in your [app settings](#).
4. Import the extension module into your function trigger.
5. Configure the extension instance, if needed. Configuration requirements should be called out in the extension's documentation.

Important

Third-party Python worker extension libraries aren't supported or warrantied by Microsoft. You must make sure that any extensions that you use in your function

app is trustworthy, and you bear the full risk of using a malicious or poorly written extension.

Third-parties should provide specific documentation on how to install and consume their extensions in your function app. For a basic example of how to consume an extension, see [Consuming your extension](#).

Here are examples of using extensions in a function app, by scope:

Application-level

Python

```
# <project_root>/requirements.txt
application-level-extension==1.0.0
```

Python

```
# <project_root>/Trigger/__init__.py

from application_level_extension import AppExtension
AppExtension.configure(key=value)

def main(req, context):
    # Use context.app_ext_attributes here
```

Creating extensions

Extensions are created by third-party library developers who have created functionality that can be integrated into Azure Functions. An extension developer designs, implements, and releases Python packages that contain custom logic designed specifically to be run in the context of function execution. These extensions can be published either to the PyPI registry or to GitHub repositories.

To learn how to create, package, publish, and consume a Python worker extension package, see [Develop Python worker extensions for Azure Functions](#).

Application-level extensions

An extension that's inherited from [AppExtensionBase](#) runs in an *application* scope.

`AppExtensionBase` exposes the following abstract class methods for you to implement:

[\[\] Expand table](#)

Method	Description
<code>init</code>	Called after the extension is imported.
<code>configure</code>	Called from function code when it's needed to configure the extension.
<code>post_function_load_app_level</code>	Called right after the function is loaded. The function name and function directory are passed to the extension. Keep in mind that the function directory is read-only, and any attempt to write to a local file in this directory fails.
<code>pre_invocation_app_level</code>	Called right before the function is triggered. The function context and function invocation arguments are passed to the extension. You can usually pass other attributes in the context object for the function code to consume.
<code>post_invocation_app_level</code>	Called right after the function execution finishes. The function context, function invocation arguments, and invocation return object are passed to the extension. This implementation is a good place to validate whether execution of the lifecycle hooks succeeded.

Function-level extensions

An extension that inherits from [FuncExtensionBase](#) runs in a specific function trigger.

`FuncExtensionBase` exposes the following abstract class methods for implementations:

[\[\] Expand table](#)

Method	Description
<code>__init__</code>	The constructor of the extension. It's called when an extension instance is initialized in a specific function. When you're implementing this abstract method, you might want to accept a <code>filename</code> parameter and pass it to the parent's method <code>super().__init__(filename)</code> for proper extension registration.
<code>post_function_load</code>	Called right after the function is loaded. The function name and function directory are passed to the extension. Keep in mind that the function directory is read-only, and any attempt to write to a local file in this directory fails.
<code>pre_invocation</code>	Called right before the function is triggered. The function context and function invocation arguments are passed to the extension. You can usually

Method	Description
	pass other attributes in the context object for the function code to consume.
<code>post_invocation</code>	Called right after the function execution finishes. The function context, function invocation arguments, and invocation return object are passed to the extension. This implementation is a good place to validate whether execution of the lifecycle hooks succeeded.

Cross-origin resource sharing

Azure Functions supports cross-origin resource sharing (CORS). CORS is configured [in the portal](#) and through the [Azure CLI](#). The CORS allowed origins list applies at the function app level. With CORS enabled, responses include the `Access-Control-Allow-Origin` header. For more information, see [Cross-origin resource sharing](#).

Cross-origin resource sharing (CORS) is fully supported for Python function apps.

Async

By default, a host instance for Python can process only one function invocation at a time. This is because Python is a single-threaded runtime. For a function app that processes a large number of I/O events or is being I/O bound, you can significantly improve performance by running functions asynchronously. For more information, see [Improve throughout performance of Python apps in Azure Functions](#).

Shared memory (preview)

To improve throughput, Azure Functions lets your out-of-process Python language worker share memory with the Functions host process. When your function app is hitting bottlenecks, you can enable shared memory by adding an application setting named `FUNCTIONS_WORKER_SHARED_MEMORY_DATA_TRANSFER_ENABLED` with a value of `1`. With shared memory enabled, you can then use the `DOCKER_SHM_SIZE` setting to set the shared memory to something like `268435456`, which is equivalent to 256 MB.

For example, you might enable shared memory to reduce bottlenecks when you're using Blob Storage bindings to transfer payloads larger than 1 MB.

This functionality is available only for function apps that are running in Premium and Dedicated (Azure App Service) plans. To learn more, see [Shared memory](#).

Known issues and FAQ

Azure Functions Python developer guide

Article • 07/30/2024

This guide is an introduction to developing Azure Functions by using Python. The article assumes that you've already read the [Azure Functions developers guide](#).

Important

This article supports both the v1 and v2 programming model for Python in Azure Functions. The Python v1 model uses a `functions.json` file to define functions, and the new v2 model lets you instead use a decorator-based approach. This new approach results in a simpler file structure, and it's more code-centric. Choose the **v2** selector at the top of the article to learn about this new programming model.

As a Python developer, you might also be interested in these topics:

Get started

- [Visual Studio Code](#): Create your first Python app using Visual Studio Code.
- [Terminal or command prompt](#): Create your first Python app from the command prompt using Azure Functions Core Tools.
- [Samples](#): Review some existing Python apps in the Learn samples browser.

Development options

Both Python Functions programming models support local development in one of the following environments:

Python v2 programming model:

- [Visual Studio Code](#)
- [Terminal or command prompt](#)

Python v1 programming model:

- [Visual Studio Code](#)
- [Terminal or command prompt](#)

You can also create Python v1 functions in the Azure portal.

Tip

Although you can develop your Python-based Azure functions locally on Windows, Python is supported only on a Linux-based hosting plan when it's running in Azure. For more information, see the [list of supported operating system/runtime combinations](#).

Programming model

Azure Functions expects a function to be a stateless method in your Python script that processes input and produces output. By default, the runtime expects the method to be implemented as a global method in the *function_app.py* file.

Triggers and bindings can be declared and used in a function in a decorator based approach. They're defined in the same file, *function_app.py*, as the functions. As an example, the following *function_app.py* file represents a function trigger by an HTTP request.

Python

```
@app.function_name(name="HttpTrigger1")
@app.route(route="req")
def main(req):
    user = req.params.get("user")
    return f"Hello, {user}!"
```

You can also explicitly declare the attribute types and return type in the function by using Python type annotations. Doing so helps you use the IntelliSense and autocomplete features that are provided by many Python code editors.

Python

```
import azure.functions as func

app = func.FunctionApp()

@app.function_name(name="HttpTrigger1")
@app.route(route="req")
def main(req: func.HttpRequest) -> str:
    user = req.params.get("user")
    return f"Hello, {user}!"
```

To learn about known limitations with the v2 model and their workarounds, see [Troubleshoot Python errors in Azure Functions](#).

Alternative entry point

The entry point is only in the *function_app.py* file. However, you can reference functions within the project in *function_app.py* by using [blueprints](#) or by importing.

Folder structure

The recommended folder structure for a Python functions project looks like the following example:

```
Windows Command Prompt

<project_root>/
| - .venv/
| - .vscode/
| - function_app.py
| - additional_functions.py
| - tests/
| | - test_my_function.py
| - .funcignore
| - host.json
| - local.settings.json
| - requirements.txt
| - Dockerfile
```

The main project folder, *<project_root>*, can contain the following files:

- *.venv/*: (Optional) Contains a Python virtual environment that's used by local development.
- *.vscode/*: (Optional) Contains the stored Visual Studio Code configuration. To learn more, see [Visual Studio Code settings](#).
- *function_app.py*: The default location for all functions and their related triggers and bindings.
- *additional_functions.py*: (Optional) Any other Python files that contain functions (usually for logical grouping) that are referenced in *function_app.py* through blueprints.
- *tests/*: (Optional) Contains the test cases of your function app.
- *.funcignore*: (Optional) Declares files that shouldn't get published to Azure. Usually, this file contains *.vscode/* to ignore your editor setting, *.venv/* to ignore local

Python virtual environment, `tests/` to ignore test cases, and `local.settings.json` to prevent local app settings being published.

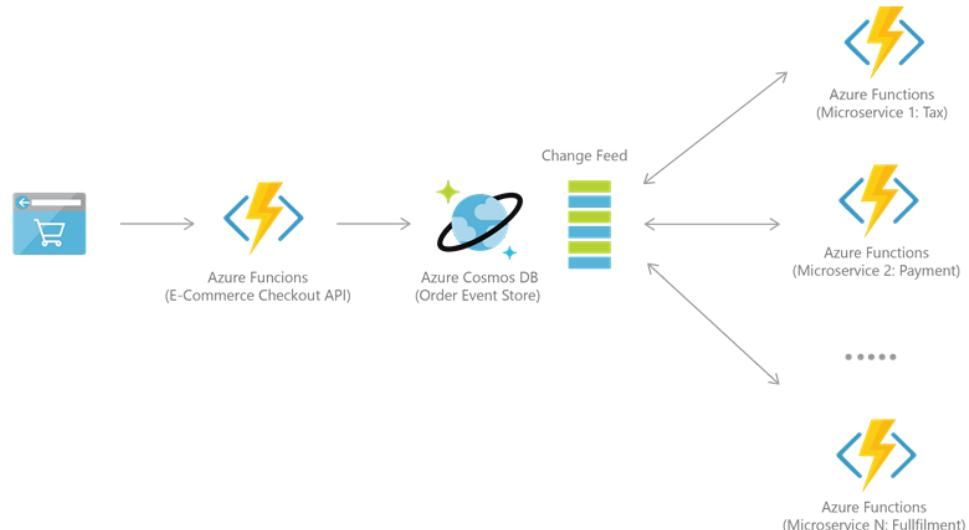

- `host.json`: Contains configuration options that affect all functions in a function app instance. This file does get published to Azure. Not all options are supported when running locally. To learn more, see [host.json](#).
- `local.settings.json`: Used to store app settings and connection strings when it's running locally. This file doesn't get published to Azure. To learn more, see [local.settings.json](#).
- `requirements.txt`: Contains the list of Python packages the system installs when it publishes to Azure.
- `Dockerfile`: (Optional) Used when publishing your project in a [custom container](#).

When you deploy your project to a function app in Azure, the entire contents of the main project folder, `<project_root>`, should be included in the package, but not the folder itself, which means that `host.json` should be in the package root. We recommend that you maintain your tests in a folder along with other functions (in this example, `tests/`). For more information, see [Unit testing](#).

Connect to a database

Azure Functions integrates well with [Azure Cosmos DB](#) for many [use cases](#), including IoT, ecommerce, gaming, etc.

For example, for [event sourcing](#), the two services are integrated to power event-driven architectures using Azure Cosmos DB's [change feed](#) functionality. The change feed provides downstream microservices the ability to reliably and incrementally read inserts and updates (for example, order events). This functionality can be used to provide a persistent event store as a message broker for state-changing events and drive order processing workflow between many microservices (which can be implemented as [serverless Azure Functions](#)).

To connect to Azure Cosmos DB, first [create an account, database, and container](#). Then you can connect your function code to Azure Cosmos DB using [trigger and bindings](#), like this [example](#).

To implement more complex app logic, you can also use the Python library for Cosmos DB. An asynchronous I/O implementation looks like this:

Python

```

pip install azure-cosmos
pip install aiohttp

from azure.cosmos.aio import CosmosClient
from azure.cosmos import exceptions
from azure.cosmos.partition_key import PartitionKey
import asyncio

# Replace these values with your Cosmos DB connection information
endpoint = "https://azure-cosmos-nosql.documents.azure.com:443/"
key = "master_key"
database_id = "cosmicwerx"
container_id = "cosmiccontainer"
partition_key = "/partition_key"

# Set the total throughput (RU/s) for the database and container
database_throughput = 1000

# Singleton CosmosClient instance
client = CosmosClient(endpoint, credential=key)

# Helper function to get or create database and container
async def get_or_create_container(client, database_id, container_id,
partition_key):

```

```

database = await client.create_database_if_not_exists(id=database_id)
print(f'Database "{database_id}" created or retrieved successfully.')

        container = await
database.create_container_if_not_exists(id=container_id,
partition_key=PartitionKey(path=partition_key))
        print(f'Container with id "{container_id}" created')

    return container

async def create_products():
    container = await get_or_create_container(client, database_id,
container_id, partition_key)
    for i in range(10):
        await container.upsert_item({
            'id': f'item{i}',
            'productName': 'Widget',
            'productModel': f'Model {i}'
        })

async def get_products():
    items = []
    container = await get_or_create_container(client, database_id,
container_id, partition_key)
    async for item in container.read_all_items():
        items.append(item)
    return items

async def query_products(product_name):
    container = await get_or_create_container(client, database_id,
container_id, partition_key)
    query = f"SELECT * FROM c WHERE c.productName = '{product_name}'"
    items = []
    async for item in container.query_items(query=query,
enable_cross_partition_query=True):
        items.append(item)
    return items

async def main():
    await create_products()
    all_products = await get_products()
    print('All Products:', all_products)

    queried_products = await query_products('Widget')
    print('Queried Products:', queried_products)

if __name__ == "__main__":
    asyncio.run(main())

```

Blueprints

The Python v2 programming model introduces the concept of *blueprints*. A blueprint is a new class that's instantiated to register functions outside of the core function application. The functions registered in blueprint instances aren't indexed directly by the function runtime. To get these blueprint functions indexed, the function app needs to register the functions from blueprint instances.

Using blueprints provides the following benefits:

- Lets you break up the function app into modular components, which enables you to define functions in multiple Python files and divide them into different components per file.
- Provides extensible public function app interfaces to build and reuse your own APIs.

The following example shows how to use blueprints:

First, in an *http_blueprint.py* file, an HTTP-triggered function is first defined and added to a blueprint object.

Python

```
import logging

import azure.functions as func

bp = func.Blueprint()

@bp.route(route="default_template")
def default_template(req: func.HttpRequest) -> func.HttpResponse:
    logging.info('Python HTTP trigger function processed a request.')

    name = req.params.get('name')
    if not name:
        try:
            req_body = req.get_json()
        except ValueError:
            pass
        else:
            name = req_body.get('name')

    if name:
        return func.HttpResponse(
            f"Hello, {name}. This HTTP-triggered function "
            f"executed successfully.")
    else:
        return func.HttpResponse(
            "This HTTP-triggered function executed successfully. "
            "Pass a name in the query string or in the request body for a"
            " personalized response.",
```

```
    status_code=200
)
```

Next, in the `function_app.py` file, the `blueprint` object is imported and its functions are registered to the function app.

Python

```
import azure.functions as func
from http_blueprint import bp

app = func.FunctionApp()

app.register_functions(bp)
```

ⓘ Note

Durable Functions also supports blueprints. To create blueprints for Durable Functions apps, register your orchestration, activity, and entity triggers and client bindings using the [azure-functions-durable](#) Blueprint class, as shown [here](#). The resulting blueprint can then be registered as normal. See our [sample](#) for an example.

Triggers and inputs

Inputs are divided into two categories in Azure Functions: trigger input and other input. Although they're defined using different decorators, their usage is similar in Python code. Connection strings or secrets for trigger and input sources map to values in the `local.settings.json` file when they're running locally, and they map to the application settings when they're running in Azure.

As an example, the following code demonstrates how to define a Blob Storage input binding:

JSON

```
// local.settings.json
{
  "IsEncrypted": false,
  "Values": {
    "FUNCTIONS_WORKER_RUNTIME": "python",
    "STORAGE_CONNECTION_STRING": "<AZURE_STORAGE_CONNECTION_STRING>",
    "AzureWebJobsStorage": "<azure-storage-connection-string>"}
```

```
}
```

Python

```
# function_app.py
import azure.functions as func
import logging

app = func.FunctionApp()

@app.route(route="req")
@app.read_blob(arg_name="obj", path="samples/{id}",
               connection="STORAGE_CONNECTION_STRING")
def main(req: func.HttpRequest, obj: func.InputStream):
    logging.info(f'Python HTTP-triggered function processed: {obj.read()}')
```

When the function is invoked, the HTTP request is passed to the function as `req`. An entry is retrieved from the Azure Blob Storage account based on the *ID* in the route URL and made available as `obj` in the function body. Here, the specified storage account is the connection string that's found in the `STORAGE_CONNECTION_STRING` app setting.

For data intensive binding operations, you may want to use a separate storage account. For more information, see [Storage account guidance](#).

SDK type bindings (preview)

For select triggers and bindings, you can work with data types implemented by the underlying Azure SDKs and frameworks. These *SDK type bindings* let you interact with binding data as if you were using the underlying service SDK.

Functions supports Python SDK type bindings for Azure Blob storage, which lets you work with blob data using the underlying `BlobClient` type.

ⓘ Important

SDK type bindings support for Python is currently in preview:

- You must use the Python v2 programming model.
- Currently, only synchronous SDK types are supported.

Prerequisites

- Azure Functions runtime version version 4.34, or a later version.
- Python ↗ version 3.9, or a later supported version.

Enable SDK type bindings for the Blob storage extension

1. Add the `azurefunctions-extensions-bindings-blob` extension package to the `requirements.txt` file in the project, which should include at least these packages:

```
text  
  
azure-functions  
azurefunctions-extensions-bindings-blob
```

2. Add this code to the `function_app.py` file in the project, which imports the SDK type bindings:

```
Python  
  
import azurefunctions.extensions.bindings.blob as blob
```

SDK type bindings examples

This example shows how to get the `BlobClient` from both a Blob storage trigger (`blob_trigger`) and from the input binding on an HTTP trigger (`blob_input`):

```
Python  
  
import logging  
  
import azure.functions as func  
import azurefunctions.extensions.bindings.blob as blob  
  
app = func.FunctionApp(http_auth_level=func.AuthLevel.ANONYMOUS)  
  
@app.blob_trigger(  
    arg_name="client", path="PATH/TO/BLOB", connection="AzureWebJobsStorage"  
)  
def blob_trigger(client: blob.BlobClient):  
    logging.info(  
        f"Python blob trigger function processed blob \n"  
        f"Properties: {client.get_blob_properties()}\n"  
        f"Blob content head: {client.download_blob().read(size=1)}"  
    )  
  
@app.route(route="file")
```

```
@app.blob_input(  
    arg_name="client", path="PATH/TO/BLOB", connection="AzureWebJobsStorage"  
)  
def blob_input(req: func.HttpRequest, client: blob.BlobClient):  
    logging.info(  
        f"Python blob input function processed blob \n"  
        f"Properties: {client.get_blob_properties()}\n"  
        f"Blob content head: {client.download_blob().read(size=1)}"  
    )  
    return "ok"
```

You can view other SDK type bindings samples for Blob storage in the Python extensions repository:

- [ContainerClient type ↗](#)
- [StorageStreamDownloader type ↗](#)

HTTP streams (preview)

HTTP streams lets you accept and return data from your HTTP endpoints using FastAPI request and response APIs enabled in your functions. These APIs lets the host process large data in HTTP messages as chunks instead of reading an entire message into memory.

This feature makes it possible to handle large data stream, OpenAI integrations, deliver dynamic content, and support other core HTTP scenarios requiring real-time interactions over HTTP. You can also use FastAPI response types with HTTP streams. Without HTTP streams, the size of your HTTP requests and responses are limited by memory restrictions that can be encountered when processing entire message payloads all in memory.

ⓘ Important

HTTP streams support for Python is currently in preview and requires you to use the Python v2 programming model.

Prerequisites

- [Azure Functions runtime](#) version 4.34.1, or a later version.
- [Python ↗](#) version 3.8, or a later [supported version](#).

Enable HTTP streams

HTTP streams are disabled by default. You need to enable this feature in your application settings and also update your code to use the FastAPI package. Note that when enabling HTTP streams, the function app will default to using HTTP streaming, and the original HTTP functionality will not work.

1. Add the `azurefunctions-extensions-http-fastapi` extension package to the `requirements.txt` file in the project, which should include at least these packages:

```
text  
  
azure-functions  
azurefunctions-extensions-http-fastapi
```

2. Add this code to the `function_app.py` file in the project, which imports the FastAPI extension:

```
Python  
  
from azurefunctions.extensions.http.fastapi import Request,  
StreamingResponse
```

3. When you deploy to Azure, add the following [application setting](#) in your function app:

```
"PYTHON_ENABLE_INIT_INDEXING": "1"
```

If you are deploying to Linux Consumption, also add

```
"PYTHON_ISOLATE_WORKER_DEPENDENCIES": "1"
```

When running locally, you also need to add these same settings to the `local.settings.json` project file.

HTTP streams examples

After you enable the HTTP streaming feature, you can create functions that stream data over HTTP.

This example is an HTTP triggered function that streams HTTP response data. You might use these capabilities to support scenarios like sending event data through a pipeline for real time visualization or detecting anomalies in large sets of data and providing instant notifications.

```
Python
```

```

import time

import azure.functions as func
from azurefunctions.extensions.http.fastapi import Request,
StreamingResponse

app = func.FunctionApp(http_auth_level=func.AuthLevel.ANONYMOUS)

def generate_sensor_data():
    """Generate real-time sensor data."""
    for i in range(10):
        # Simulate temperature and humidity readings
        temperature = 20 + i
        humidity = 50 + i
        yield f"data: {{'temperature': {temperature}, 'humidity': {humidity}}}\n\n"
    time.sleep(1)

@app.route(route="stream", methods=[func.HttpMethod.GET])
async def stream_sensor_data(req: Request) -> StreamingResponse:
    """Endpoint to stream real-time sensor data."""
    return StreamingResponse(generate_sensor_data(), media_type="text/event-stream")

```

This example is an HTTP triggered function that receives and processes streaming data from a client in real time. It demonstrates streaming upload capabilities that can be helpful for scenarios like processing continuous data streams and handling event data from IoT devices.

Python

```

import azure.functions as func
from azurefunctions.extensions.http.fastapi import JSONResponse, Request

app = func.FunctionApp(http_auth_level=func.AuthLevel.ANONYMOUS)

@app.route(route="streaming_upload", methods=[func.HttpMethod.POST])
async def streaming_upload(req: Request) -> JSONResponse:
    """Handle streaming upload requests."""
    # Process each chunk of data as it arrives
    async for chunk in req.stream():
        process_data_chunk(chunk)

    # Once all data is received, return a JSON response indicating
    # successful processing
    return JSONResponse({"status": "Data uploaded and processed
successfully"})

```

```
def process_data_chunk(chunk: bytes):
    """Process each data chunk."""
    # Add custom processing logic here
    pass
```

Calling HTTP streams

You must use an HTTP client library to make streaming calls to a function's FastAPI endpoints. The client tool or browser you're using might not natively support streaming or could only return the first chunk of data.

You can use a client script like this to send streaming data to an HTTP endpoint:

Python

```
import httpx # Be sure to add 'httpx' to 'requirements.txt'
import asyncio

async def stream_generator(file_path):
    chunk_size = 2 * 1024 # Define your own chunk size
    with open(file_path, 'rb') as file:
        while chunk := file.read(chunk_size):
            yield chunk
            print(f"Sent chunk: {len(chunk)} bytes")

async def stream_to_server(url, file_path):
    timeout = httpx.Timeout(60.0, connect=60.0)
    async with httpx.AsyncClient(timeout=timeout) as client:
        response = await client.post(url,
content=stream_generator(file_path))
    return response

async def stream_response(response):
    if response.status_code == 200:
        async for chunk in response.aiter_raw():
            print(f"Received chunk: {len(chunk)} bytes")
    else:
        print(f"Error: {response}")

async def main():
    print('helloworld')
    # Customize your streaming endpoint served from core tool in variable
    'url' if different.
    url = 'http://localhost:7071/api/streaming_upload'
    file_path = r'<file path>'

    response = await stream_to_server(url, file_path)
    print(response)
```

```
if __name__ == "__main__":
    asyncio.run(main())
```

Outputs

Output can be expressed both in return value and output parameters. If there's only one output, we recommend using the return value. For multiple outputs, you'll have to use output parameters.

To produce multiple outputs, use the `set()` method provided by the `azure.functions.Out` interface to assign a value to the binding. For example, the following function can push a message to a queue and also return an HTTP response.

Python

```
# function_app.py
import azure.functions as func

app = func.FunctionApp()

@app.write_blob(arg_name="msg", path="output-container/{name}",
                connection="CONNECTION_STRING")
def test_function(req: func.HttpRequest,
                  msg: func.Out[str]) -> str:

    message = req.params.get('body')
    msg.set(message)
    return message
```

Logging

Access to the Azure Functions runtime logger is available via a root [logging](#) handler in your function app. This logger is tied to Application Insights and allows you to flag warnings and errors that occur during the function execution.

The following example logs an info message when the function is invoked via an HTTP trigger.

Python

```
import logging

def main(req):
    logging.info('Python HTTP trigger function processed a request.')
```

More logging methods are available that let you write to the console at different trace levels:

[+] Expand table

Method	Description
<code>critical(_message_)</code>	Writes a message with level CRITICAL on the root logger.
<code>error(_message_)</code>	Writes a message with level ERROR on the root logger.
<code>warning(_message_)</code>	Writes a message with level WARNING on the root logger.
<code>info(_message_)</code>	Writes a message with level INFO on the root logger.
<code>debug(_message_)</code>	Writes a message with level DEBUG on the root logger.

To learn more about logging, see [Monitor Azure Functions](#).

Logging from created threads

To see logs coming from your created threads, include the `context` argument in the function's signature. This argument contains an attribute `thread_local_storage` that stores a local `invocation_id`. This can be set to the function's current `invocation_id` to ensure the context is changed.

Python

```
import azure.functions as func
import logging
import threading

def main(req, context):
    logging.info('Python HTTP trigger function processed a request.')
    t = threading.Thread(target=log_function, args=(context,))
    t.start()

def log_function(context):
    context.thread_local_storage.invocation_id = context.invocation_id
    logging.info('Logging from thread.')
```

Log custom telemetry

By default, the Functions runtime collects logs and other telemetry data that are generated by your functions. This telemetry ends up as traces in Application Insights. Request and dependency telemetry for certain Azure services are also collected by default by [triggers and bindings](#).

To collect custom request and custom dependency telemetry outside of bindings, you can use the [OpenCensus Python Extensions](#). This extension sends custom telemetry data to your Application Insights instance. You can find a list of supported extensions at the [OpenCensus repository](#).

ⓘ Note

To use the OpenCensus Python extensions, you need to enable [Python worker extensions](#) in your function app by setting `PYTHON_ENABLE_WORKER_EXTENSIONS` to `1`. You also need to switch to using the Application Insights connection string by adding the [APPLICATIONINSIGHTS CONNECTION STRING](#) setting to your [application settings](#), if it's not already there.

text

```
// requirements.txt
...
opencensus-extension-azure-functions
opencensus-ext-requests
```

Python

```
import json
import logging

import requests
from opencensus.extension.azure.functions import OpenCensusExtension
from opencensus.trace import config_integration

config_integration.trace_integrations(['requests'])

OpenCensusExtension.configure()

def main(req, context):
    logging.info('Executing HttpTrigger with OpenCensus extension')

    # You must use contexttracer to create spans
    with context.tracer.span("parent"):
        response = requests.get(url='http://example.com')

    return json.dumps({
        'method': req.method,
```

```
'response': response.status_code,
'ctx_func_name': context.function_name,
'ctx_func_dir': context.function_directory,
'ctx_invocation_id': context.invocation_id,
'ctx_trace_context_Traceparent': context.trace_context.Traceparent,
'ctx_trace_context_Tracestate': context.trace_context.Tracestate,
'ctx_retry_context_RetryCount': context.retry_context.retry_count,
'ctx_retry_context_MaxRetryCount':
context.retry_context.max_retry_count,
})
```

HTTP trigger

The HTTP trigger is defined as a method that takes a named binding parameter, which is an [HttpRequest](#) object, and returns an [HttpResponse](#) object. You apply the `function_name` decorator to the method to define the function name, while the HTTP endpoint is set by applying the `route` decorator.

This example is from the HTTP trigger template for the Python v2 programming model, where the binding parameter name is `req`. It's the sample code that's provided when you create a function by using Azure Functions Core Tools or Visual Studio Code.

Python

```
@app.function_name(name="HttpTrigger1")
@app.route(route="hello")
def test_function(req: func.HttpRequest) -> func.HttpResponse:
    logging.info('Python HTTP trigger function processed a request.')

    name = req.params.get('name')
    if not name:
        try:
            req_body = req.get_json()
        except ValueError:
            pass
    else:
        name = req_body.get('name')

    if name:
        return func.HttpResponse(f"Hello, {name}. This HTTP-triggered
function executed successfully.")
    else:
        return func.HttpResponse(
            "This HTTP-triggered function executed successfully. Pass a
name in the query string or in the request body for a personalized
response.",
            status_code=200
        )
```

From the `HttpRequest` object, you can get request headers, query parameters, route parameters, and the message body. In this function, you obtain the value of the `name` query parameter from the `params` parameter of the `HttpRequest` object. You read the JSON-encoded message body by using the `get_json` method.

Likewise, you can set the `status_code` and `headers` for the response message in the returned `HttpResponse` object.

To pass in a name in this example, paste the URL that's provided when you're running the function, and then append it with `?name={name}`.

Web frameworks

You can use Asynchronous Server Gateway Interface (ASGI)-compatible and Web Server Gateway Interface (WSGI)-compatible frameworks, such as Flask and FastAPI, with your HTTP-triggered Python functions. You must first update the `host.json` file to include an HTTP `routePrefix`, as shown in the following example:

```
JSON

{
  "version": "2.0",
  "logging": {
    {
      "applicationInsights": {
        {
          "samplingSettings": {
            {
              "isEnabled": true,
              "excludedTypes": "Request"
            }
          }
        },
        "extensionBundle": {
          {
            "id": "Microsoft.Azure.Functions.ExtensionBundle",
            "version": "[2.*, 3.0.0)"
          },
          "extensions": {
            {
              "http": {
                {
                  "routePrefix": ""
                }
              }
            }
          }
        }
      }
    }
  }
}
```

The framework code looks like the following example:

ASGI

`AsgiFunctionApp` is the top-level function app class for constructing ASGI HTTP functions.

Python

```
# function_app.py

import azure.functions as func
from fastapi import FastAPI, Request, Response

fast_app = FastAPI()

@fast_app.get("/return_http_no_body")
async def return_http_no_body():
    return Response(content="", media_type="text/plain")

app = func.AsgiFunctionApp(app=fast_app,
                           http_auth_level=func.AuthLevel.ANONYMOUS)
```

Scaling and performance

For scaling and performance best practices for Python function apps, see the [Python scaling and performance](#) article.

Context

To get the invocation context of a function when it's running, include the `context` argument in its signature.

For example:

Python

```
import azure.functions

def main(req: azure.functions.HttpRequest,
         context: azure.functions.Context) -> str:
    return f'{context.invocation_id}'
```

The [Context](#) class has the following string attributes:

[Expand table](#)

Attribute	Description
<code>function_directory</code>	The directory in which the function is running.
<code>function_name</code>	The name of the function.
<code>invocation_id</code>	The ID of the current function invocation.
<code>thread_local_storage</code>	The thread local storage of the function. Contains a local <code>invocation_id</code> for logging from created threads .
<code>trace_context</code>	The context for distributed tracing. For more information, see Trace Context .
<code>retry_context</code>	The context for retries to the function. For more information, see retry-policies .

Global variables

It isn't guaranteed that the state of your app will be preserved for future executions. However, the Azure Functions runtime often reuses the same process for multiple executions of the same app. To cache the results of an expensive computation, declare it as a global variable.

Python

```
CACHED_DATA = None

def main(req):
    global CACHED_DATA
    if CACHED_DATA is None:
        CACHED_DATA = load_json()

    # ... use CACHED_DATA in code
```

Environment variables

In Azure Functions, [application settings](#), such as service connection strings, are exposed as environment variables when they're running. There are two main ways to access these settings in your code.

[\[\] Expand table](#)

Method	Description
<code>os.environ["myAppSetting"]</code>	Tries to get the application setting by key name, and raises an error when it's unsuccessful.
<code>os.getenv("myAppSetting")</code>	Tries to get the application setting by key name, and returns <code>null</code> when it's unsuccessful.

Both of these ways require you to declare `import os`.

The following example uses `os.environ["myAppSetting"]` to get the [application setting](#), with the key named `myAppSetting`:

Python

```
import logging
import os

import azure.functions as func

app = func.FunctionApp()

@app.function_name(name="HttpTrigger1")
@app.route(route="req")
def main(req: func.HttpRequest) -> func.HttpResponse:
    # Get the setting named 'myAppSetting'
    my_app_setting_value = os.environ["myAppSetting"]
    logging.info(f'My app setting value:{my_app_setting_value}')
```

For local development, application settings are [maintained in the `local.settings.json` file](#).

Python version

Azure Functions supports the following Python versions:

[\[\] Expand table](#)

Functions version	Python* versions
4.x	3.11
	3.10
	3.9
	3.8
	3.7

Functions version	Python* versions
3.x	3.9
	3.8
	3.7

* Official Python distributions

To request a specific Python version when you create your function app in Azure, use the `--runtime-version` option of the [az functionapp create](#) command. The Functions runtime version is set by the `--functions-version` option. The Python version is set when the function app is created, and it can't be changed for apps running in a Consumption plan.

The runtime uses the available Python version when you run it locally.

Changing Python version

To set a Python function app to a specific language version, you need to specify the language and the version of the language in the `LinuxFxVersion` field in the site configuration. For example, to change the Python app to use Python 3.8, set `linuxFxVersion` to `python|3.8`.

To learn how to view and change the `linuxFxVersion` site setting, see [How to target Azure Functions runtime versions](#).

For more general information, see the [Azure Functions runtime support policy](#) and [Supported languages in Azure Functions](#).

Package management

When you're developing locally by using Core Tools or Visual Studio Code, add the names and versions of the required packages to the `requirements.txt` file, and then install them by using `pip`.

For example, you can use the following `requirements.txt` file and `pip` command to install the `requests` package from PyPI.

```
txt
requests==2.19.1
```

Bash

```
pip install -r requirements.txt
```

When running your functions in an [App Service plan](#), dependencies that you define in `requirements.txt` are given precedence over built-in Python modules, such as `logging`. This precedence can cause conflicts when built-in modules have the same names as directories in your code. When running in a [Consumption plan](#) or an [Elastic Premium plan](#), conflicts are less likely because your dependencies aren't prioritized by default.

To prevent issues running in an App Service plan, don't name your directories the same as any Python native modules and don't include Python native libraries in your project's `requirements.txt` file.

Publishing to Azure

When you're ready to publish, make sure that all your publicly available dependencies are listed in the `requirements.txt` file. You can locate this file at the root of your project directory.

You can find the project files and folders that are excluded from publishing, including the virtual environment folder, in the root directory of your project.

There are three build actions supported for publishing your Python project to Azure: remote build, local build, and builds using custom dependencies.

You can also use Azure Pipelines to build your dependencies and publish by using continuous delivery (CD). To learn more, see [Continuous delivery with Azure Pipelines](#).

Remote build

When you use remote build, dependencies that are restored on the server and native dependencies match the production environment. This results in a smaller deployment package to upload. Use remote build when you're developing Python apps on Windows. If your project has custom dependencies, you can [use remote build with extra index URL](#).

Dependencies are obtained remotely based on the contents of the `requirements.txt` file. [Remote build](#) is the recommended build method. By default, Core Tools requests a remote build when you use the following `func azure functionapp publish` command to publish your Python project to Azure.

Bash

```
func azure functionapp publish <APP_NAME>
```

Remember to replace `<APP_NAME>` with the name of your function app in Azure.

The [Azure Functions Extension for Visual Studio Code](#) also requests a remote build by default.

Local build

Dependencies are obtained locally based on the contents of the `requirements.txt` file. You can prevent doing a remote build by using the following [func azure functionapp publish](#) command to publish with a local build:

command

```
func azure functionapp publish <APP_NAME> --build local
```

Remember to replace `<APP_NAME>` with the name of your function app in Azure.

When you use the `--build local` option, project dependencies are read from the `requirements.txt` file, and those dependent packages are downloaded and installed locally. Project files and dependencies are deployed from your local computer to Azure. This results in a larger deployment package being uploaded to Azure. If for some reason you can't get the `requirements.txt` file by using Core Tools, you must use the custom dependencies option for publishing.

We don't recommend using local builds when you're developing locally on Windows.

Custom dependencies

When your project has dependencies that aren't found in the [Python Package Index](#), there are two ways to build the project. The first way, the `build` method, depends on how you build the project.

Remote build with extra index URL

When your packages are available from an accessible custom package index, use a remote build. Before you publish, be sure to [create an app setting](#) named `PIP_EXTRA_INDEX_URL`. The value for this setting is the URL of your custom package

index. Using this setting tells the remote build to run `pip install` by using the `--extra-index-url` option. To learn more, see the [Python pip install documentation](#).

You can also use basic authentication credentials with your extra package index URLs. To learn more, see [Basic authentication credentials](#) in the Python documentation.

Install local packages

If your project uses packages that aren't publicly available to our tools, you can make them available to your app by putting them in the `_app_/python_packages` directory. Before you publish, run the following command to install the dependencies locally:

command

```
pip install --target="<PROJECT_DIR>/python_packages/lib/site-packages" -r requirements.txt
```

When you're using custom dependencies, you should use the `--no-build` publishing option, because you've already installed the dependencies into the project folder.

command

```
func azure functionapp publish <APP_NAME> --no-build
```

Remember to replace `<APP_NAME>` with the name of your function app in Azure.

Unit testing

Functions that are written in Python can be tested like other Python code by using standard testing frameworks. For most bindings, it's possible to create a mock input object by creating an instance of an appropriate class from the `azure.functions` package. Since the `azure.functions` package isn't immediately available, be sure to install it via your `requirements.txt` file as described in the [package management](#) section above.

With `my_second_function` as an example, the following is a mock test of an HTTP-triggered function:

First, create the `<project_root>/function_app.py` file and implement the `my_second_function` function as the HTTP trigger and `shared_code.my_second_helper_function`.

Python

```
# <project_root>/function_app.py
import azure.functions as func
import logging

# Use absolute import to resolve shared_code modules
from shared_code import my_second_helper_function

app = func.FunctionApp()

# Define the HTTP trigger that accepts the ?value=<int> query parameter
# Double the value and return the result in HttpResponseMessage
@app.function_name(name="my_second_function")
@app.route(route="hello")
def main(req: func.HttpRequest) -> func.HttpResponse:
    logging.info('Executing my_second_function.')

    initial_value: int = int(req.params.get('value'))
    doubled_value: int = my_second_helper_function.double(initial_value)

    return func.HttpResponse(
        body=f'{initial_value} * 2 = {doubled_value}',
        status_code=200
    )
```

Python

```
# <project_root>/shared_code/__init__.py
# Empty __init__.py file marks shared_code folder as a Python package
```

Python

```
# <project_root>/shared_code/my_second_helper_function.py

def double(value: int) -> int:
    return value * 2
```

You can start writing test cases for your HTTP trigger.

Python

```
# <project_root>/tests/test_my_second_function.py
import unittest
import azure.functions as func

from function_app import main

class TestFunction(unittest.TestCase):
    def test_my_second_function(self):
```

```
# Construct a mock HTTP request.
req = func.HttpRequest(method='GET',
                       body=None,
                       url='/api/my_second_function',
                       params={'value': '21'})

# Call the function.
func_call = main.build().get_user_function()
resp = func_call(req)

# Check the output.
self.assertEqual(
    resp.get_body(),
    b'21 * 2 = 42',
)
```

Inside your `.venv` Python virtual environment folder, install your favorite Python test framework, such as `pip install pytest`. Then run `pytest tests` to check the test result.

Temporary files

The `tempfile.gettempdir()` method returns a temporary folder, which on Linux is `/tmp`. Your application can use this directory to store temporary files that are generated and used by your functions when they're running.

ⓘ Important

Files written to the temporary directory aren't guaranteed to persist across invocations. During scale out, temporary files aren't shared between instances.

The following example creates a named temporary file in the temporary directory (`/tmp`):

Python

```
import logging
import azure.functions as func
import tempfile

from os import listdir

#---
tempFilePath = tempfile.gettempdir()
fp = tempfile.NamedTemporaryFile()
fp.write(b'Hello world!')
filesDirListInTemp = listdir(tempFilePath)
```

We recommend that you maintain your tests in a folder that's separate from the project folder. This action keeps you from deploying test code with your app.

Preinstalled libraries

A few libraries come with the Python functions runtime.

The Python standard library

The Python standard library contains a list of built-in Python modules that are shipped with each Python distribution. Most of these libraries help you access system functionality, such as file input/output (I/O). On Windows systems, these libraries are installed with Python. On Unix-based systems, they're provided by package collections.

To view the library for your Python version, go to:

- [Python 3.8 standard library ↗](#)
- [Python 3.9 standard library ↗](#)
- [Python 3.10 standard library ↗](#)
- [Python 3.11 standard library ↗](#)

Azure Functions Python worker dependencies

The Azure Functions Python worker requires a specific set of libraries. You can also use these libraries in your functions, but they aren't a part of the Python standard. If your functions rely on any of these libraries, they might be unavailable to your code when it's running outside of Azure Functions.

Note

If your function app's *requirements.txt* file contains an `azure-functions-worker` entry, remove it. The functions worker is automatically managed by the Azure Functions platform, and we regularly update it with new features and bug fixes. Manually installing an old version of worker in the *requirements.txt* file might cause unexpected issues.

Note

If your package contains certain libraries that might collide with worker's dependencies (for example, protobuf, tensorflow, or grpcio), configure `PYTHON_ISOLATE_WORKER_DEPENDENCIES` to `1` in app settings to prevent your application from referring to worker's dependencies.

The Azure Functions Python library

Every Python worker update includes a new version of the [Azure Functions Python library \(azure.functions\)](#). This approach makes it easier to continuously update your Python function apps, because each update is backwards-compatible. For a list of releases of this library, go to [azure-functions PyPi](#).

The runtime library version is fixed by Azure, and it can't be overridden by *requirements.txt*. The `azure-functions` entry in *requirements.txt* is only for linting and customer awareness.

Use the following code to track the actual version of the Python functions library in your runtime:

Python

```
getattr(azure.functions, '__version__', '< 1.2.1')
```

Runtime system libraries

For a list of preinstalled system libraries in Python worker Docker images, see the following:

[+] Expand table

Functions runtime	Debian version	Python versions
Version 3.x	Buster	Python 3.7 Python 3.8 Python 3.9

Python worker extensions

The Python worker process that runs in Azure Functions lets you integrate third-party libraries into your function app. These extension libraries act as middleware that can inject specific operations during the lifecycle of your function's execution.

Extensions are imported in your function code much like a standard Python library module. Extensions are run based on the following scopes:

[+] Expand table

Scope	Description
Application-level	When imported into any function trigger, the extension applies to every function execution in the app.
Function-level	Execution is limited to only the specific function trigger into which it's imported.

Review the information for each extension to learn more about the scope in which the extension runs.

Extensions implement a Python worker extension interface. This action lets the Python worker process call into the extension code during the function's execution lifecycle. To learn more, see [Create extensions](#).

Using extensions

You can use a Python worker extension library in your Python functions by doing the following:

1. Add the extension package in the *requirements.txt* file for your project.
2. Install the library into your app.
3. Add the following application settings:
 - Locally: Enter `"PYTHON_ENABLE_WORKER_EXTENSIONS": "1"` in the `Values` section of your *local.settings.json* file.
 - Azure: Enter `PYTHON_ENABLE_WORKER_EXTENSIONS=1` in your [app settings](#).
4. Import the extension module into your function trigger.
5. Configure the extension instance, if needed. Configuration requirements should be called out in the extension's documentation.

Important

Third-party Python worker extension libraries aren't supported or warrantied by Microsoft. You must make sure that any extensions that you use in your function app is trustworthy, and you bear the full risk of using a malicious or poorly written extension.

Third-parties should provide specific documentation on how to install and consume their extensions in your function app. For a basic example of how to consume an extension, see [Consuming your extension](#).

Here are examples of using extensions in a function app, by scope:

Application-level

Python

```
# <project_root>/requirements.txt
application-level-extension==1.0.0
```

Python

```
# <project_root>/Trigger/__init__.py

from application_level_extension import AppExtension
AppExtension.configure(key=value)

def main(req, context):
    # Use context.app_ext_attributes here
```

Creating extensions

Extensions are created by third-party library developers who have created functionality that can be integrated into Azure Functions. An extension developer designs, implements, and releases Python packages that contain custom logic designed specifically to be run in the context of function execution. These extensions can be published either to the PyPI registry or to GitHub repositories.

To learn how to create, package, publish, and consume a Python worker extension package, see [Develop Python worker extensions for Azure Functions](#).

Application-level extensions

An extension that's inherited from [AppExtensionBase](#) runs in an *application* scope.

`AppExtensionBase` exposes the following abstract class methods for you to implement:

[] [Expand table](#)

Method	Description
<code>init</code>	Called after the extension is imported.
<code>configure</code>	Called from function code when it's needed to configure the extension.

Method	Description
<code>post_function_load_app_level</code>	Called right after the function is loaded. The function name and function directory are passed to the extension. Keep in mind that the function directory is read-only, and any attempt to write to a local file in this directory fails.
<code>pre_invocation_app_level</code>	Called right before the function is triggered. The function context and function invocation arguments are passed to the extension. You can usually pass other attributes in the context object for the function code to consume.
<code>post_invocation_app_level</code>	Called right after the function execution finishes. The function context, function invocation arguments, and invocation return object are passed to the extension. This implementation is a good place to validate whether execution of the lifecycle hooks succeeded.

Function-level extensions

An extension that inherits from [FuncExtensionBase](#) runs in a specific function trigger.

`FuncExtensionBase` exposes the following abstract class methods for implementations:

[+] [Expand table](#)

Method	Description
<code>__init__</code>	The constructor of the extension. It's called when an extension instance is initialized in a specific function. When you're implementing this abstract method, you might want to accept a <code>filename</code> parameter and pass it to the parent's method <code>super().__init__(filename)</code> for proper extension registration.
<code>post_function_load</code>	Called right after the function is loaded. The function name and function directory are passed to the extension. Keep in mind that the function directory is read-only, and any attempt to write to a local file in this directory fails.
<code>pre_invocation</code>	Called right before the function is triggered. The function context and function invocation arguments are passed to the extension. You can usually pass other attributes in the context object for the function code to consume.
<code>post_invocation</code>	Called right after the function execution finishes. The function context, function invocation arguments, and invocation return object are passed to the extension. This implementation is a good place to validate whether execution of the lifecycle hooks succeeded.

Cross-origin resource sharing

Azure Functions supports cross-origin resource sharing (CORS). CORS is configured in the portal and through the Azure CLI. The CORS allowed origins list applies at the function app level. With CORS enabled, responses include the `Access-Control-Allow-Origin` header. For more information, see [Cross-origin resource sharing](#).

Cross-origin resource sharing (CORS) is fully supported for Python function apps.

Async

By default, a host instance for Python can process only one function invocation at a time. This is because Python is a single-threaded runtime. For a function app that processes a large number of I/O events or is being I/O bound, you can significantly improve performance by running functions asynchronously. For more information, see [Improve throughout performance of Python apps in Azure Functions](#).

Shared memory (preview)

To improve throughput, Azure Functions lets your out-of-process Python language worker share memory with the Functions host process. When your function app is hitting bottlenecks, you can enable shared memory by adding an application setting named `FUNCTIONS_WORKER_SHARED_MEMORY_DATA_TRANSFER_ENABLED` with a value of `1`. With shared memory enabled, you can then use the `DOCKER_SHM_SIZE` setting to set the shared memory to something like `268435456`, which is equivalent to 256 MB.

For example, you might enable shared memory to reduce bottlenecks when you're using Blob Storage bindings to transfer payloads larger than 1 MB.

This functionality is available only for function apps that are running in Premium and Dedicated (Azure App Service) plans. To learn more, see [Shared memory](#).

Known issues and FAQ

Here are two troubleshooting guides for common issues:

- [ModuleNotFoundError and ImportError](#)
- [Can't import 'cygrpc'](#)

Here are two troubleshooting guides for known issues with the v2 programming model:

- Couldn't load file or assembly
- Unable to resolve the Azure Storage connection named Storage

All known issues and feature requests are tracked in a [GitHub issues list](#). If you run into a problem and can't find the issue in GitHub, open a new issue, and include a detailed description of the problem.

Develop Python worker extensions for Azure Functions

Article • 04/25/2023

Azure Functions lets you integrate custom behaviors as part of Python function execution. This feature enables you to create business logic that customers can easily use in their own function apps. To learn more, see the [Python developer reference](#). Worker extensions are supported in both the v1 and v2 Python programming models.

In this tutorial, you'll learn how to:

- ✓ Create an application-level Python worker extension for Azure Functions.
- ✓ Consume your extension in an app the way your customers do.
- ✓ Package and publish an extension for consumption.

Prerequisites

Before you start, you must meet these requirements:

- [Python 3.7 or above](#). To check the full list of supported Python versions in Azure Functions, see the [Python developer guide](#).
- The [Azure Functions Core Tools](#), version 4.0.5095 or later, which supports using the extension with the [v2 Python programming model](#). Check your version with `func -version`.
- [Visual Studio Code](#) installed on one of the [supported platforms](#).

Create the Python Worker extension

The extension you create reports the elapsed time of an HTTP trigger invocation in the console logs and in the HTTP response body.

Folder structure

The folder for your extension project should be like the following structure:

```
<python_worker_extension_root>/  
| - .venv/
```

```
| - python_worker_extension_timer/
| | - __init__.py
| - setup.py
| - readme.md
```

Folder/file	Description
.venv/	(Optional) Contains a Python virtual environment used for local development.
python_worker_extension/	Contains the source code of the Python worker extension. This folder contains the main Python module to be published into PyPI.
setup.py	Contains the metadata of the Python worker extension package.
readme.md	Contains the instruction and usage of your extension. This content is displayed as the description in the home page in your PyPI project.

Configure project metadata

First you create `setup.py`, which provides essential information about your package. To make sure that your extension is distributed and integrated into your customer's function apps properly, confirm that `'azure-functions >= 1.7.0, < 2.0.0'` is in the `install_requires` section.

In the following template, you should change `author`, `author_email`, `install_requires`, `license`, `packages`, and `url` fields as needed.

Python

```
from setuptools import find_packages, setup
setup(
    name='python-worker-extension-timer',
    version='1.0.0',
    author='Your Name Here',
    author_email='your@email.here',
    classifiers=[
        'Intended Audience :: End Users/Desktop',
        'Development Status :: 5 - Production/Stable',
        'Intended Audience :: End Users/Desktop',
        'License :: OSI Approved :: Apache Software License',
        'Programming Language :: Python',
        'Programming Language :: Python :: 3.7',
        'Programming Language :: Python :: 3.8',
        'Programming Language :: Python :: 3.9',
        'Programming Language :: Python :: 3.10',
    ],
    description='Python Worker Extension Demo',
    include_package_data=True,
```

```
long_description=open('readme.md').read(),
install_requires=[
    'azure-functions >= 1.7.0, < 2.0.0',
    # Any additional packages that will be used in your extension
],
extras_require={},
license='MIT',
packages=find_packages(where='.'),
url='https://your-github-or-pypi-link',
zip_safe=False,
)
```

Next, you'll implement your extension code in the application-level scope.

Implement the timer extension

Add the following code in `python_worker_extension_timer/__init__.py` to implement the application-level extension:

Python

```
import typing
from logging import Logger
from time import time
from azure.functions import AppExtensionBase, Context, HttpResponse
class TimerExtension(AppExtensionBase):
    """A Python worker extension to record elapsed time in a function
invocation
"""

@classmethod
def init(cls):
    # This records the starttime of each function
    cls.start_timestamps: typing.Dict[str, float] = {}

@classmethod
def configure(cls, *args, append_to_http_response:bool=False, **kwargs):
    # Customer can use
TimerExtension.configure(append_to_http_response=)
    # to decide whether the elapsed time should be shown in HTTP
response
    cls.append_to_http_response = append_to_http_response

@classmethod
def pre_invocation_app_level(
    cls, logger: Logger, context: Context,
    func_args: typing.Dict[str, object],
    *args, **kwargs
) -> None:
    logger.info(f'Recording start time of {context.function_name}')
    cls.start_timestamps[context.invocation_id] = time()
```

```

@classmethod
def post_invocation_app_level(
    cls, logger: Logger, context: Context,
    func_args: typing.Dict[str, object],
    func_ret: typing.Optional[object],
    *args, **kwargs
) -> None:
    if context.invocation_id in cls.start_timestamps:
        # Get the start_time of the invocation
        start_time: float =
    cls.start_timestamps.pop(context.invocation_id)
    end_time: float = time()
    # Calculate the elapsed time
    elapsed_time = end_time - start_time
    logger.info(f'Time taken to execute {context.function_name} is
{elapsed_time} sec')
    # Append the elapsed time to the end of HTTP response
    # if the append_to_http_response is set to True
    if cls.append_to_http_response and isinstance(func_ret,
    HttpResponse):
        func_ret._HttpResponse__body += f' (TimeElapsed:
{elapsed_time} sec)'.encode()

```

This code inherits from [AppExtensionBase](#) so that the extension applies to every function in the app. You could have also implemented the extension on a function-level scope by inheriting from [FuncExtensionBase](#).

The `init` method is a class method that's called by the worker when the extension class is imported. You can do initialization actions here for the extension. In this case, a hash map is initialized for recording the invocation start time for each function.

The `configure` method is customer-facing. In your readme file, you can tell your customers when they need to call `Extension.configure()`. The readme should also document the extension capabilities, possible configuration, and usage of your extension. In this example, customers can choose whether the elapsed time is reported in the `HttpResponse`.

The `pre_invocation_app_level` method is called by the Python worker before the function runs. It provides the information from the function, such as function context and arguments. In this example, the extension logs a message and records the start time of an invocation based on its `invocation_id`.

Similarly, the `post_invocation_app_level` is called after function execution. This example calculates the elapsed time based on the start time and current time. It also overwrites the return value of the HTTP response.

Create a readme.md

Create a `readme.md` file in the root of your extension project. This file contains the instructions and usage of your extension. The `readme.md` content is displayed as the description in the home page in your PyPI project.

markdown

```
# Python Worker Extension Timer
```

In this file, tell your customers when they need to call
``Extension.configure()``.

The `readme` should also document the extension capabilities, possible configuration, and usage of your extension.

Consume your extension locally

Now that you've created an extension, you can use it in an app project to verify it works as intended.

Create an HTTP trigger function

1. Create a new folder for your app project and navigate to it.
2. From the appropriate shell, such as Bash, run the following command to initialize the project:

Bash

```
func init --python
```

3. Use the following command to create a new HTTP trigger function that allows anonymous access:

Bash

```
func new -t HttpTrigger -n HttpTrigger -a anonymous
```

Activate a virtual environment

1. Create a Python virtual environment, based on OS as follows:

Windows

Console

```
py -m venv .venv
```

2. Activate the Python virtual environment, based on OS as follows:

Windows

Console

```
.venv\Scripts\Activate.ps1
```

Configure the extension

1. Install remote packages for your function app project using the following command:

Bash

```
pip install -r requirements.txt
```

2. Install the extension from your local file path, in editable mode as follows:

Bash

```
pip install -e <PYTHON_WORKER_EXTENSION_ROOT>
```

In this example, replace `<PYTHON_WORKER_EXTENSION_ROOT>` with the root file location of your extension project.

When a customer uses your extension, they'll instead add your extension package location to the requirements.txt file, as in the following examples:

PyPI

Python

```
# requirements.txt  
python_worker_extension_timer==1.0.0
```

3. Open the local.settings.json project file and add the following field to `Values`:

JSON

```
"PYTHON_ENABLE_WORKER_EXTENSIONS": "1"
```

When running in Azure, you instead add `PYTHON_ENABLE_WORKER_EXTENSIONS=1` to the [app settings in the function app](#).

4. Add following two lines before the `main` function in `_init.py_` file for the v1 programming model, or in the `function_app.py` file for the v2 programming model:

Python

```
from python_worker_extension_timer import TimerExtension  
TimerExtension.configure(append_to_http_response=True)
```

This code imports the `TimerExtension` module and sets the `append_to_http_response` configuration value.

Verify the extension

1. From your app project root folder, start the function host using `func host start -verbose`. You should see the local endpoint of your function in the output as `https://localhost:7071/api/HttpTrigger`.
2. In the browser, send a GET request to `https://localhost:7071/api/HttpTrigger`. You should see a response like the following, with the `TimeElapsed` data for the request appended.

```
This HTTP triggered function executed successfully. Pass a name in the query string or in the request body for a personalized response.  
(TimeElapsed: 0.0009996891021728516 sec)
```

Publish your extension

After you've created and verified your extension, you still need to complete these remaining publishing tasks:

- ✓ Choose a license.
- ✓ Create a `readme.md` and other documentation.
- ✓ Publish the extension library to a Python package registry or a version control system (VCS).

PyPI

To publish your extension to PyPI:

1. Run the following command to install `twine` and `wheel` in your default Python environment or a virtual environment:

Bash

```
pip install twine wheel
```

2. Remove the old `dist/` folder from your extension repository.

3. Run the following command to generate a new package inside `dist/`:

Bash

```
python setup.py sdist bdist_wheel
```

4. Run the following command to upload the package to PyPI:

Bash

```
twine upload dist/*
```

You may need to provide your PyPI account credentials during upload. You can also test your package upload with `twine upload -r testpypi dist/*`. For more information, see the [Twine documentation](#).

After these steps, customers can use your extension by including your package name in their `requirements.txt`.

For more information, see the [official Python packaging tutorial](#).

Examples

- You can view completed sample extension project from this article in the [python_worker_extension_timer](#) sample repository.
- OpenCensus integration is an open-source project that uses the extension interface to integrate telemetry tracing in Azure Functions Python apps. See the [opencensus-python-extensions-azure](#) repository to review the implementation of this Python worker extension.

Improve throughput performance of Python apps in Azure Functions

Article • 02/14/2023

When developing for Azure Functions using Python, you need to understand how your functions perform and how that performance affects the way your function app gets scaled. The need is more important when designing highly performant apps. The main factors to consider when designing, writing, and configuring your functions apps are horizontal scaling and throughput performance configurations.

Horizontal scaling

By default, Azure Functions automatically monitors the load on your application and creates more host instances for Python as needed. Azure Functions uses built-in thresholds for different trigger types to decide when to add instances, such as the age of messages and queue size for QueueTrigger. These thresholds aren't user configurable. For more information, see [Event-driven scaling in Azure Functions](#).

Improving throughput performance

The default configurations are suitable for most of Azure Functions applications. However, you can improve the performance of your applications' throughput by employing configurations based on your workload profile. The first step is to understand the type of workload that you're running.

Workload type	Function app characteristics	Examples
I/O-bound	<ul style="list-style-type: none">App needs to handle many concurrent invocations.App processes a large number of I/O events, such as network calls and disk read/writes.	<ul style="list-style-type: none">Web APIs
CPU-bound	<ul style="list-style-type: none">App does long-running computations, such as image resizing.App does data transformation.	<ul style="list-style-type: none">Data processingMachine learning inference

As real world function workloads are usually a mix of I/O and CPU bound, you should profile the app under realistic production loads.

Performance-specific configurations

After you understand the workload profile of your function app, the following are configurations that you can use to improve the throughput performance of your functions.

- [Async](#)
- [Multiple language worker](#)
- [Max workers within a language worker process](#)
- [Event loop](#)
- [Vertical Scaling](#)

Async

Because [Python is a single-threaded runtime](#), a host instance for Python can process only one function invocation at a time by default. For applications that process a large number of I/O events and/or is I/O bound, you can improve performance significantly by running functions asynchronously.

To run a function asynchronously, use the `async def` statement, which runs the function with [asyncio](#) directly:

Python

```
async def main():
    await some_nonblocking_socket_io_op()
```

Here's an example of a function with HTTP trigger that uses [aiohttp](#) http client:

Python

```
import aiohttp

import azure.functions as func

async def main(req: func.HttpRequest) -> func.HttpResponse:
    async with aiohttp.ClientSession() as client:
        async with client.get("PUT_YOUR_URL_HERE") as response:
            return func.HttpResponse(await response.text())

    return func.HttpResponse(body='NotFound', status_code=404)
```

A function without the `async` keyword is run automatically in a `ThreadPoolExecutor` thread pool:

Python

```
# Runs in a ThreadPoolExecutor threadpool. Number of threads is defined by
# PYTHON_THREADPOOL_THREAD_COUNT.
# The example is intended to show how default synchronous functions are
# handled.

def main():
    some_blocking_socket_io()
```

In order to achieve the full benefit of running functions asynchronously, the I/O operation/library that is used in your code needs to have `async` implemented as well. Using synchronous I/O operations in functions that are defined as asynchronous **may hurt** the overall performance. If the libraries you're using don't have `async` version implemented, you may still benefit from running your code asynchronously by [managing event loop](#) in your app.

Here are a few examples of client libraries that have implemented `async` patterns:

- [aiohttp](#) - Http client/server for `asyncio`
- [Streams API](#) - High-level `async/await`-ready primitives to work with network connection
- [Janus Queue](#) - Thread-safe `asyncio`-aware queue for Python
- [pyzmq](#) - Python bindings for ZeroMQ

Understanding `async` in Python worker

When you define `async` in front of a function signature, Python marks the function as a coroutine. When you call the coroutine, it can be scheduled as a task into an event loop. When you call `await` in an `async` function, it registers a continuation into the event loop, which allows the event loop to process the next task during the wait time.

In our Python Worker, the worker shares the event loop with the customer's `async` function and it's capable for handling multiple requests concurrently. We strongly encourage our customers to make use of `asyncio` compatible libraries, such as [aiohttp](#) and [pyzmq](#). Following these recommendations increases your function's throughput compared to those libraries when implemented synchronously.

ⓘ Note

If your function is declared as `async` without any `await` inside its implementation, the performance of your function will be severely impacted since the event loop will be blocked which prohibits the Python worker from handling concurrent requests.

Use multiple language worker processes

By default, every Functions host instance has a single language worker process. You can increase the number of worker processes per host (up to 10) by using the `FUNCTIONS_WORKER_PROCESS_COUNT` application setting. Azure Functions then tries to evenly distribute simultaneous function invocations across these workers.

For CPU bound apps, you should set the number of language workers to be the same as or higher than the number of cores that are available per function app. To learn more, see [Available instance SKUs](#).

I/O-bound apps may also benefit from increasing the number of worker processes beyond the number of cores available. Keep in mind that setting the number of workers too high can affect overall performance due to the increased number of required context switches.

The `FUNCTIONS_WORKER_PROCESS_COUNT` applies to each host that Azure Functions creates when scaling out your application to meet demand.

Note

Multiple Python workers are not supported by the Python v2 programming model at this time. This means that enabling intelligent concurrency and setting `FUNCTIONS_WORKER_PROCESS_COUNT` greater than 1 is not supported for functions developed using the v2 model.

Set up max workers within a language worker process

As mentioned in the async [section](#), the Python language worker treats functions and [coroutines](#) differently. A coroutine is run within the same event loop that the language worker runs on. On the other hand, a function invocation is run within a [ThreadPoolExecutor](#), which is maintained by the language worker as a thread.

You can set the value of maximum workers allowed for running sync functions using the `PYTHON_THREADPOOL_THREAD_COUNT` application setting. This value sets the `max_worker` argument of the `ThreadPoolExecutor` object, which lets Python use a pool of at most `max_worker` threads to execute calls asynchronously. The `PYTHON_THREADPOOL_THREAD_COUNT` applies to each worker that Functions host creates, and Python decides when to create a new thread or reuse the existing idle thread. For older Python versions(that is, 3.8, 3.7, and 3.6), `max_worker` value is set to 1. For Python version 3.9 , `max_worker` is set to `None`.

For CPU-bound apps, you should keep the setting to a low number, starting from 1 and increasing as you experiment with your workload. This suggestion is to reduce the time spent on context switches and allowing CPU-bound tasks to finish.

For I/O-bound apps, you should see substantial gains by increasing the number of threads working on each invocation. The recommendation is to start with the Python default (the number of cores) + 4 and then tweak based on the throughput values you're seeing.

For mixed workloads apps, you should balance both `FUNCTIONS_WORKER_PROCESS_COUNT` and `PYTHON_THREADPOOL_THREAD_COUNT` configurations to maximize the throughput. To understand what your function apps spend the most time on, we recommend profiling them and setting the values according to their behaviors. To learn about these application settings, see [Use multiple worker processes](#).

Note

Although these recommendations apply to both HTTP and non-HTTP triggered functions, you might need to adjust other trigger specific configurations for non-HTTP triggered functions to get the expected performance from your function apps. For more information about this, please refer to this [Best practices for reliable Azure Functions](#).

Managing event loop

You should use asyncio compatible third-party libraries. If none of the third-party libraries meet your needs, you can also manage the event loops in Azure Functions. Managing event loops give you more flexibility in compute resource management, and it also makes it possible to wrap synchronous I/O libraries into coroutines.

There are many useful Python official documents discussing the [Coroutines and Tasks ↗](#) and [Event Loop ↗](#) by using the built-in `asyncio` library.

Take the following `requests` library as an example, this code snippet uses the `asyncio` library to wrap the `requests.get()` method into a coroutine, running multiple web requests to SAMPLE_URL concurrently.

Python

```
import asyncio
import json
import logging
```

```

import azure.functions as func
from time import time
from requests import get, Response

async def invoke_get_request(eventloop: asyncio.AbstractEventLoop) ->
    Response:
    # Wrap requests.get function into a coroutine
    single_result = await eventloop.run_in_executor(
        None, # using the default executor
        get, # each task call invoke_get_request
        'SAMPLE_URL' # the url to be passed into the requests.get function
    )
    return single_result

async def main(req: func.HttpRequest) -> func.HttpResponse:
    logging.info('Python HTTP trigger function processed a request.')

    eventloop = asyncio.get_event_loop()

    # Create 10 tasks for requests.get synchronous call
    tasks = [
        asyncio.create_task(
            invoke_get_request(eventloop)
        ) for _ in range(10)
    ]

    done_tasks, _ = await asyncio.wait(tasks)
    status_codes = [d.result().status_code for d in done_tasks]

    return func.HttpResponse(body=json.dumps(status_codes),
                            mimetype='application/json')

```

Vertical scaling

You might be able to get more processing units, especially in CPU-bound operation, by upgrading to premium plan with higher specifications. With higher processing units, you can adjust the number of worker processes count according to the number of cores available and achieve higher degree of parallelism.

- [Azure Functions developer reference](#)

Troubleshoot Python errors in Azure Functions

Article • 02/25/2024

This article provides information to help you troubleshoot errors with your Python functions in Azure Functions. This article supports both the v1 and v2 programming models. Choose the model you want to use from the selector at the top of the article.

ⓘ Note

The Python v2 programming model is only supported in the 4.x functions runtime. For more information, see [Azure Functions runtime versions overview](#).

Here are the troubleshooting sections for common issues in Python functions:

Specifically with the v2 model, here are some known issues and their workarounds:

- [Could not load file or assembly](#)
- [Unable to resolve the Azure Storage connection named Storage](#)

General troubleshooting guides for Python Functions include:

- [ModuleNotFoundError and ImportError](#)
- [Cannot import 'cygrpc'](#)
- [Python exited with code 137](#)
- [Python exited with code 139](#)
- [Sync triggers failed](#)
- [Development issues in the Azure portal](#)

Troubleshoot: ModuleNotFoundError

This section helps you troubleshoot module-related errors in your Python function app. These errors typically result in the following Azure Functions error message:

Exception: ModuleNotFoundError: No module named 'module_name'.

This error occurs when a Python function app fails to load a Python module. The root cause for this error is one of the following issues:

- [The package can't be found](#)

- The package isn't resolved with proper Linux wheel
- The package is incompatible with the Python interpreter version
- The package conflicts with other packages
- The package supports only Windows and macOS platforms

View project files

To identify the actual cause of your issue, you need to get the Python project files that run on your function app. If you don't have the project files on your local computer, you can get them in one of the following ways:

- If the function app has a `WEBSITE_RUN_FROM_PACKAGE` app setting and its value is a URL, download the file by copying and pasting the URL into your browser.
- If the function app has `WEBSITE_RUN_FROM_PACKAGE` set to `1`, go to `https://<app-name>.scm.azurewebsites.net/api/vfs/data/SitePackages` and download the file from the latest `href` URL.
- If the function app doesn't have either of the preceding app settings, go to `https://<app-name>.scm.azurewebsites.net/api/settings` and find the URL under `SCM_RUN_FROM_PACKAGE`. Download the file by copying and pasting the URL into your browser.
- If suggestions resolve the issue, go to `https://<app-name>.scm.azurewebsites.net/DebugConsole` and view the content under `/home/site/wwwroot`.

The rest of this article helps you troubleshoot potential causes of this error by inspecting your function app's content, identifying the root cause, and resolving the specific issue.

Diagnose ModuleNotFoundError

This section details potential root causes of module-related errors. After you figure out which is the likely root cause, you can go to the related mitigation.

The package can't be found

Go to `.python_packages/lib/python3.6/site-packages/<package-name>` or `.python_packages/lib/site-packages/<package-name>`. If the file path doesn't exist, this missing path is likely the root cause.

Using third-party or outdated tools during deployment might cause this issue.

To mitigate this issue, see [Enable remote build](#) or [Build native dependencies](#).

The package isn't resolved with the proper Linux wheel

Go to `.python_packages/lib/python3.6/site-packages/<package-name>-<version>-dist-info` or `.python_packages/lib/site-packages/<package-name>-<version>-dist-info`. Use your favorite text editor to open the *wheel* file and check the **Tag:** section. The issue might be that the tag value doesn't contain `linux`.

Python functions run only on Linux in Azure. The Functions runtime v2.x runs on Debian Stretch, and the v3.x runtime runs on Debian Buster. The artifact is expected to contain the correct Linux binaries. When you use the `--build local` flag in Core Tools, third-party, or outdated tools, it might cause older binaries to be used.

To mitigate the issue, see [Enable remote build](#) or [Build native dependencies](#).

The package is incompatible with the Python interpreter version

Go to `.python_packages/lib/python3.6/site-packages/<package-name>-<version>-dist-info` or `.python_packages/lib/site-packages/<package-name>-<version>-dist-info`. In your text editor, open the *METADATA* file and check the **Classifiers:** section. If the section doesn't contain `Python :: 3`, `Python :: 3.6`, `Python :: 3.7`, `Python :: 3.8`, or `Python :: 3.9`, the package version is either too old or, more likely, it's already out of maintenance.

You can check the Python version of your function app from the [Azure portal](#). Navigate to your function app's **Overview** resource page to find the runtime version. The runtime version supports Python versions as described in the [Azure Functions runtime versions overview](#).

To mitigate the issue, see [Update your package to the latest version](#) or [Replace the package with equivalents](#).

The package conflicts with other packages

If you've verified that the package is resolved correctly with the proper Linux wheels, there might be a conflict with other packages. In certain packages, the PyPi documentation might clarify the incompatible modules. For example, in [azure 4.0.0](#), you find the following statement:

This package isn't compatible with `azure-storage`. If you installed `azure-storage`, or if you installed `azure 1.x/2.x` and didn't uninstall `azure-storage`, you must uninstall `azure-storage` first.

You can find the documentation for your package version in <https://pypi.org/project/<package-name>/<package-version>>.

To mitigate the issue, see [Update your package to the latest version](#) or [Replace the package with equivalents](#).

The package supports only Windows and macOS platforms

Open the `requirements.txt` with a text editor and check the package in <https://pypi.org/project/<package-name>>. Some packages run only on Windows and macOS platforms. For example, `pywin32` runs on Windows only.

The `Module Not Found` error might not occur when you're using Windows or macOS for local development. However, the package fails to import on Azure Functions, which uses Linux at runtime. This issue is likely to be caused by using `pip freeze` to export the virtual environment into `requirements.txt` from your Windows or macOS machine during project initialization.

To mitigate the issue, see [Replace the package with equivalents](#) or [Handcraft requirements.txt](#).

Mitigate ModuleNotFoundError

The following are potential mitigations for module-related issues. Use the [previously mentioned diagnoses](#) to determine which of these mitigations to try.

Enable remote build

Make sure that remote build is enabled. The way that you make sure depends on your deployment method.

Visual Studio Code

Make sure that the latest version of the [Azure Functions extension for Visual Studio Code](#) is installed. Verify that the `.vscode/settings.json` file exists and it contains the setting `"azureFunctions.scmDoBuildDuringDeployment": true`. If it doesn't, create the file with the `azureFunctions.scmDoBuildDuringDeployment` setting enabled, and then redeploy the project.

Build native dependencies

Make sure that the latest versions of both Docker and [Azure Functions Core Tools](#) are installed. Go to your local function project folder, and use `func azure functionapp publish <app-name> --build-native-deps` for deployment.

Update your package to the latest version

In the latest package version of <https://pypi.org/project/<package-name>>, check the **Classifiers:** section. The package should be `OS Independent`, or compatible with `POSIX` or `POSIX :: Linux` in **Operating System**. Also, the programming language should contain: `Python :: 3`, `Python :: 3.6`, `Python :: 3.7`, `Python :: 3.8`, or `Python :: 3.9`.

If these package items are correct, you can update the package to the latest version by changing the line `<package-name>~=<latest-version>` in *requirements.txt*.

Handcraft requirements.txt

Some developers use `pip freeze > requirements.txt` to generate the list of Python packages for their developing environments. Although this convenience should work in most cases, there can be issues in cross-platform deployment scenarios, such as developing functions locally on Windows or macOS, but publishing to a function app, which runs on Linux. In this scenario, `pip freeze` can introduce unexpected operating system-specific dependencies or dependencies for your local development environment. These dependencies can break the Python function app when it's running on Linux.

The best practice is to check the import statement from each `.py` file in your project source code and then check in only the modules in the *requirements.txt* file. This practice guarantees that the resolution of packages can be handled properly on different operating systems.

Replace the package with equivalents

First, take a look into the latest version of the package in <https://pypi.org/project/<package-name>>. This package usually has its own GitHub page. Go to the **Issues** section on GitHub and search to see whether your issue has been fixed. If it has been fixed, update the package to the latest version.

Sometimes, the package might have been integrated into [Python Standard Library](#) (such as `pathlib`). If so, because we provide a certain Python distribution in Azure Functions (Python 3.6, Python 3.7, Python 3.8, and Python 3.9), the package in your *requirements.txt* file should be removed.

However, if you're finding that the issue hasn't been fixed, and you're on a deadline, we encourage you to do some research to find a similar package for your project. Usually, the Python community provides you with a wide variety of similar libraries that you can use.

Disable dependency isolation flag

Set the application setting `PYTHON_ISOLATE_WORKER_DEPENDENCIES` to a value of `0`.

Troubleshoot: cannot import 'cygrpc'

This section helps you troubleshoot 'cygrpc'-related errors in your Python function app. These errors typically result in the following Azure Functions error message:

Cannot import name 'cygrpc' from 'grpc._cython'

This error occurs when a Python function app fails to start with a proper Python interpreter. The root cause for this error is one of the following issues:

- [The Python interpreter mismatches OS architecture](#)
- [The Python interpreter isn't supported by Azure Functions Python Worker](#)

Diagnose the 'cygrpc' reference error

There are several possible causes for errors that reference `cygrpc`, which are detailed in this section.

The Python interpreter mismatches OS architecture

This mismatch is most likely caused by a 32-bit Python interpreter being installed on your 64-bit operating system.

If you're running on an x64 operating system, ensure that your Python version 3.6, 3.7, 3.8, or 3.9 interpreter is also on a 64-bit version.

You can check your Python interpreter bitness by running the following commands:

On Windows in PowerShell, run `py -c 'import platform; print(platform.architecture()[0])'`.

On a Unix-like shell, run `python3 -c 'import platform; print(platform.architecture()[0])'`.

If there's a mismatch between Python interpreter bitness and the operating system architecture, download a proper Python interpreter from [Python Software Foundation](#).

The Python interpreter isn't supported by Azure Functions Python Worker

The Azure Functions Python Worker supports only [specific Python versions](#).

Check to see whether your Python interpreter matches your expected version by `py --version` in Windows or `python3 --version` in Unix-like systems. Ensure that the return result is one of the [supported Python versions](#).

If your Python interpreter version doesn't meet the requirements for Azure Functions, instead download a Python interpreter version that is supported by Functions from the [Python Software Foundation](#).

Troubleshoot: python exited with code 137

Code 137 errors are typically caused by out-of-memory issues in your Python function app. As a result, you get the following Azure Functions error message:

```
Microsoft.Azure.WebJobs.Script.Workers.WorkerProcessExitException : python exited with code 137
```

This error occurs when a Python function app is forced to terminate by the operating system with a `SIGKILL` signal. This signal usually indicates an out-of-memory error in your Python process. The Azure Functions platform has a [service limitation](#) that terminates any function apps that exceed this limit.

To analyze the memory bottleneck in your function app, see [Profile Python function app in local development environment](#).

Troubleshoot: python exited with code 139

This section helps you troubleshoot segmentation fault errors in your Python function app. These errors typically result in the following Azure Functions error message:

Microsoft.Azure.WebJobs.Script.Workers.WorkerProcessExitException : python exited with code 139

This error occurs when a Python function app is forced to terminate by the operating system with a `SIGSEGV` signal. This signal indicates violation of the memory segmentation, which can result from an unexpected reading from or writing into a restricted memory region. In the following sections, we provide a list of common root causes.

A regression from third-party packages
